Steam, Edition: 41

Steam/its generation and use is the longest continuously published engineering text of its kind in the world. It has always been, and continues to be, written and published by The Babcock & Wilcox Company, *the Original*, headquartered in Barberton, Ohio, and incorporated in Delaware, The United States of America.

The Babcock & Wilcox Company

Preface

Dear Reader:

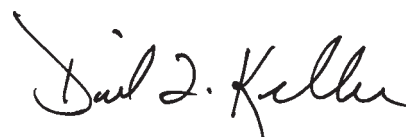

The founders of our company, George Babcock and Stephen Wilcox, invented the safety water tube boiler. This invention resulted in the commercialization of large-scale utility generating stations. Rapid increases in generation of safe, dependable and economic electricity literally fueled the Industrial Revolution and dramatically increased the standard of living in the United States and industrialized economies worldwide throughout the twentieth century.

Advancements in technology to improve efficiency and reduce environmental emissions have continued for nearly 140 years, creating a unique and valuable body of applied engineering that represents the individual and collective contributions of several generations of employees. As in other areas of science and engineering, our field has continued to evolve, resulting in an extensive amount of new material that has been incorporated into our 41st edition of *Steam/its generation and use*. This edition required an extensive amount of personal time and energy from hundreds of employees and reflects our commitment to both our industry and our future.

Today it is clear that the challenge to generate power more efficiently from fossil fuels, while minimizing impacts to our environment and global climate, will require significant technological advancements. These advances will require creativity, perseverance and ingenuity on the part of our employees and our customers. For inspiration, we can recall the relentless drive and imagination of one of our first customers, Mr. Thomas Alva Edison. For strength, we will continue to embrace our Core Values of Quality, Integrity, Service and People which have served us well over our long history as a company.

I thank our shareholders, our employees, our customers, our partners and our suppliers for their continued dedication, cooperation and support as we move forward into what will prove to be a challenging and rewarding century.

To help guide us all along the way, I am very pleased to present *Edition: 41*.

David L. Keller
President and Chief Operating Officer

Table of Contents

Acknowledgments	viii to ix
System of Units: English and Système International	x
Editors' Foreword	xi
Introduction to <i>Steam</i>	Intro-1 to 17
Selected Color Plates, Edition: 41	Plates 1 to 8

Section I – Steam Fundamentals

Chapter 1	Steam Generation – An Overview	1-1 to 1-17
2	Thermodynamics of Steam	2-1 to 2-27
3	Fluid Dynamics	3-1 to 3-17
4	Heat Transfer	4-1 to 4-33
5	Boiling Heat Transfer, Two-Phase Flow and Circulation	5-1 to 5-21
6	Numerical Modeling for Fluid Flow, Heat Transfer, and Combustion	6-1 to 6-25
7	Metallurgy, Materials and Mechanical Properties	7-1 to 7-25
8	Structural Analysis and Design	8-1 to 8-17

Section II – Steam Generation from Chemical Energy

Chapter 9	Sources of Chemical Energy	9-1 to 9-19
10	Principles of Combustion	10-1 to 10-31
11	Oil and Gas Utilization	11-1 to 11-17
12	Solid Fuel Processing and Handling	12-1 to 12-19
13	Coal Pulverization	13-1 to 13-15
14	Burners and Combustion Systems for Pulverized Coal	14-1 to 14-21
15	Cyclone Furnaces	15-1 to 15-13
16	Stokers	16-1 to 16-11
17	Fluidized-Bed Combustion	17-1 to 17-15
18	Coal Gasification	18-1 to 18-17
19	Boilers, Superheaters and Reheaters	19-1 to 19-21
20	Economizers and Air Heaters	20-1 to 20-17
21	Fuel Ash Effects on Boiler Design and Operation	21-1 to 21-27
22	Performance Calculations	22-1 to 22-21
23	Boiler Enclosures, Casing and Insulation	23-1 to 23-9
24	Boiler Cleaning and Ash Handling Systems	24-1 to 24-21
25	Boiler Auxiliaries	25-1 to 25-23

Section III – Applications of Steam

Chapter 26	Fossil Fuel Boilers for Electric Power	26-1 to 26-17
27	Boilers for Industry and Small Power	27-1 to 27-21
28	Chemical and Heat Recovery in the Paper Industry	28-1 to 28-29
29	Waste-to-Energy Installations	29-1 to 29-23
30	Wood and Biomass Installations	30-1 to 30-11
31	Marine Applications	31-1 to 31-13

Section IV – Environmental Protection

Chapter 32	Environmental Considerations	32-1 to 32-17
33	Particulate Control	33-1 to 33-13
34	Nitrogen Oxides Control	34-1 to 34-15
35	Sulfur Dioxide Control	35-1 to 35-19
36	Environmental Measurement	36-1 to 36-15

Section V – Specification, Manufacturing and Construction

Chapter 37	Equipment Specification, Economics and Evaluation	37-1 to 37-17
38	Manufacturing	38-1 to 38-13
39	Construction	39-1 to 39-19

Section VI – Operations

Chapter 40	Pressure, Temperature, Quality and Flow Measurement	40-1 to 40-25
41	Controls for Fossil Fuel-Fired Steam Generating Plants	41-1 to 41-21
42	Water and Steam Chemistry, Deposits and Corrosion	42-1 to 42-29
43	Boiler Operations	43-1 to 43-17

Section VII – Service and Maintenance

Chapter 44	Maintaining Availability	44-1 to 44-21
45	Condition Assessment	45-1 to 45-21

Section VIII – Steam Generation from Nuclear Energy

Chapter 46	Steam Generation from Nuclear Energy	46-1 to 46-25
47	Fundamentals of Nuclear Energy	47-1 to 47-15
48	Nuclear Steam Generators	48-1 to 48-15
49	Nuclear Services and Operations	49-1 to 49-21
50	Nuclear Equipment Manufacture	50-1 to 50-13

Appendices

Appendix 1	Conversion Factors, SI Steam Properties and Useful Tables	T-1 to T-16
2	Codes and Standards	C-1 to C-6
	Symbols, Acronyms and Abbreviations	S-1 to S-10
	B&W Trademarks in Edition: 41	TM-1
	Index	I-1 to I-22

Acknowledgments

Steam/its generation and use is the culmination of the work of hundreds of B&W employees who have contributed directly and indirectly to this edition and to the technology upon which it is based. Particular recognition goes to individuals who formally committed to preparing and completing this expanded 41st edition.

System of Units

English and Système International

To recognize the globalization of the power industry, the 41st edition of *Steam* incorporates the Système International d'Unités (SI) along with the continued use of English or U.S. Customary System (USCS) units. English units continue to be the primary system of units with SI provided as secondary units in parentheses. In some instances, SI units alone have been provided where these units are common usage. In selected figures and tables where dual units could detract from clarity (logarithmic scales, for example) SI conversions are provided within the figure titles or as a table footnote.

Extensive English-SI conversion tables are provided in Appendix 1. This appendix also contains a complete SI set of the Steam Tables, Mollier diagram, pressure-enthalpy diagram and psychrometric chart.

The decision was made to provide exact conversions rounded to an appropriate number of figures. This was done to avoid confusion about the original source values.

Absolute pressure is denoted by *psi* or *kPa/MPa* and gauge pressure by *psig* or *kPa/MPa gauge*. The difference between *absolute pressure* and *pressure difference* is identified by the context. Finally, in Chapters 10 and 22, as well as selected other areas of *Steam* which provide extensive numerical examples, only English units have been provided for clarity.

For reference and clarity, power in British thermal units per hour (Btu/h) has typically been converted to megawatts-thermal and is denoted by MW_t , while megawatts-electric in both systems of units has been denoted by MW .

The editors hope that these conversion practices will make *Steam* easily usable by the broadest possible audience.

Editors' Foreword

When we completed the 40th edition of *Steam* in 1992, we had a sense that perhaps our industry was stabilizing. But activity has again accelerated. Today, efficiencies are being driven even higher. Emissions are being driven even lower. Many current technologies are being stretched, and new technologies are being developed, tested and installed. We have once again changed much of *Steam* to reflect our industry's activity and anticipated developments.

Recognizing the rich history of this publication, we previously drew words from an 1883 edition's preface to say that "*we have revised the whole, and added much new and valuable matter.*" For this new 41st edition we can draw from the 1885 edition to say "*Having again revised Steam, and enlarged it by the addition of new and useful information, not published heretofore, we shall feel repaid for the labor if it shall prove of value to our customers.*"

We hope this new edition is of equal value to our partners and suppliers, government personnel, students and educators, and all present and future employees of The Babcock & Wilcox Company.

Introduction to Steam

Throughout history, mankind has reached beyond the acceptable to pursue a challenge, achieving significant accomplishments and developing new technology. This process is both scientific and creative. Entire civilizations, organizations, and most notably, individuals have succeeded by simply doing what has never been done before. A prime example is the safe and efficient use of steam.

One of the most significant series of events shaping today's world is the industrial revolution that began in the late seventeenth century. The desire to generate steam on demand sparked this revolution, and technical advances in steam generation allowed it to continue. Without these developments, the industrial revolution as we know it would not have taken place.

It is therefore appropriate to say that few technologies developed through human ingenuity have done so much to advance mankind as the safe and dependable generation of steam.

Steam as a resource

In 200 B.C., a Greek named Hero designed a simple machine that used steam as a power source (Fig. 1). He began with a cauldron of water, placed above an open fire. As the fire heated the cauldron, the cauldron shell transferred the heat to the water. When the water reached the boiling point of 212F (100C), it changed form and turned into steam. The steam passed through two pipes into a hollow sphere, which was pivoted at both sides. As the steam escaped through two tubes attached to the sphere, each bent at an angle, the sphere moved, rotating on its axis.

Hero, a mathematician and scientist, labeled the device *aeolipile*, meaning rotary steam engine. Although the invention was only a novelty, and Hero made no suggestion for its use, the idea of generating steam to do useful work was born. Even today, the basic idea has remained the same – generate heat, transfer the heat to water, and produce steam.

Intimately related to steam generation is the steam turbine, a device that changes the energy of steam into mechanical work. In the early 1600s, an Italian named Giovanni Branca produced a unique invention (Fig. 2). He first produced steam, based on Hero's aeolipile. By channeling the steam to a wheel that rotated, the steam pressure caused the wheel to turn. Thus began the development of the steam turbine.

The primary use of steam turbines today is for electric power production. In one of the most complex systems ever designed by mankind, superheated high-pressure steam is produced in a boiler and channeled to turbine-generators to produce electricity.

Fig. 1 Hero's aeolipile.

Today's steam plants are a complex and highly sophisticated combination of engineered elements. Heat is obtained either from primary fossil fuels like coal, oil or natural gas, or from nuclear fuel in the form of uranium. Other sources of heat-producing energy include waste heat and exhaust gases, bagasse and biomass, spent chemicals and municipal waste, and geothermal and solar energy.

Each fuel contains potential energy, or a heating value measured in Btu/lb (J/kg). The goal is to release this energy, most often by a controlled combustion process or, with uranium, through fission. The heat is then transferred to water through tube walls and other components or liquids. The heated water then changes form, turning into steam. The steam is normally heated further to specific temperatures and pressures.

Steam is also a vital resource in industry. It drives pumps and valves, helps produce paper and wood products, prepares foods, and heats and cools large buildings and institutions. Steam also propels much of the world's naval fleets and a high percentage of commercial marine transport. In some countries, steam plays a continuing role in railway transportation.

Steam generators, commonly referred to as *boilers*, range in size from those needed to heat a small building to those used individually to produce 1300 megawatts of electricity in a power generating station – enough power for more than one million people. These larger units deliver more than ten million pounds of superheated steam per hour (1260 kg/s) with steam temperatures exceeding 1000F (538C) and pressures exceeding 3800 psi (26.2 MPa).

Today's steam generating systems owe their dependability and safety to the design, fabrication and operation of safe water tube boilers, first patented by George Babcock and Stephen Wilcox in 1867 (Fig. 3).

Because the production of steam power is a tremendous resource, it is our challenge and responsibility to further develop and use this resource safely, efficiently, dependably, and in an environmentally-friendly manner.

The early use of steam

Steam generation as an industry began almost two thousand years after Hero's invention, in the seventeenth century. Many conditions began to stimulate the development of steam use in a power cycle. Mining for ores and minerals had expanded greatly and large quantities of fuel were needed for ore refining.

Fig. 2 Branca's steam turbine.

Fig. 3 First Babcock & Wilcox boiler, patented in 1867.

Fuels were needed for space heating and cooking and for general industrial and military growth. Forests were being stripped and coal was becoming an important fuel. Coal mining was emerging as a major industry.

As mines became deeper, they were often flooded with underground water. The English in particular were faced with a very serious curtailment of their industrial growth if they could not find some economical way to pump water from the mines. Many people began working on the problem and numerous patents were issued for machines to pump water from the mines using *the expansive power of steam*. The early machines used wood and charcoal for fuel, but coal eventually became the dominant fuel.

The most common source of steam at the time was a *shell boiler*, little more than a large kettle filled with water and heated at the bottom (Fig. 4).

Not all early developments in steam were directed toward pumps and engines. In 1680, Dr. Denis Papin, a Frenchman, invented a steam digester for food pro-

Fig. 4 Haycock shell boiler, 1720.

cessing, using a boiler under heavy pressure. To avoid explosion, Papin added a device which is the first safety valve on record. Papin also invented a boiler with an internal firebox, the earliest record of such construction.

Many experiments concentrated on using steam pressure or atmospheric pressure combined with a vacuum. The result was the first commercially successful steam engine, patented by Thomas Savery in 1698, to pump water by direct displacement (Fig. 5). The patent credits Savery with an engine for raising water by the impellant force of fire, meaning steam. The mining industry needed the invention, but the engine had a limited pumping height set by the pressure the boiler and other vessels could withstand. Before its replacement by Thomas Newcomen's engine (described below), John Desaguliers improved the Savery engine, adding the Papin safety valve and using an internal jet for the condensing part of the cycle.

Steam engine developments continued and the earliest cylinder-and-piston unit was based on Papin's suggestion, in 1690, that the condensation of steam should be used to make a vacuum beneath a piston, after the piston had been raised by expanding steam. Newcomen's atmospheric pressure engine made practical use of this principle.

While Papin neglected his own ideas of a steam engine to develop Savery's invention, Thomas Newcomen and his assistant John Cawley adapted Papin's suggestions in a practical engine. Years of experimentation ended with success in 1711 (Fig. 6). Steam admitted from the boiler to a cylinder raised a piston by expansion and assistance from a counterweight on the other end of a beam, actuated by the piston. The steam valve was then closed and the steam in the cylinder was condensed by a spray of cold water. The vacuum which formed caused the piston to be forced downward by atmospheric pressure, doing work on a pump. Condensed water in the cylinder was expelled through a valve by the entry of steam which was at a pressure slightly above atmospheric. A 25 ft (7.6 m) oak beam, used to transmit power from the cylinder to the water pump, was a dominant feature

Fig. 6 Newcomen's beam engine, 1711.

of what came to be called the *beam engine*. The boiler used by Newcomen, a plain copper brewer's kettle, was known as the Haycock type. (See Fig. 4.)

The key technical challenge remained the need for higher pressures, which meant a more reliable and stronger boiler. Basically, evolution of the steam boiler paralleled evolution of the steam engine.

During the late 1700s, the inventor James Watt pursued developments of the steam engine, now physically separated from the boiler. Evidence indicates that he helped introduce the first *waggon boiler*, so named because of its shape (Fig. 7). Watt concentrated on the engine and developed the separate steam condenser to create the vacuum and also replaced atmospheric pressure with steam pressure, improving the engine's efficiency. He also established the measurement of horsepower, calculating that one horse could raise 550 lb (249 kg) of weight a distance of 1 ft (0.3 m) in one second, the equivalent of 33,000 lb (14,969 kg) a distance of one foot in one minute.

Fig. 5 Savery's engine, circa 1700.

Fig. 7 Waggon boiler, 1769.

Fire tube boilers

The next outstanding inventor and builder was Richard Trevithick, who had observed many pumping stations at his father's mines. He realized that the problem with many pumping systems was the boiler capacity. Whereas copper was the only material previously available, hammered wrought iron plates could now be used, although the maximum length was 2 ft (0.6 m). Rolled iron plates became available in 1875.

In 1804, Trevithick designed a higher pressure engine, made possible by the successful construction of a high pressure boiler (Fig. 8). Trevithick's boiler design featured a cast iron cylindrical shell and dished end.

As demand grew further, it became necessary to either build larger boilers with more capacity or put up with the inconveniences of operating many smaller units. Engineers knew that the longer the hot gases were in contact with the shell and the greater the exposed surface area, the greater the capacity and efficiency.

While a significant advance, Newcomen's engine and boiler were so thermally inefficient that they were frequently only practical at coal mine sites. To make the system more widely applicable, developers of steam engines began to think in terms of fuel economy. Noting that nearly half the heat from the fire was lost because of short contact time between the hot gases and the boiler heating surface, Dr. John Allen may have made the first calculation of boiler efficiency in 1730. To reduce heat loss, Allen developed an internal furnace with a smoke flue winding through the water, like a coil in a still. To prevent a deficiency of combustion air, he suggested the use of bellows to force the gases through the flue. This probably represents the first use of forced draft.

Later developments saw the single pipe flue replaced by many gas tubes, which increased the amount of

heating surface. These *fire tube* boilers were essentially the design of about 1870. However, they were limited in capacity and pressure and could not meet the needs that were developing for higher pressures and larger unit sizes. Also, there was the ominous record of explosions and personal injury because of direct heating of the pressure shell, which contained large volumes of water and steam at high temperature and pressure.

The following appeared in the 1898 edition of *Steam: That the ordinary forms of boilers (fire tube boilers) are liable to explode with disastrous effect is conceded. That they do so explode is witnessed by the sad list of casualties from this cause every year, and almost every day. In the year 1880, there were 170 explosions reported in the United States, with a loss of 259 lives, and 555 persons injured. In 1887 the number of explosions recorded was 198, with 652 persons either killed or badly wounded. The average reported for ten years past has been about the same as the two years given, while doubtless many occur which are not recorded.*

Inventors recognized the need for a new design, one that could increase capacity and limit the consequences of pressure part rupture at high pressure and temperature. *Water tube* boiler development began.

Early water tube design

A patent granted to William Blakey in 1766, covering an improvement in Savery's steam engine, includes a form of steam generator (Fig. 9). This probably was the first step in the development of the water tube boiler. However, the first successful use of a water tube design was by James Rumsey, an American inventor who patented several types of boilers in 1788. Some of these boilers used water tube designs.

At about this time John Stevens, also an American, invented a water tube boiler consisting of a group of small tubes closed at one end and connected at the

Fig. 8 Trevithick boiler, 1804.

Fig. 9 William Blakey boiler, 1766.

Fig. 10 John Stevens water tube boiler, 1803.

other to a central reservoir (Fig. 10). Patented in the United States (U.S.) in 1803, this boiler was used on a Hudson River steam boat. The design was short lived, however, due to basic engineering problems in construction and operation.

Blakey had gone to England to obtain his patents, as there were no similar laws in North America. Stevens, a lawyer, petitioned the U.S. Congress for a patent law to protect his invention and such a law was enacted in 1790. It may be said that part of the basis of present U.S. patent laws grew out of the need to protect a water tube boiler design. Fig. 11 shows another form of water tube boiler, this one patented by John Cox Stevens in 1805.

In 1822, Jacob Perkins built a water tube boiler that is the predecessor of the once-through steam generator. A number of cast iron bars with longitudinal holes were arranged over the fire in three tiers by connecting the ends outside of the furnace with a series of bent pipes. Water was fed to the top tier by a feed pump and superheated steam was discharged from the lower tier to a collecting chamber.

The Babcock & Wilcox Company

It was not until 1856, however, that a truly successful water tube boiler emerged. In that year, Stephen Wilcox, Jr. introduced his version of the water tube design with improved water circulation and increased heating surface (Fig. 12). Wilcox had designed a boiler

Fig. 11 Water tube boiler with tubes connecting water chamber below and steam chamber above. John Cox Stevens, 1805.

Fig. 12 Inclined water tubes connecting front and rear water spaces, complete with steam space above. Stephen Wilcox, 1856.

with inclined water tubes that connected water spaces at the front and rear, with a steam chamber above. Most important, as a water tube boiler, his unit was inherently *safe*. His design revolutionized the boiler industry.

In 1866, Wilcox partnered with his long-time friend, George H. Babcock. The following year, U.S. Patent No. 65,042 was granted to George H. Babcock and Steven Wilcox, Jr., and the partnership of Babcock, Wilcox and Company was formed. In 1870 or 1871, Babcock and Wilcox became the sole proprietors, dropping *Company* from the name, and the firm was known as Babcock & Wilcox until its incorporation in 1881, when it changed its name to The Babcock & Wilcox Company (B&W). (see Fig. 3).

Industrial progress continued. In 1876, a giant-sized Corliss steam engine, a device invented in Rhode Island in 1849, went on display at the Centennial Ex-

Fig. 13 Babcock & Wilcox Centennial boiler, 1876.

hibition in Philadelphia, Pennsylvania, as a symbol of worldwide industrial development. Also on prominent display was a 150 horsepower water tube boiler (Fig. 13) by George Babcock and Stephen Wilcox, who were by then recognized as engineers of unusual ability. Their professional reputation was high and their names carried prestige. By 1877, the Babcock & Wilcox boiler had been modified and improved by the partners several times (Fig. 14).

At the exhibition, the public was awed by the size of the Corliss engine. It weighed 600 tons and had cylinders 3 ft (0.9 m) in diameter. But this giant size was to also mark the end of the steam engine, in favor of more efficient prime movers, such as the steam turbine. This transition would add momentum to further development of the Babcock & Wilcox water tube boiler. By 1900, the steam turbine gained importance as the major steam powered source of rotary motion, due primarily to its lower maintenance costs, greater overloading tolerance, fewer number of moving parts, and smaller size.

Perhaps the most visible technical accomplishments of the time were in Philadelphia and New York City. In 1881 in Philadelphia, the Brush Electric Light Company began operations with four boilers totaling 292 horsepower. In New York the following year, Thomas Alva Edison threw the switch to open the Pearl Street Central station, ushering in the *age of the cities*. The boilers in Philadelphia and the four used by Thomas Edison in New York were built by B&W, now incorporated. The boilers were heralded as *sturdy, safe and*

Fig. 14 Babcock & Wilcox boiler developed in 1877.

reliable. When asked in 1888 to comment on one of the units, Edison wrote: *It is the best boiler God has permitted man yet to make*. (Fig. 15).

The historic Pearl Street Central station opened with 59 customers using about 1300 lamps. The B&W boilers consumed 5 tons of coal and 11,500 gal (43,532 l) of water per day.

The B&W boiler of 1881 was a safe and efficient steam generator, ready for the part it would play in worldwide industrial development.

Water tube marine boilers

The first water tube marine boiler built by B&W was for the *Monroe* of the U.S. Army's Quartermaster

George Herman Babcock

George Herman Babcock was born June 17, 1832 near Otsego, New York. His father was a well known inventor and mechanic. When George was 12 years old, his parents moved to Westerly, Rhode Island, where he met Stephen Wilcox, Jr.

At age 19, Babcock started the *Literary Echo*, editing the paper and running a printing business. With his father, he invented the first polychromatic printing press, and he also patented a job press which won a prize at the London Crystal Palace International Exposition in 1855.

In the early 1860s, he was made chief draftsman of the Hope Iron Works at Providence, Rhode Island, where he renewed his acquaintance with Stephen Wilcox and worked with him in developing the first B&W boiler. In 1886, Babcock became the sixth president of the American Society of Mechanical Engineers.

He was the first president of The Babcock & Wilcox Company, a position he held until his death in 1893.

department. A major step in water tube marine boiler design came in 1889, with a unit for the steam yacht *Reverie*. The U.S. Navy then ordered three ships featuring a more improved design that saved about 30% in weight from previous designs. This design was again improved in 1899, for a unit installed in the U.S. cruiser *Alert*, establishing the superiority of the water tube boiler for marine propulsion. In this installation, the firing end of the boiler was reversed, placing the firing door in what had been the rear wall of the boiler. The furnace was thereby enlarged in the direction in which combustion took place, greatly improving combustion conditions.

The development of marine boilers for naval and merchant ship propulsion has paralleled that for land use (see Fig. 16). Throughout the twentieth century and into the twenty-first, dependable water tube marine boilers have contributed greatly to the excellent performance of naval and commercial ships worldwide.

Bent tube design

The success and widespread use of the inclined straight tube B&W boiler stimulated other inventors to explore new ideas. In 1880, Allan Stirling developed a design connecting the steam generating tubes directly to a steam separating drum and featuring low headroom above the furnace. The Stirling Boiler Company was formed to manufacture and market an improved Stirling® design, essentially the same as shown in Fig. 17.

The merits of *bent tubes* for certain applications

were soon recognized by George Babcock and Stephen Wilcox, and what had become the Stirling Consolidated Boiler Company in Barberton, Ohio, was purchased by B&W in 1906. After the problems of internal tube cleaning were solved, the bent tube boiler replaced the straight tube design. The continuous and economical production of clean, dry steam, even when using poor quality feedwater, and the ability to meet sudden load swings were features of the new B&W design.

Electric power

Until the late 1800s, steam was used primarily for heat and as a tool for industry. Then, with the advent of practical electric power generation and distribution, utility companies were formed to serve industrial and residential users across wide areas. The pioneer stations in the U.S. were the Brush Electric Light Company and the Commonwealth Edison Company. Both used B&W boilers exclusively.

During the first two decades of the twentieth century, there was an increase in steam pressures and temperatures to 275 psi (1.9 MPa) and 560F (293C), with 146F (81C) superheat. In 1921, the North Tessa station of the Newcastle Electric Supply Company in northern England went into operation with steam at 450 psi (3.1 MPa) and a temperature of 650F (343C). The steam was reheated to 500F (260C) and regenerative feedwater heating was used to attain a boiler feedwater temperature of 300F (149C). Three years later, the Crawford Avenue station of the Commonwealth Edison Company and the Philo and Twin

Stephen Wilcox, Jr.

Stephen Wilcox was born February 12, 1830 at Westerly, Rhode Island.

The first definite information concerning his engineering activities locates him in Providence, Rhode Island, about 1849, trying to introduce a caloric engine. In 1853, in association with Amos Taylor of Mystic, Connecticut, he patented a letoff motion for looms. In 1856, a patent for a steam boiler was issued to Stephen Wilcox and O.M. Stillman. While this boiler differed materially from later designs, it is notable as his first recorded step into the field of steam generation.

In 1866 with George Babcock, Wilcox developed the first B&W boiler, which was patented the following year.

In 1869 he went to New York as selling agent for the Hope Iron Works and took an active part in improving the boiler and the building of the business. He was vice president of The Babcock & Wilcox Company from its incorporation in 1881 until his death in 1893.

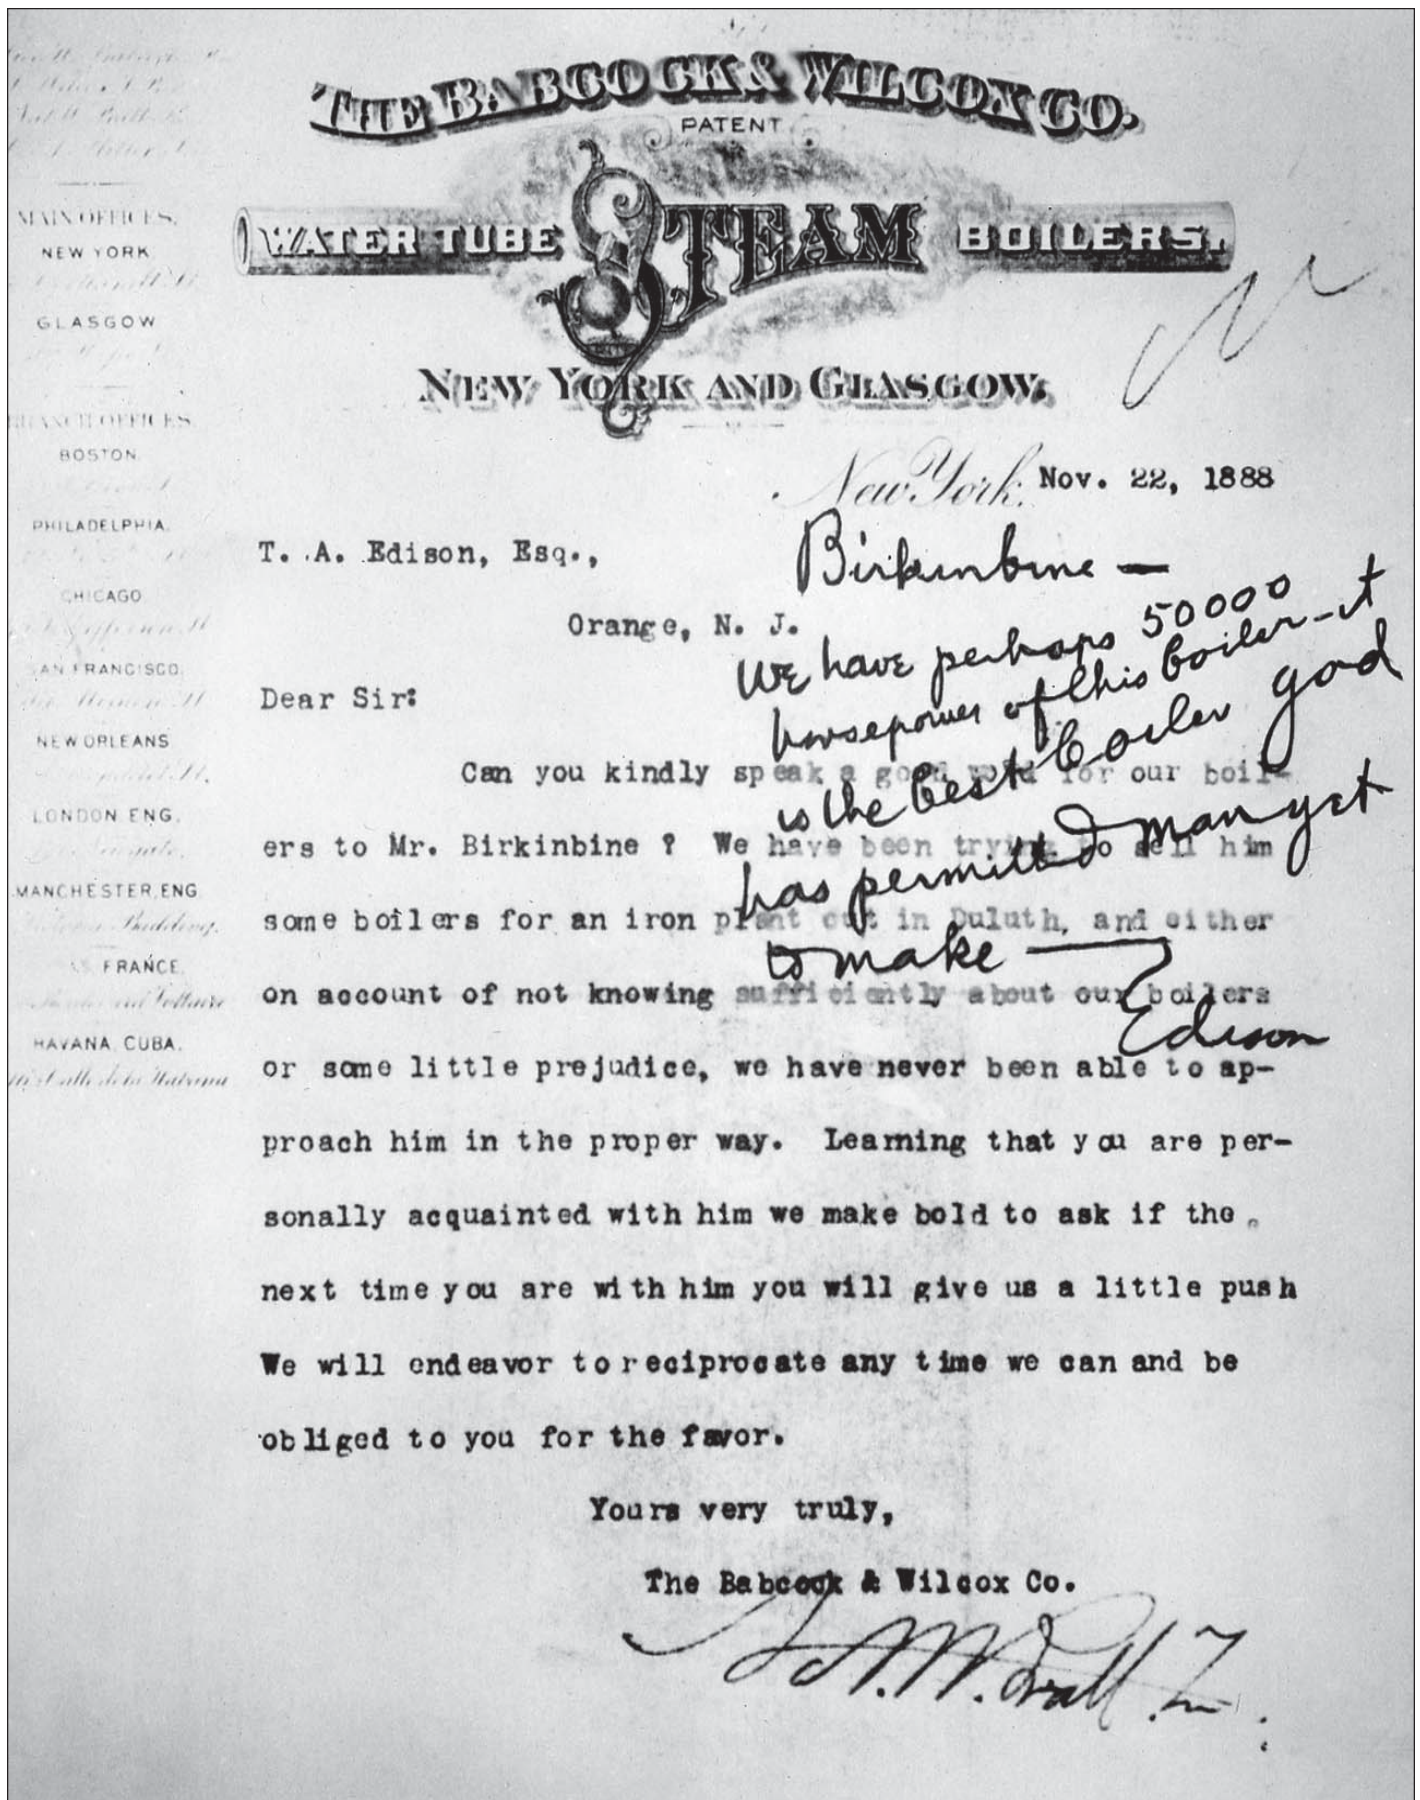

Fig. 15 Thomas Edison's endorsement, 1888.

Branch stations of the present American Electric Power system were placed in service with steam at 550 psi (38 MPa) and 725F (385C) at the turbine throttle. The steam was reheated to 700F (371C).

A station designed for much higher steam pressure, the Weymouth (later named Edgar) station of the Boston Edison Company in Massachusetts, began operation in 1925. The 3150 kW high pressure unit used steam at 1200 psi (8.3 MPa) and 700F (371C), reheated to 700F (371C) for the main turbines (Fig. 18).

Pulverized coal and water-cooled furnaces

Other major changes in boiler design and fabrication occurred in the 1920s. Previously, as power generating stations increased capacity, they increased the number of boilers, but attempts were being made to increase the size of the boilers as well. Soon the size requirement became such that existing furnace designs and methods of burning coal, primarily stokers, were no longer adequate.

Pulverized coal was the answer in achieving higher volumetric combustion rates and increased boiler capacity. This could not have been fully exploited without the use of water-cooled furnaces. Such furnaces eliminated the problem of rapid deterioration of the refractory walls due to slag (molten ash). Also, these designs lowered the temperature of the gases leaving the furnace and thereby reduced fouling (accumulation of ash) of convection pass heating surfaces to manageable levels. The first use of pulverized coal in furnaces of stationary steam boilers had been demonstrated at the Oneida Street plant in Milwaukee, Wisconsin, in 1918.

Fig. 16 Two drum Integral Furnace marine boiler.

Integral Furnace boiler

Water cooling was applied to existing boiler designs, with its circulatory system essentially independent of the boiler steam-water circulation. In the early 1930s, however, a new concept was developed that arranged

Requirements of a Perfect Steam Boiler – 1875

In 1875, George Babcock and Stephen Wilcox published their conception of the perfect boiler, listing twelve principles that even today generally represent good design practice:

1st. Proper workmanship and simple construction, using materials which experience has shown to be best, thus avoiding the necessity of early repairs.

2nd. A mud-drum to receive all impurities deposited from the water, and so placed as to be removed from the action of the fire.

3rd. A steam and water capacity sufficient to prevent any fluctuation in steam pressure or water level.

4th. A water surface for the disengagement of the steam from the water, of sufficient extent to prevent foaming.

5th. A constant and thorough circulation of water throughout the boiler, so as to maintain all parts at the same temperature.

6th. The water space divided into sections so arranged that, should any section fail, no general explosion can occur and the destructive effects will be confined to the escape of the contents. Large and free passages between

the different sections to equalize the water line and pressure in all.

7th. A great excess of strength over any legitimate strain, the boiler being so constructed as to be free from strains due to unequal expansion, and, if possible, to avoid joints exposed to the direct action of the fire.

8th. A combustion chamber so arranged that the combustion of the gases started in the furnace may be completed before the gases escape to the chimney.

9th. The heating surface as nearly as possible at right angles to the currents of heated gases, so as to break up the currents and extract the entire available heat from the gases.

10th. All parts readily accessible for cleaning and repairs. This is a point of the greatest importance as regards safety and economy.

11th. Proportioned for the work to be done, and capable of working to its full rated capacity with the highest economy.

12th. Equipped with the very best gauges, safety valves and other fixtures.

Fig. 17 Early Stirling® boiler arranged for hand firing.

Fig. 18 High pressure reheat boiler, 1925.

the furnace water-cooled surface and the boiler surface together, each as an integral part of the unit (Fig. 19).

Shop-assembled water tube boilers

In the late 1940s, the increasing need for industrial and heating boilers, combined with the increasing costs of field-assembled equipment, led to development of the shop-assembled *package* boiler. These units are now designed in capacities up to 600,000 lb/h (75.6 kg/s) at pressures up to 1800 psi (12.4 MPa) and temperatures to 1000F (538C).

Further developments

In addition to reducing furnace maintenance and the fouling of convection heating surfaces, water cooling also helped to generate more steam. Boiler tube bank surface was reduced because additional steam generating surface was available in the furnace. Increased feedwater and steam temperatures and increased steam pressures, for greater cycle efficiency, further reduced boiler tube bank surface and permitted the use of additional superheater surface.

As a result, Radiant boilers for steam pressures above 1800 psi (12.4 MPa) generally consist of furnace wall tubes, superheaters, and such heat recovery accessories as economizers and air heaters (Fig. 20). Units for lower pressures, however, have considerable steam generating surface in tube banks (boiler banks) in addition to the water-cooled furnace (Fig. 21).

Universal Pressure boilers

An important milestone in producing electricity at the lowest possible cost took place in 1957. The first

Fig. 19 Integral Furnace boiler, 1933.

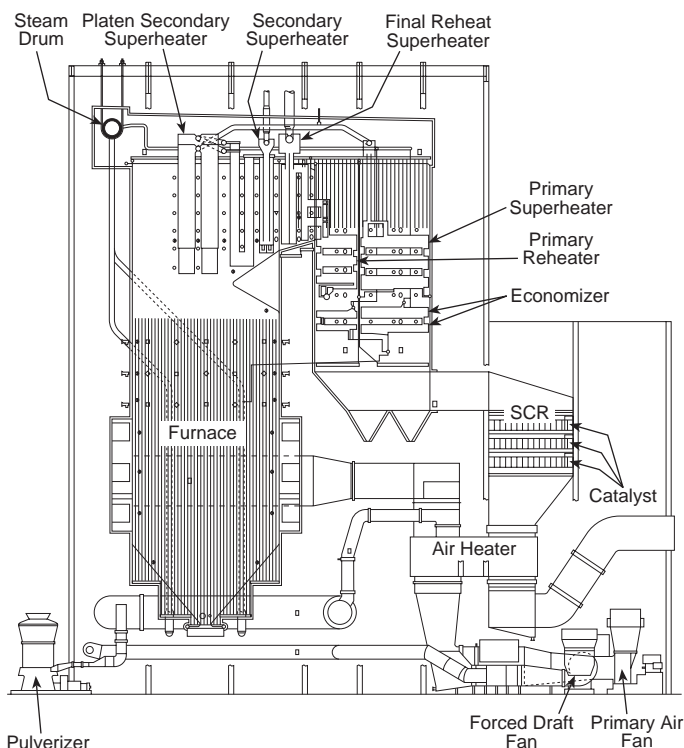

Fig. 20 Typical B&W® Radiant utility boiler.

boiler with steam pressure above the critical value of 3200 psi (22.1 MPa) began commercial operation. This 125 MW B&W Universal Pressure (UP®) steam generator (Fig. 22), located at Ohio Power Company's Philo plant, delivered 675,000 lb/h (85 kg/s) steam at 4550 psi (31.4 MPa); the steam was superheated to 1150F (621C) with two reheats to 1050 and 1000F (566 and 538C).

B&W built and tested its first once-through steam generator for 600 psi (4.1 MPa) in 1916, and built an experimental 5000 psi (34.5 MPa) unit in the late 1920s.

The UP boiler, so named because it can be designed for subcritical or supercritical operation, is capable of rapid load pickup. Increases in load rates up to 5% per minute can be attained.

Fig. 23 shows a typical 1300 MW UP boiler rated at 9,775,000 lb/h (1232 kg/s) steam at 3845 psi (26.5 MPa) and 1010F (543C) with reheat to 1000F (538C). In 1987, one of these B&W units, located in West Virginia, achieved 607 days of continuous operation.

Most recently, UP boilers with spiral wound furnaces (SWUP™ steam generators) have gained wider acceptance for their on/off cycling capabilities and their ability to operate at variable pressure with higher low load power cycle efficiency (see Fig. 24).

Subcritical units, however, remain the dominant design in the existing worldwide boiler fleet. Coal has remained the dominant fuel because of its abundant supply in many countries.

Other fuels and systems

B&W has continued to develop steam generators that can produce power from an ever widening array of fuels in an increasingly clean and environmentally acceptable manner. Landmark developments by B&W include atmospheric fluidized-bed combustion instal-

lations, both bubbling and circulating bed, for reduced emissions.

Waste-to-energy systems also became a major effort worldwide. B&W has installed both mass burn and refuse-derived fuel units to meet this growing demand for waste disposal and electric power generation. B&W installed the world's first waste-to-energy boiler in 1972. In 2000, an acquisition by Babcock & Wilcox expanded the company's capabilities in design and construction of waste-to-energy and biomass boilers and other multi-fuel burning plants.

For the paper industry, B&W installed the first chemical recovery boiler in the U.S. in 1940. Since that time, B&W has developed a long tradition of firsts in this industry and has installed one of the largest black liquor chemical recovery units operating in the world today.

Modified steam cycles

High efficiency cycles involve combinations of gas turbines and steam power in cogeneration, and direct thermal to electrical energy conversion. One direct conversion system includes using conventional fuel or char byproduct from coal gasification or liquefaction.

Despite many complex cycles devised to increase overall plant efficiency, the conventional steam cycle

Fig. 21 Lower pressure Stirling® boiler design.

Fig. 22 125 MW B&W® Universal Pressure (UP®) boiler, 1957.

remains the most economical. The increasing use of high steam pressures and temperatures, reheat superheaters, economizers, and air heaters has led to improved efficiency in the modern steam power cycle.

Nuclear power

Since 1942, when Enrico Fermi demonstrated a controlled self-sustaining reaction, nuclear fission has been recognized as an important source of heat for producing steam for power generation. The first significant application of this new source was the land-based prototype reactor for the U.S.S. *Nautilus* submarine (Fig. 25), operated at the National Reactor

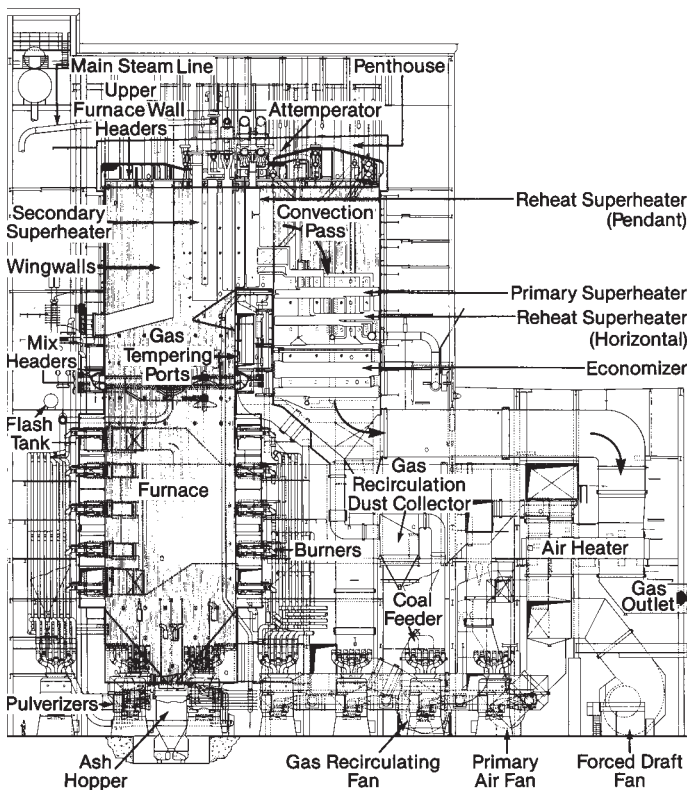

Fig. 23 1300 MW B&W® Universal Pressure (UP®) boiler.

Fig. 24 Boiler with spiral wound universal pressure (SWUP™) furnace.

Testing Station in Idaho in the early 1950s. This prototype reactor, designed by B&W, was also the basis for land-based pressurized water reactors now being used for electric power generation worldwide. B&W and its affiliates have continued their active involvement in both naval and land-based programs.

The first nuclear electric utility installation was the 90 MW unit at the Shippingport atomic power station in Pennsylvania. This plant, built partly by Duquesne Light Company and partly by the U.S. Atomic Energy Commission, began operations in 1957.

Spurred by the trend toward larger unit capacity, developments in the use of nuclear energy for electric power reached a milestone in 1967 when, in the U.S., nuclear units constituted almost 50% of the 54,000 MW of new capacity ordered that year. Single unit capacity designs have reached 1300 MW. Activity regarding nuclear power was also strong outside the

Fig. 25 U.S.S. *Nautilus* – world's first nuclear-powered ship.

U.S., especially in Europe. By 2004, there were 103 reactors licensed to operate in the U.S. Fifty of the operating units had net capacities greater than 1000 MW.

Throughout this period, the nuclear power program in Canada continued to develop based on a design called the Canada Deuterium Uranium (CANDU) reactor system. This system is rated high in both availability and dependability. By 2003, there were 21 units in Canada, all with B&W nuclear steam generators, an additional 11 units operating outside of Canada, and 18 units operating, under construction or planned that are based on CANDU technology.

The B&W recirculating steam generators in these units have continually held excellent performance records and are being ordered to replace aging equipment. (See Fig. 26.)

While the use of nuclear power has remained somewhat steady in the U.S., the future of nuclear power is uncertain as issues of plant operating safety and long-term waste disposal are still being resolved. However, nuclear power continues to offer one of the least polluting forms of large-scale power generation available and may eventually see a resurgence in new construction.

Materials and fabrication

Pressure parts for water tube boilers were originally made of iron and later of steel. Now, steam drums and nuclear pressure vessels are fabricated from heavy steel plates and steel forgings joined by welding. The development of the steam boiler has been necessarily concurrent with advances in metallurgy and progressive improvements in the fabrication and welding of steel and steel alloys.

The cast iron generating tubes used in the first B&W boilers were later superseded by steel tubes. Shortly after 1900, B&W developed a commercial process for the manufacture of hot finished seamless steel boiler tubes, combining strength and reliability with reasonable cost. In the midst of World War II, B&W completed a mill to manufacture tubes by the electric resistance welding (ERW) process. This tubing has now been used in thousands of steam generating units throughout the world.

The cast iron tubes used for steam and water storage in the original B&W boilers were soon replaced by drums. By 1888, drum construction was improved by changing from wrought iron to steel plates rolled into cylinders.

Before 1930, riveting was the standard method of joining boiler drum plates. Drum plate thickness was limited to about 2.75 in. (70 mm) because no satisfactory method was known to secure a tight joint in thicker plates. The only alternative available was to forge and machine a solid ingot of steel into a drum, which was an extremely expensive process. This method was only used on boilers operating at what was then considered high pressure, above 700 psi (4.8 MPa).

The story behind the development of fusion welding was one of intensive research activity beginning in 1926. Welding techniques had to be improved in many respects. Equally, if not more important, an acceptable test procedure had to be found and instituted that would examine the drum without destroying it

in the test. After extensive investigation of various testing methods, the medical radiography (x-ray) machine was adapted in 1929 to production examination of welds. By utilizing both x-ray examination and physical tests of samples of the weld material, the soundness of the welds could be determined without affecting the drum.

In 1930, the U.S. Navy adopted a specification for construction of welded boiler drums for naval vessels. In that same year, the first welded drums ever accepted by an engineering authority were part of the B&W boilers installed in several naval cruisers. Also in 1930, the Boiler Code Committee of the American Society of Mechanical Engineers (ASME) issued complete rules and specifications for the fusion welding of drums for power boilers. In 1931, B&W shipped the first welded power boiler drum built under this code.

The x-ray examination of welded drums, the rules declared for the qualification of welders, and the control of welding operations were major first steps in the development of modern methods of quality control in the boiler industry. Quality assurance has received additional stimulus from the naval nuclear propulsion program and from the U.S. Nuclear Regulatory Commission in connection with the licensing of nuclear plants for power generation.

Research and development

Since the founding of the partnership of Babcock, Wilcox and Company in 1867 and continuing to the present day, research and development have played important roles in B&W's continuing service to the power industry. From the initial improvements of Wilcox's original safety water tube boiler to the first supercritical pressure boilers, and from the first privately operated nuclear research reactor to today's advanced environmental systems, innovation and the new ideas of its employees have placed B&W at the forefront of safe, efficient and clean steam generation and energy conversion technology. Today, research and development activities remain an integral part of B&W's focus on tomorrow's product and process requirements.

Fig. 26 B&W replacement recirculating steam generators.

A key to the continued success of B&W is the ability to bring together cross-disciplinary research teams of experts from the many technical specialties in the steam generation field. These are combined with state-of-the-art test facilities and computer systems.

Expert scientists and engineers use equipment designed specifically for research programs in all aspects of fossil power development, nuclear steam systems, materials development and evaluation, and manufacturing technology. Research focuses upon areas of central importance to B&W and steam power generation. However, partners in these research programs have grown to include the U.S. Departments of Energy and Defense, the Environmental Protection Agency, public and private research institutes, state governments, and electric utilities.

Key areas of current research include environmental protection, fuels and combustion technology, heat transfer and fluid mechanics, materials and manufacturing technologies, structural analysis and design, fuels and water chemistry, and measurement and monitoring technology.

Environmental protection

Environmental protection is a key element in all modern steam producing systems where low cost steam and electricity must be produced with minimum impact on the environment. Air pollution control is a key issue for all combustion processes, and B&W has been a leader in this area. Several generations of low nitrogen oxides (NO_x) burners and combustion technology for coal-, oil- and gas-fired systems have been developed, tested and patented by B&W. Post-combustion NO_x reduction has focused on both selective catalytic and non-catalytic reduction systems. Combined with low NO_x burners, these technologies have reduced NO_x levels by up to 95% from historical uncontrolled levels. Ongoing research and testing are being combined with fundamental studies and computer numerical modeling to produce the ultra-low NO_x steam generating systems of tomorrow.

Since the early 1970s, extensive research efforts have been underway to reduce sulfur dioxide (SO_2) emissions. These efforts have included combustion modifications and post-combustion removal. Research during this time aided in the development of B&W's wet SO_2 scrubbing system. This system has helped control emissions from more than 32,000 MW of boiler capacity. Current research focuses on improved removal and operational efficiency, and multi-pollution control technology. B&W has installed more than 9000 MW of boiler capacity using various dry scrubbing technologies. Major pilot facilities have permitted the testing of in-furnace injection, in-duct injection, and dry scrubber systems, as well as atomization, gas conditioning and combined SO_2 , NO_x and particulate control. (See Fig. 27.)

Since 1975, B&W has been a leader in fluidized-bed combustion (FBC) technology which offers the ability to simultaneously control SO_2 and NO_x formation as an integral part of the combustion process, as well as burn a variety of waste and other difficult to combust fuels. This work led to the first large scale (20

Fig. 27 B&W boiler with SO_2 , NO_x , and particulate control systems.

MW) bubbling-bed system installation in the U.S. B&W's research and development work has focused on process optimization, limestone utilization, and performance characteristics of various fuels and sorbents.

Additional areas of ongoing environmental research include air toxic emissions characterization, efficient removal of mercury, multi-pollutant emissions control, and sulfur trioxide (SO_3) capture, among others (Fig. 28). B&W also continues to review and evaluate processes to characterize, reuse, and if needed, safely dispose of solid waste products.

Fuels and combustion technology

A large number of fuels have been used to generate steam. This is even true today as an ever-widening and varied supply of waste and byproduct fuels such as municipal refuse, coal mine tailings and biomass wastes, join coal, oil and natural gas to meet steam production needs. These fuels must be burned and their combustion products successfully handled while addressing two key trends: 1) declining fuel quality (lower heating value and poorer combustion), and 2) more restrictive emissions limits.

Major strengths of B&W and its work in research and development have been: 1) the characterization of fuels and their ashes, 2) combustion of difficult fuels, and 3) effective heat recovery from the products of combustion. (See Fig. 29.) B&W has earned inter-

Fig. 28 Tests for multi-pollutant emissions control.

national recognition for its fuels analysis capabilities that are based upon generally accepted procedures, as well as specialized B&W procedures. Detailed analyses include, but are not limited to: heating value, chemical constituents, grindability, abrasion resistance, erosiveness, ignition, combustion characteristics, ash composition/viscosity/fusion temperature, and particle size. The results of these tests assist in pulverizer specification and design, internal boiler dimension selection, efficiency calculations, predicted unit availability, ash removal system design, sootblower placement, and precipitator performance evaluation. Thousands of coal and ash samples have been analyzed and catalogued, forming part of the basis for B&W's design methods.

Combustion and fuel preparation facilities are maintained that can test a broad range of fuels at large scale. The 6×10^6 Btu/h (1.8 MW_t) small boiler

Fig. 29 Atomic absorption test for ash composition.

simulator (Fig. 30) permits a simulation of the time-temperature history of the entire combustion process. The subsystems include a vertical test furnace; fuel subsystem for pulverizing, collecting and firing solid fuels; fuel storage and feeding; emission control modules; gas and stack particulate analyzers for O₂, CO, CO₂ and NO_x; and instrumentation for solids grinding characterization.

Research continues in the areas of gas-side corrosion, boiler fouling and cleaning characteristics, advanced pulp and paper black liquor combustion, oxygen and oxygen enhanced firing systems, and coal gasification, among others.

Heat transfer and fluid dynamics

Heat transfer is a critical technology in the design of steam generation equipment. For many years, B&W has been conducting heat transfer research from hot gases to tube walls and from the tube walls to enclosed water, steam and air. Early in the 1950s, research in heat transfer and fluid mechanics was initiated in the supercritical pressure region above 3200 psi (22.1 MPa). This work was the technical foundation for the large number of supercritical pressure once-through steam generators currently in service in the electric power industry.

A key advancement in steam-water flow was the invention of the ribbed tube, patented by B&W in 1960. By preventing deterioration of heat transfer under many flow conditions (called critical heat flux or departure from nucleate boiling), the internally ribbed tube made possible the use of natural circulation boilers at virtually all pressures up to the critical point. Extensive experimental studies have provided the critical heat flux data necessary for the design of boilers with both ribbed and smooth bore tubes.

Fig. 30 B&W's small boiler simulator.

Closely related to heat transfer, and of equal importance in steam generating equipment, is fluid mechanics. Both low pressure fluids (air and gas in ducts and flues) and high pressure fluids (water, steam-water mixtures, steam and fuel oil) must be investigated. The theories of single-phase fluid flow are well understood, but the application of theory to the complex, irregular and multiple parallel path geometry of practical situations is often difficult and sometimes impossible. In these cases, analytical procedures must be supplemented or replaced by experimental methods. If reliable extrapolations are possible, economical modeling techniques can be used. Where extrapolation is not feasible, large-scale testing at full pressure, temperature and flow rate is needed.

Advances in numerical modeling technology have made possible the evaluation of the complex three-dimensional flow, heat transfer and combustion processes in coal-fired boiler furnaces. B&W is a leader in the development of numerical computational models to evaluate the combustion of coal, biomass, black liquor and other fuels that have a discrete phase, and the application of these models to full boiler and system analysis (Fig. 31). Continuing development and validation of these models will enhance new boiler designs and expand applications. These models are also valuable tools in the design and evaluation of combustion processes, pollutant formation, and environmental control equipment.

Research, analytical and field test studies in boiling heat transfer, two-phase flow, and stability, among other key areas, continue today by B&W alone and in cooperation with a range of world class organizations.

Materials and manufacturing technologies

Because advanced steam producing and energy conversion systems require the application and fabrication of a wide variety of carbon, alloy and stainless steels, nonferrous metals, and nonmetallic materials, it is essential that experienced metallurgical and materials science personnel are equipped with the finest investigative tools. Areas of primary interest in the metallurgical field are fabrication processes such as welding, room temperature and high temperature material properties, resistance to corrosion properties, wear resistance properties, robotic welding, and changes in such material properties under various operating conditions. Development of oxidation-resistant alloys that retain strength at high temperature, and determination of short-term and long-term high temperature properties permitted the increase in steam temperature that has been and continues to be of critical importance in increasing power plant efficiency and reducing the cost of producing electricity.

Advancements in manufacturing have included a process to manufacture large pressure components entirely from weld wire, designing a unique manu-

Fig. 31 B&W has developed advanced computational numerical models to evaluate complex flow, heat transfer and combustion processes.

facturing process for bi-metallic tubing, using pressure forming to produce metallic heat exchangers, developing air blown ultra-high temperature fibrous insulation, and combining sensor and control capabilities to improve quality and productivity of manufacturing processes.

Research and development activities also include the study of materials processing, joining processes, process metallurgy, analytical and physical metallurgical examination, and mechanical testing. The results are subsequently applied to product improvement.

Structural analysis and design

The complex geometries and high stresses under which metals must serve in many products require careful study to allow prediction of stress distribution and intensity. Applied mechanics, a discipline with highly sophisticated analytical and experimental techniques, can provide designers with calculation methods and other information to assure the safety of structures and reduce costs by eliminating unnecessarily conservative design practices. The analytical techniques involve advanced mathematical procedures and computational tools as well as the use of advanced computers. An array of experimental tools and techniques are used to supplement these powerful analytical techniques.

Computational finite element analysis has largely displaced experimental measurement for establishing detailed local stress relationships. B&W has developed and applied some of the most advanced computer programs in the design of components for the power industry. Advanced techniques permit the evaluation of stresses resulting from component response to thermal and mechanical (including vibratory) loading.

Fracture mechanics, the evaluation of crack formation and growth, is an important area where analytical techniques and new experimental methods permit a better understanding of failure modes and the pre-

diction of remaining component life. This branch of technology has contributed to the feasibility and safety of advanced designs in many types of equipment.

To provide part of the basis for these models, extensive computer-controlled experimental facilities allow the assessment of mechanical properties for materials under environments similar to those in which they will operate. Some of the evaluations include tensile and impact testing, fatigue and corrosion fatigue, fracture toughness, as well as environmentally assisted cracking.

Fuel and water chemistry

Chemistry plays an important role in supporting the effective operation of steam generating systems. Therefore, diversified chemistry capabilities are essential to support research, development and engineering. The design and operation of fuel burning equipment must be supported by expert analysis of a wide variety of solid, liquid and gaseous fuels and their products of combustion, and characterization of their behavior under various conditions. Long-term operation of steam generating equipment requires extensive water programs including high purity water analysis, water treatment and water purification. Equipment must also be chemically cleaned at intervals to remove water-side deposits.

To develop customized programs to meet specific needs, B&W maintains a leadership position in these areas through an expert staff for fuels characterization, water chemistry and chemical cleaning. Studies focus on water treatment, production and measurement of ultra-high purity water (parts per billion), water-side deposit analysis, and corrosion product transport.

B&W was involved in the introduction of oxygen water treatment for U.S. utility applications. Specialized chemical cleaning evaluations are conducted to prepare cleaning programs for utility boilers, industrial boilers and nuclear steam generators. Special analyses are frequently required to develop boiler-specific cleaning solvent solutions that will remove the desired deposits without damaging the equipment.

Measurements and monitoring technology

Development, evaluation and accurate assessment of modern power systems require increasingly precise measurements in difficult to reach locations, often in hostile environments. To meet these demanding needs, B&W continues the investigation of specialized sensors, measurement and nondestructive examination. B&W continues to develop diagnostic methods that lead to advanced systems for burner and combustion systems as well as boiler condition assessment.

These techniques have been used to aid in laboratory research such as void fraction measurements for steam-water flows. They have also been applied to operating steam generating systems. New methods have been introduced by B&W to nondestructively measure oxide thicknesses on the inside of boiler tubes, detect hydrogen damage, and detect and measure corrosion fatigue cracks. Acoustic pyrometry systems have been introduced by B&W to nonintrusively measure high temperature gases in boiler furnaces.

Steam/its generation and use

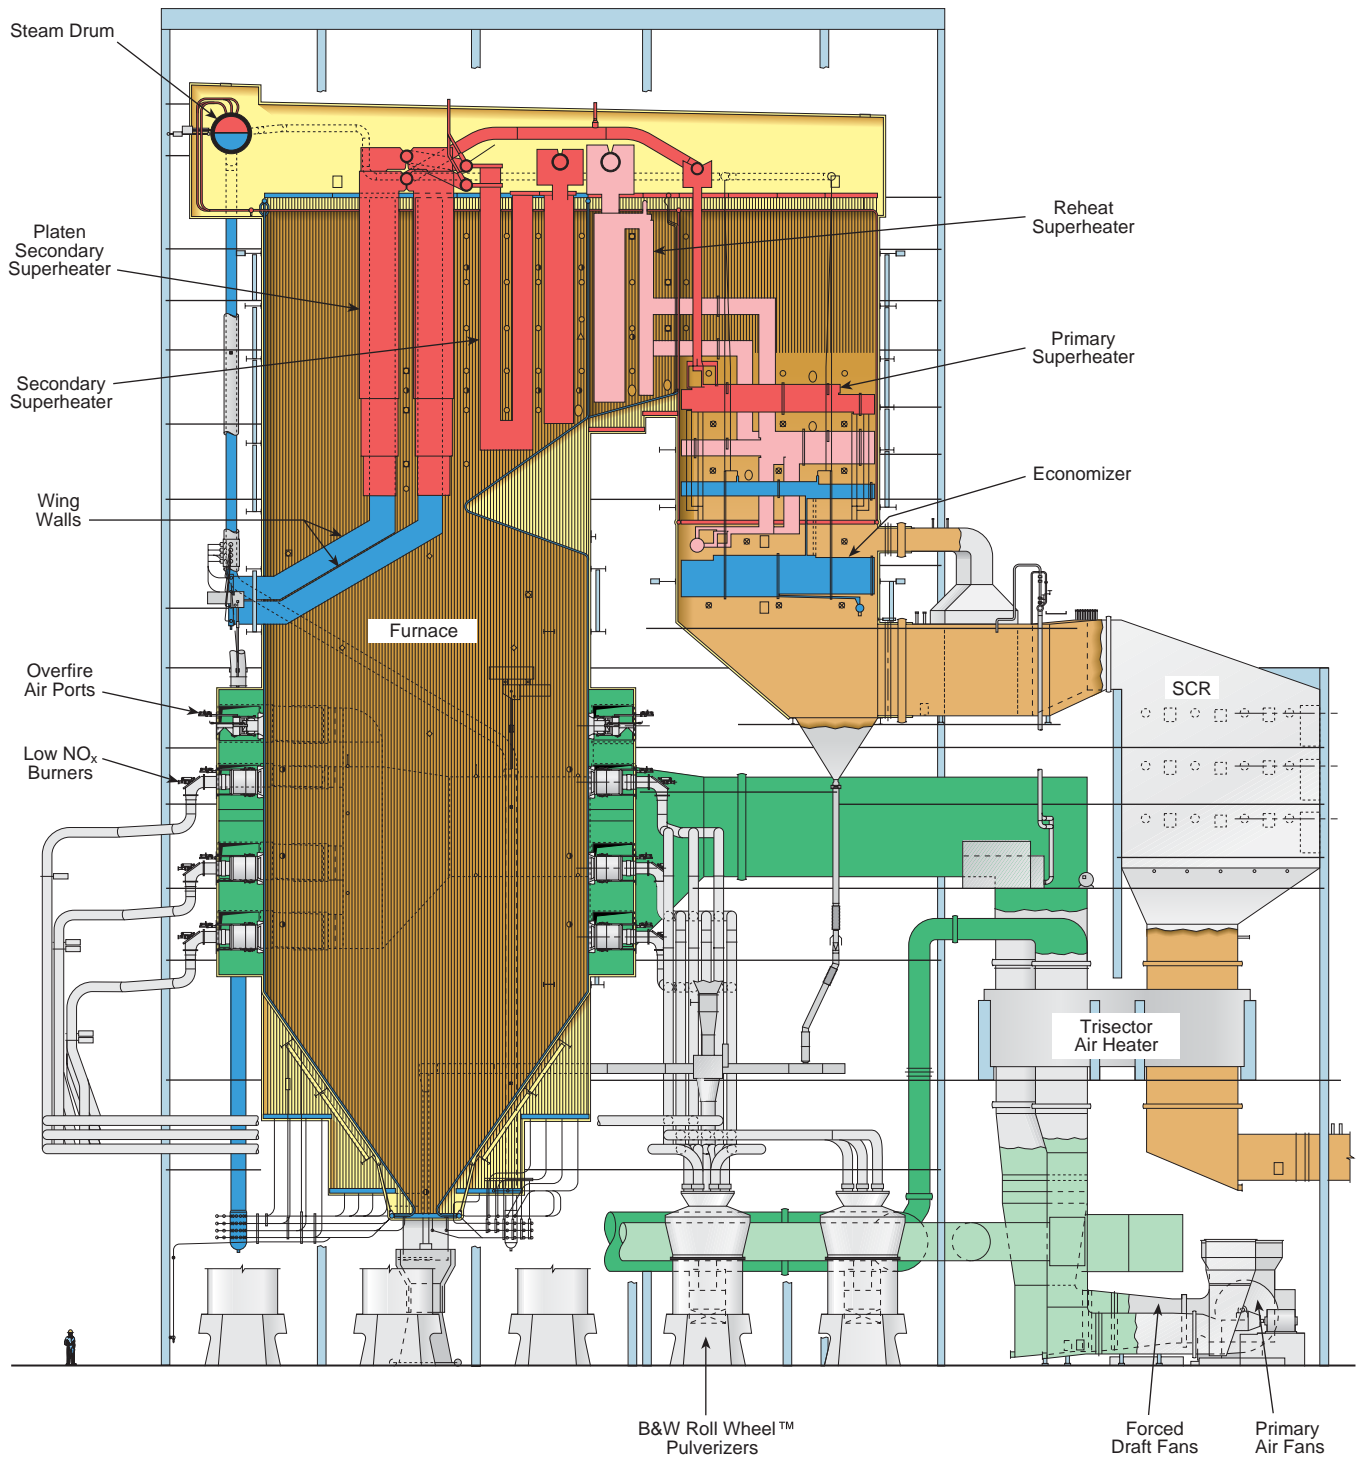

This updated and expanded edition provides a broad, in-depth look at steam generating technology and equipment, including related auxiliaries that are of interest to engineers and students in the steam power industry. The reader will find discussions of the fundamental technologies such as thermodynamics, fluid mechanics, heat transfer, solid mechanics, numerical and computational methods, materials science and fuels science. The various components of the steam generating equipment, plus their integration and performance evaluation, are covered in depth. Extensive additions and updates have been made to the chapters covering environmental control technologies and numerical modeling. Key elements of the balance of the steam generating system life including operation, condition assessment, maintenance, and retrofits are also discussed.

Section I

Steam Fundamentals

Steam is uniquely adapted, by its availability and advantageous properties, for use in industrial and heating processes and in power cycles. The fundamentals of the steam generating process and the core technologies upon which performance and equipment design are based are described in this section of eight chapters. Chapter 1 provides an initial overview of the process, equipment and design of steam generating systems, and how they interface with other processes that produce power and use steam. This is followed by fundamental discussions of thermodynamics, fluid dynamics, heat transfer, and the complexities of boiling and steam-water flow in Chapters 2 through 5. New Chapter 6 is dedicated to exploring the dramatic increase in the use of advanced computational numerical analysis in the design of modern steam generators. The section concludes with Chapters 7 and 8 discussing key elements of material science and structural analysis that permit the safe and efficient design of the steam generating units and components.

Chapter 1

Steam Generation – An Overview

Steam generators, or boilers, use heat to convert water into steam for a variety of applications. Primary among these are electric power generation and industrial process heating. Steam is a key resource because of its wide availability, advantageous properties and nontoxic nature. Steam flow rates and operating conditions are the principal design considerations for any steam generator and can vary dramatically: from 1000 lb/h (0.1 kg/s) in one process use to more than 10 million lb/h (1260 kg/s) in large electric power plants; from about 14.7 psi (0.1013 MPa) and 212F (100C) in some heating applications to more than 4500 psi (31.03 MPa) and 1100F (593C) in advanced cycle power plants.

Fuel use and handling add to the complexity and variety of steam generating systems. The fuels used in most steam generators are coal, natural gas and oil. However, nuclear energy also plays a major role in at least the electric power generation area. Also, an increasing variety of biomass materials and process byproducts have become heat sources for steam generation. These include peat, wood and wood wastes, bagasse, straw, coffee grounds, corn husks, coal mine wastes (culm), and waste heat from steelmaking furnaces. Even renewable energy sources, e.g., solar, are being used to generate steam. The steam generating process has also been adapted to incorporate functions such as chemical recovery from paper pulping processes, volume reduction for municipal solid waste or trash, and hazardous waste destruction.

Steam generators designed to accomplish these tasks range from a small package boiler (Fig. 1) to large, high capacity utility boilers used to generate 1300 MW of electricity (Fig. 2). The former is a factory-assembled, fully-automated, gas-fired boiler, which can supply saturated steam for a large building, perhaps for a hospital. It arrives at the site with all controls and equipment assembled. The large field-erected utility boiler will produce more than 10 million lb/h (1260 kg/s) steam at 3860 psi (26.62 MPa) and 1010F (543C). Such a unit, or its companion nuclear option (Fig. 3), is part of some of the most complex and demanding engineering systems in operation today. Other examples, illustrating the range of combustion systems, are shown by the 750 t/d (680 tm/d) mass-fired refuse power boiler in Fig. 4 and the circulating fluidized-bed combustion boiler in Fig. 5.

The central job of the boiler designer in any of these

applications is to combine fundamental science, technology, empirical data, and practical experience to produce a steam generating system that meets the steam supply requirements in the most economical package. Other factors in the design process include fuel characteristics, environmental protection, thermal efficiency, operations, maintenance and operating costs, regulatory requirements, and local geographic and weather conditions, among others. The design process involves balancing these complex and sometimes competing factors. For example, the reduction of pollutants such as nitrogen oxides (NO_x) may require a larger boiler volume, increasing capital costs and potentially increasing maintenance costs. Such a design activity is firmly based upon the physical and thermal sciences such as solid mechanics, thermodynamics, heat transfer, fluid mechanics and materials science. However, the real world is so complex and variable, and so interrelated, that it is only by applying the art of boiler design to combine science and practice that the most economical and dependable design can be achieved.

Steam generator design must also strive to address in advance the many changes occurring in the world to provide the best possible option. Fuel prices are expected to escalate while fuel supplies become less certain, thereby enforcing the need for continued efficiency improvement and fuel flexibility. Increased environmental protection will drive improvements in combustion to reduce NO_x and in efficiency to reduce carbon dioxide (CO_2) emissions. Demand growth continues in many areas where steam generator load

Fig. 1 Small shop-assembled package boiler.

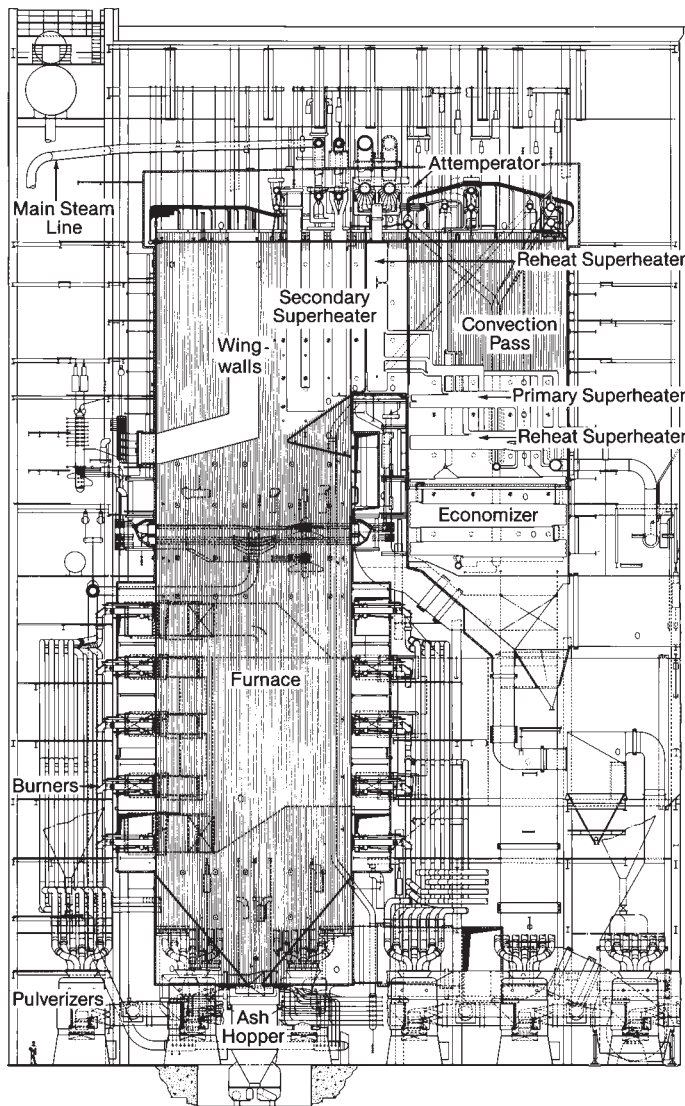

Fig. 2 1300 MW coal-fired utility steam generator.

may have to cycle up and down more frequently and at a faster rate.

There are technologies such as pressurized fluidized-bed combustion and integrated gasification combined cycle systems, plus others, which actually integrate the environmental control with the entire steam generation process to reduce emissions and increase

Fig. 3 900 MW nuclear power system.

power plant thermal efficiency. Also, modularization and further standardization will help reduce fabrication and erection schedules to meet more dynamic capacity addition needs.

Steam generation fundamentals

Boiling

The process of boiling water to make steam is a familiar phenomenon. Thermodynamically, instead of increasing the water temperature, the energy used results in a change of phase from a liquid to a gaseous state, i.e., water to steam. A steam generating system should provide a continuous process for this conversion.

The simplest case for such a device is a kettle boiler where a fixed quantity of water is heated (Fig. 6). The applied heat raises the water temperature. Eventually, for the given pressure, the boiling (*saturation*) temperature is reached and bubbles begin to form. As heat continues to be applied, the temperature remains constant, and steam escapes from the water surface. If the steam is continuously removed from the vessel, the temperature will remain constant until all of the water is evaporated. At this point, heat addition would increase the temperature of the kettle and of any steam remaining in the vessel. To provide a continuous process, all that is needed is a regulated supply of water to the vessel to equal the steam being generated and removed.

Technical and economic factors indicate that the most effective way to produce high pressure steam is to heat relatively small diameter tubes containing a continuous flow of water. Regardless of whether the energy source is nuclear or fossil fuel, two distinct boiling systems are

Fig. 4 Babcock & Wilcox 750 ton per day mass-fired refuse power boiler.

used to accomplish this task: those that include a steam drum (see Fig. 7a), or fixed steam-water separation point, and those that do not (see Fig. 7b), termed once-through steam generators (OTSG).

The most common and simplest to control is the steam drum system. In this system, the drum serves as the point of separation of steam from water throughout its boiler's load range. Subcooled water (less than boiling temperature) enters the tube to which heat is applied. As the water flows through the tube, it is heated to the boiling point, bubbles are formed, and *wet* steam is generated. In most boilers, a steam-water mixture leaves the tube and enters the steam drum, where steam is separated from water. The remaining water is then mixed with the replacement water and returned to the heated tube.

Without a steam drum, i.e., for an OTSG system, subcooled water also enters the tube to which heat is applied, but the flowing water turns into steam somewhere along the flow path (length of tube), dependent upon water flow rate (boiler load) and heat input rates. Shown in Fig. 7b, the flow rate and heat input are closely controlled and coordinated so that all of the water is evaporated and only steam leaves the tube. There is no need for the steam drum (fixed steam-water separation point).

Circulation

For both types of boiling systems described above, water must continuously pass through, or circulate through, the tubes for the system to generate steam continuously. For an OTSG, water makes one pass through the boiler's tubes before becoming steam to be sent to the turbine-generator. However, for those boilers with a fixed steam-water separation point or steam drum, a molecule of water can make many passes through a circulation loop before it leaves as

Fig. 5 Coal-fired circulating fluidized-bed combustion steam generator.

Fig. 6 Simple kettle boiler.

steam to the turbine-generator. Options for this latter system are shown in Fig. 8.

Two different approaches to circulation are commonly used: natural or thermal circulation, and forced or pumped circulation. Natural circulation is illustrated in Fig. 8a. In the *downcomer*, unheated tube segment A-B, no steam is present. Heat addition generates a steam-water mixture in segment B-C. Because the steam and steam-water mixture in segment B-C are less dense than the water segment A-B, gravity will cause the water to flow downward in segment A-B and will

Fig. 7 Boiling process in tubular geometries.

Fig. 8 Simple circulation systems.

cause the steam-water mixture (B-C) to move upward into the steam drum. The rate of water flow or circulation depends upon the difference in average density between the unheated water and the heated steam-water mixture.

The total circulation rate in a natural circulation system depends primarily upon four factors: 1) the height of the boiler, 2) the operating pressure, 3) the heat input rate, and 4) the free flow areas of the components. Taller boilers result in a larger total pressure difference between the heated and unheated legs and therefore can produce larger total flow rates. Higher operating pressures provide higher density steam and higher density steam-water mixtures. This reduces the total weight difference between the heated and unheated segments and tends to reduce flow rate. Higher heat input typically increases the amount of steam in the heated segments and reduces the average density of the steam-water mixture, increasing total flow rate. An increase in the cross-sectional (free flow) areas for the water or steam-water mixtures may increase the circulation rate. For each unit of steam produced, the amount of water entering the tube can vary from 3 to 25 units.

Forced or pumped circulation is illustrated in Fig. 8b. A mechanical pump is added to the simple flow loop and the pressure difference created by the pump controls the water flow rate.

The steam-water separation in the drum requires careful consideration. In small, low pressure boilers, steam-water separation can be easily accomplished with a large drum approximately half full of water. Natural gravity steam-water separation (similar to a kettle) can be sufficient. However, in today's high ca-

capacity, high pressure units, mechanical steam-water separators are needed to economically provide moisture-free steam from the drum. With such devices installed in the drum, the vessel diameter and cost can be significantly reduced.

At very high pressures, a point is reached where water no longer exhibits boiling behavior. Above this critical pressure [3200.11 psi (22.1 MPa)], the water temperature continuously increases with heat addition. Steam generators can be designed to operate at pressures above this critical pressure. Drums and steam-water separation are no longer required and the steam generator operates effectively on the once-through principle.

There are a large number of design methods used to evaluate the expected flow rate for a specific steam generator design and set of operating conditions. In addition, there are several criteria which establish the minimum required flow rate and maximum allowable steam content or quality in individual tubes, as well as the maximum allowable flow rates for the steam drum.

System arrangement and key components

Most applications of steam generators involve the production of electricity or the supply of process steam. In some cases, a combination of the two applications, called *cogeneration*, is used. In each application, the steam generator is a major part of a larger system that has many subsystems and components. Fig. 9 shows a modern coal-fired power generating facility; Fig. 10 identifies the major subsystems. Key subsystems include fuel receiving and preparation, steam generator

and combustion, environmental protection, turbine-generator, and heat rejection including cooling tower.

First, follow the fuel and products of combustion (flue gas) through the system. The fuel handling system stores the fuel supply (coal in this example), prepares the fuel for combustion and transports it to the steam generator. The associated air system supplies air to the burners through a forced draft fan. The steam generator subsystem, which includes the air heater, burns the fuel-air mixture, recovers the heat, and generates the controlled high pressure and high temperature steam. The flue gas leaves the steam generator subsystem and selective catalytic reduction (SCR) system if supplied, then passes through particulate collection and sulfur dioxide (SO₂) scrubbing systems where pollutants are collected and the ash and solid scrubber residue are removed. The remaining flue gas is then sent to the stack through an induced draft fan.

Next, follow the steam-water path. The steam generator (boiler) evaporates water and supplies high temperature, high pressure steam, under carefully controlled conditions, to a turbine-generator set that produces the electricity. The steam may also be reheated in the steam generator, after passing through part of a multi-stage turbine system, by running the exhaust steam back to the boiler convection pass (reheater not shown). Ultimately, the steam is passed from the turbine to the condenser where the remaining waste heat is rejected. Before the water from the condenser is returned to the boiler, it passes through several pumps and heat exchangers (feedwater heaters) to increase its pressure and temperature. The heat absorbed by the condenser is eventually rejected to the atmosphere by one or more cooling towers. These cool-

Fig. 9 Coal-fired utility power plant.

ing towers are perhaps the most visible component in the power system (Fig. 9). The natural draft cooling tower shown is basically a hollow cylindrical structure which circulates air and moisture to absorb the heat rejected by the condenser. Such cooling towers exist at most modern power plant sites, both nuclear- and fossil fuel-fired.

For an industrial power system, many of the same features are needed. However, the turbine-generator and heat rejection portions are replaced by the process application, such as radiant space heaters or heat exchangers.

In a nuclear power system (Fig. 11), the fossil fuel-fired steam generator is replaced by a nuclear reactor vessel and, typically, two or more steam generators. The coal handling system is replaced by a nuclear reactor fuel bundle handling and storage facility, and the large scale air pollution control equipment is not needed.

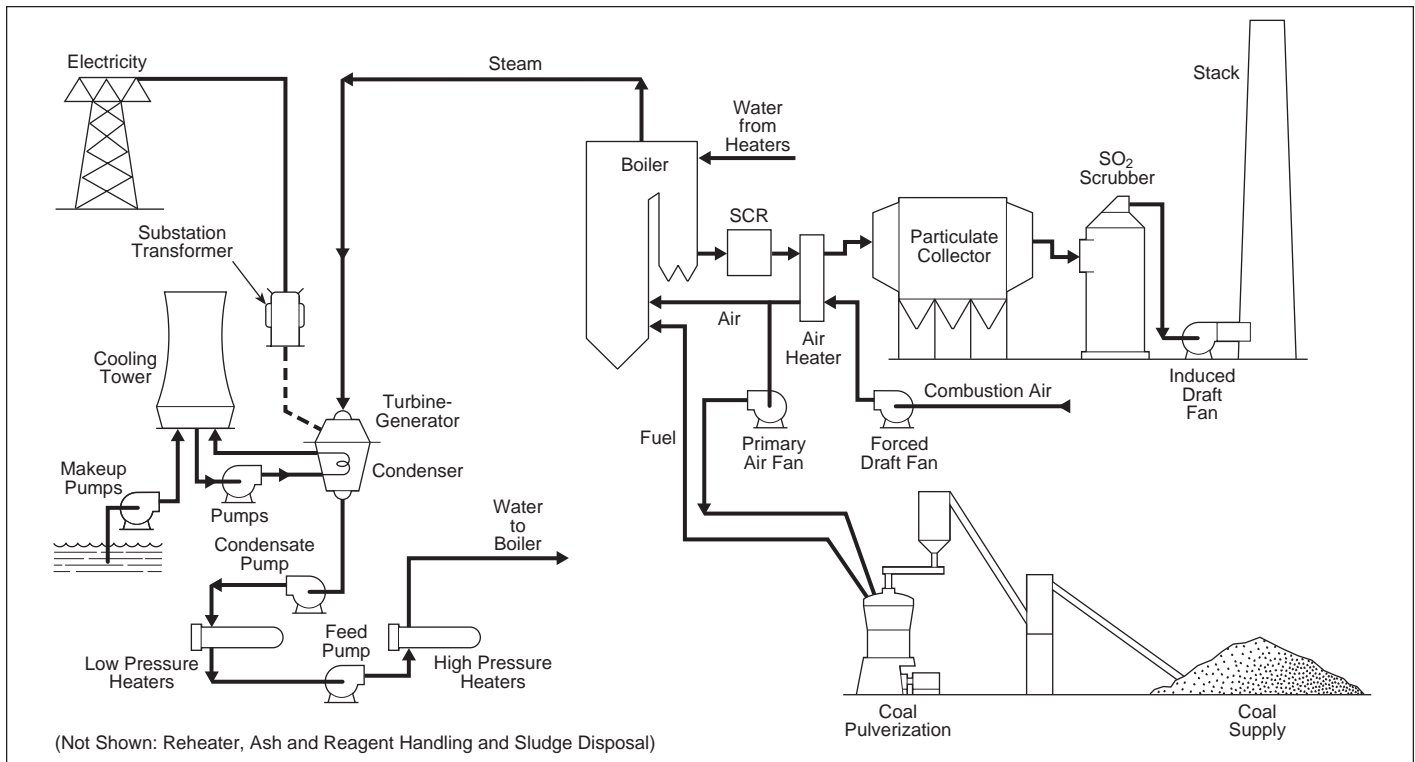

Fig. 10 Coal-fired utility power plant schematic.

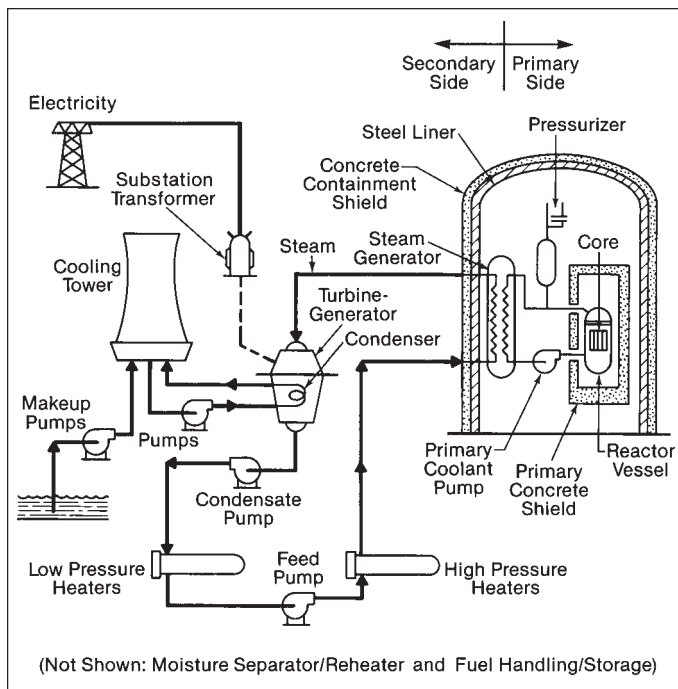

Fig. 11 Nuclear power plant schematic.

Fossil steam generator classifications

Modern steam generating systems can be classified by various criteria. These include end use, firing method, operating pressure, fuel, and circulation method.

Utility steam generators are used primarily to generate electricity in large central power stations. They are designed to optimize overall thermodynamic efficiency at the highest possible availability. New units are typically characterized by large, main steam flow rates with superheated steam outlet pressures from 1800 to 3860 psi (12.41 to 26.62 MPa) with steam temperatures at or above 1050F (566C). A key characteristic of newer units is the use of a reheater section to increase overall cycle efficiency.

Industrial steam generators generally supply steam to processes or manufacturing activities and are designed with particular attention to: 1) process controlled (usually lower) pressures, 2) high reliability with minimum maintenance, 3) use of one or more locally inexpensive fuels, especially process byproducts or wastes, and 4) low initial capital and minimum operating costs. On a capacity basis, the larger users of such industrial units are the pulp and paper industry, municipal solid waste reduction industry, food processing industry, petroleum/petrochemical industry, independent power producers and cogenerators, and some large manufacturing operations. Operating pressures range from 150 to 1800 psi (1.04 to 12.41 MPa) with saturated or superheated steam conditions.

Impact of energy source

The primary fuel selected has perhaps the most significant impact on the steam generator system configuration and design. In the case of nuclear energy, a truly unique system for containing the fuel and the nuclear reaction products has been developed with an

intense focus on safety and protecting the public from radiation exposure. Acceptable materials performance in the radiative environment and the long term thermal-hydraulic and mechanical performance are central to system design. When fossil, biomass, or byproduct fuels are burned, widely differing provisions must be made for fuel handling and preparation, fuel combustion, heat recovery, fouling of heat transfer surfaces, corrosion of materials, and emissions control. For example, in a natural gas-fired unit (Fig. 12), there is minimal need for fuel storage and handling. Only a small furnace is needed for combustion, and closely spaced heat transfer surfaces may be used because of lack of ash deposits (fouling). The corrosion allowance is relatively small and the emissions control function is primarily for NO_x formed during the combustion process. The result is a relatively small, compact and economical design.

If a solid fuel such as coal (which has a significant level of noncombustible ash) is used, the overall system is much more complex. This system could include extensive fuel handling and preparation facilities, a much larger furnace, and more widely spaced heat transfer surfaces. Additional components could be special cleaning equipment to reduce the impact of fouling and erosion, air preheating to dry the fuel and enhance combustion, more extensive environmental equipment, and equipment to collect and remove solid wastes.

The impact of fuel alone on a utility boiler design is clearly indicated in Fig. 12, where both steam generators produce the same steam flow rate. Further adding to the size and cost difference, but not shown, are the facts that the coal-fired boiler will be wider (dimension not shown) and will require more flue gas cleanup equipment to meet emissions requirements. The particular challenge when burning different solid fuels is indicated in Fig. 13, where provision is made for burning both pulverized (finely ground) coal using the burners and for wood chips and bark which are burned on the moving grate (stoker) at the bottom of the unit.

Impact of steam conditions

The steam temperature and pressure for different boiler applications can have a significant impact on design. Fig. 14 identifies several typical boiler types, as well as the relative amount of heat input needed, for water heating, evaporation (boiling), superheating, and reheating, if required. The relative amount of energy needed for evaporation is dramatically reduced as operating pressure is increased. As a result, the relative amount of physical heat transfer surface (tubes) dedicated to each function can be dramatically different.

Fossil fuel systems

Fossil fuel steam generator components

Modern steam generators are a complex configuration of thermal-hydraulic (steam and water) sections which preheat and evaporate water, and superheat steam. These surfaces are arranged so that: 1) the fuel can be burned completely and efficiently while minimizing emissions, 2) the steam is generated at the required flow rate, pressure and temperature, and 3)

Fig. 12 Comparison of gas- and coal-fired steam generators.

the maximum amount of energy is recovered. A relatively simple coal-fired utility boiler is illustrated in Fig. 15. The major components in the steam generating and heat recovery system include:

1. furnace and convection pass,
2. steam superheaters (primary and secondary),
3. steam reheater,
4. boiler or steam generating bank (industrial units only),
5. economizer,
6. steam drum,
7. attemperator and steam temperature control system, and
8. air heater.

These components are supported by a number of sub-systems and pieces of equipment such as coal pulverizers, combustion system, flues, ducts, fans, gas-side cleaning equipment and ash removal equipment.

The *furnace* is a large enclosed open space for fuel combustion and for cooling of the flue gas before it enters the convection pass. Excessive gas temperatures leaving the furnace and entering the tube bundles could cause particle accumulation on the tubes or excessive tube metal temperatures. The specific geometry and dimensions of the furnace are highly influenced by the fuel and type of combustion equipment. In this case, finely ground or pulverized coal is blown into the furnace where it burns in suspension. The products of combustion then rise through the upper furnace. The superheater, reheater and economizer surfaces are typically located in the flue gas horizontal and vertical downflow sections of the boiler enclosure, called the *convection pass*.

In modern steam generators, the furnace and convection pass walls are composed of steam- or water-cooled carbon steel or low alloy tubes to maintain wall

metal temperatures within acceptable limits. These tubes are connected at the top and bottom by headers, or manifolds. These headers distribute or collect the water, steam or steam-water mixture. The furnace wall tubes in most modern units also serve as key steam generating components or surfaces. The tubes are welded together with steel bars to provide membrane wall panels which are gas-tight, continuous and rigid. The tubes are usually prefabricated into ship-pable membrane panels with openings for burners, observation doors, sootblowers (boiler gas-side surface cleaning equipment) and gas injection ports.

Superheaters and *reheaters* are specially designed in-line tube bundles that increase the temperature of saturated steam. In general terms, they are simple single-phase heat exchangers with steam flowing inside the tubes and the flue gas passing outside, generally in crossflow. These critical components are manufactured from steel alloy material because of their high operating temperature. They are typically configured to help control steam outlet temperatures, keep metal temperatures within acceptable limits, and control steam flow pressure loss.

The main difference between superheaters and reheaters is the steam pressure. In a typical drum boiler, the superheater outlet pressure might be 2700 psi (18.62 MPa) while the reheater outlet might be only 580 psi (4.0 MPa). The physical design and location of the surfaces depend upon the desired outlet temperatures, heat absorption, fuel ash characteristics and cleaning equipment. These surfaces can be either horizontal or vertical as shown. The superheater and sometimes reheater are often divided into multiple sections to help control steam temperature and optimize heat recovery.

The heat transfer surface in the furnace may not be sufficient to generate enough saturated steam for

Fig. 13 Large industrial boiler with multiple fuel capability.

the particular end use. If this is the case, an additional bank of heat exchanger tubes called the *boiler bank* or *steam generating bank* is added. (See Fig. 13.) This is needed on many smaller, low pressure industrial boilers, but is not often needed in high pressure utility boilers. This boiler bank is typically composed of the *steam drum* on top, a second drum on the bottom, and a series of bent connecting tubes. The steam drum internals and tube sizes are arranged so that subcooled water travels down the tubes (farthest from the furnace) into the lower drum. The water is then distributed to the other tubes where it is partially converted to steam and returned to the steam drum. The lower drum is often called the *mud drum* because this is where sediments found in the boiler water tend to settle out and collect.

The *economizer* is a counterflow heat exchanger for recovering energy from the flue gas beyond the superheater and, if used, the reheater. It increases the temperature of the water entering the steam drum. The tube bundle is typically an arrangement of parallel horizontal serpentine tubes with the water flowing inside but in the opposite direction (counterflow) to the flue gas. Tube spacing is as tight as possible to promote heat transfer while still permitting adequate tube surface cleaning and limiting flue gas-side pressure loss. By design, steam is usually not generated inside these tubes.

The *steam drum* is a large cylindrical vessel at the top of the boiler, in which saturated steam is separated from the steam-water mixture leaving the boiler tubes. Drums can be quite large with diameters of 3 to 6 ft

(0.9 to 1.8 m) and lengths approaching 100 ft (30.5 m). They are fabricated from thick steel plates rolled into cylinders with hemispherical heads. They house the steam-water separation equipment, purify the steam, mix the replacement or feedwater and chemicals, and provide limited water storage to accommodate small changes in unit load. Major connections to the steam drum are provided to receive the steam-water mixture from the boiler tubes, remove saturated steam, add replacement or makeup water, and return the near saturated water back to the inlet of the boiler tubes.

The *steam temperature control* system can be complex and include combinations of recirculating some of the flue gas to the bottom or top of the furnace, providing special gas flow passages at the back end of the steam generator, adjusting the combustion system, and adding water or low temperature steam to the high temperature steam flow (*attenuation*). The component most frequently used for the latter is called a *spray attenuator*. In large utility units, attenuators with direct injection of water or low temperature steam are used for dynamic control because of their rapid response. They are specially designed to resist thermal shock and are frequently located at the inlet of the superheater or between superheater sections to better control the superheater outlet metal temperatures. Positioning of individual superheater sections can also help maintain proper outlet steam temperatures.

The *air heater* is not a portion of the steam-water circuitry, but serves a key role in the steam generator system heat transfer and efficiency. In many cases, especially in high pressure boilers, the temperature of the flue gas leaving the economizer is still quite high. The air heater recovers much of this energy and adds it to the combustion air to reduce fuel use. Designs include tubular, flat plate, and regenerative heat exchangers, among others.

Steam-water flow system

The steam-water components are arranged for the most economical system to provide a continuous supply of steam. The circulation system (excluding reheater) for a natural circulation, subcritical pressure, drum type steam generator is shown in Fig. 16. Feed-

Fig. 14 Steam generator energy absorption by function.

water enters the bottom header (A) of the economizer and passes upward in the opposite direction to the flue gas. It is collected in an outlet header (B), which may also be located in the flue gas stream. The water then flows through a number of pipes which connect the economizer outlet header to the steam drum. It is sometimes appropriate to run these tubes vertically (B-C) through the convection pass to economizer outlet headers located at the top of the boiler. These tubes can then serve as water-cooled supports for the horizontal superheater and reheater when these banks span too great a distance for end support. The feedwater is injected into the steam drum (D) where it mixes with the water discharged from the steam-water separators before entering connections to the downcomer pipes (D-E) which exit the steam drum.

The water travels around the furnace water wall circuits to generate steam. The water flows through the downcomer pipes (D-E) to the bottom of the furnace where *supply* tubes (E-F) route the circulating water to the individual lower furnace panel wall headers (F). The water rises through the furnace walls to individual outlet headers (G), absorbing energy to become a steam-water mixture. The mixture leaves the furnace wall outlet headers by means of *riser* tubes (G-D), to be discharged into the drum and steam-water separators. The separation equipment returns essentially steam-free water to the downcomer inlet connections. The residual moisture in the steam that leaves the primary steam separation devices is removed in secondary steam separators, and dry steam is discharged to the superheater through a number of drum outlet connections (H-I and H-J).

The steam circuitry serves dual functions: cooling the convection pass enclosure, and generating the required superheated steam conditions. Steam from the drum passes through multiple connections to a

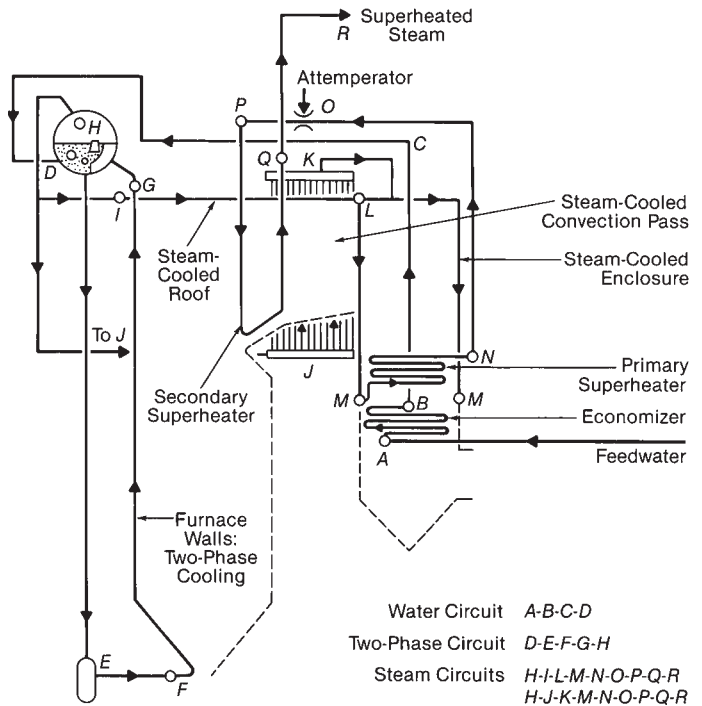

Fig. 16 Coal-fired boiler steam-water circulation system.

header (I) supplying the roof tubes and, separately, to headers (J) supplying the membrane panels in the pendant convection pass (so named because the superheater/reheater vertical tubes are hanging from supports above). The steam flows through these membrane panels to outlet headers (K). Steam from these headers and the roof tube outlet headers (L) then provides the cooling for the horizontal convection pass enclosure (L-M) (so named because the superheater/reheater/economizer tubes are horizontal in this flue gas downpass). Steam flows downward through these panels and is collected in outlet headers (M) just upstream of the economizer bank.

Steam flow then rises through the primary superheater and discharges through the outlet header (N) and connecting piping equipped with a spray attemperator (O). It then enters the secondary superheater inlet header (P), flowing through the superheater sections to an outlet header (Q). A discharge pipe (R) terminates outside of the boiler enclosure where the main steam lines route the steam flow to the control valves and turbine.

Combustion system and auxiliaries

Most of the non-steam generating components and auxiliaries used in coal-fired steam generators are part of the fuel preparation and combustion systems. These include:

1. fuel preparation: feeders and coal pulverizers,
2. combustion system: burners, flame scanners, lighters, controls, windbox,
3. air-gas handling: fans, flues and ducts, dampers, control and measurement systems, silencers, and
4. other components and auxiliaries: sootblowers (heat transfer surface cleaning equipment), ash collection and handling equipment, control and monitoring equipment.

Fig. 15 Coal-fired utility boiler.

Because of their intimate relationship with the steam generation process, many of these components are supplied with the boiler. If not, careful specification and interaction with the steam generator manufacturer are critical.

The combustion system has a dramatic impact on overall furnace design. Wall mounted burners are shown in Figs. 15 and 17. These are typical for large coal-, oil-, or gas-fired units today. However, a variety of other systems are also used and are continuing to be developed to handle the variety of fuel characteristics and unit sizes. Other combustion systems include stokers (Figs. 4 and 13), Cyclone furnaces, and fluidized-bed combustion units (Fig. 5). All have their strengths and weaknesses for particular applications. Key elements of these systems involve the need to control the formation and emission of pollutants, provide complete efficient combustion, and handle inert material found in the fuel. The fuel characteristics play a central role in how these functions are met and how the equipment is sized and designed.

Air-gas flow system

Many of these auxiliaries are identified in Fig. 17 along with the air-gas flow path in the large coal-fired utility boiler. Air is supplied by the *forced draft fan* (A) to the air heater (B) where it is heated to recover energy and enhance combustion. Most of the hot air (typically 70 to 80%), called secondary air, passes directly to the windboxes (C) where it is distributed to individual burners. The remaining 20 to 30%, called primary air, passes to the booster (or primary air) fan and then to the coal pulverizers (D) where the coal is dried and ground. The hot primary air then pneumatically conveys the pulverized coal to the burners (E) where it is mixed with the secondary air for combustion. The coal and air are rapidly mixed and burned in the furnace (F) and the flue gas then passes up through the furnace, being cooled primarily by radiation until it reaches the furnace exit (G). The gas then progressively passes through the secondary superheater, reheater, primary superheater and economizer before leaving the steam generator enclosure (H). The gas passes through the air heater (B) and then through any pollution control equipment and *induced draft fan* (I) before being exhausted to the atmosphere.

Emissions control

A key element of fossil fuel-fired steam generator system design is environmental protection. A broad range of government regulations sets limits on primary gaseous, liquid and solid waste emissions from the steam generating process. For coal-, oil-, and gas-fired units, the primary air pollutant emissions include sulfur dioxide (SO_2), nitrogen oxides (NO_x) and airborne particulate or flyash. Water discharges include trace chemicals used to control corrosion and fouling as well as waste heat rejected from the condenser. Solid waste primarily involves the residual ash from the fuel and any spent sorbent from the pollution control systems.

The gaseous and solid waste from the fuel and combustion process can be minimized by fuel selection,

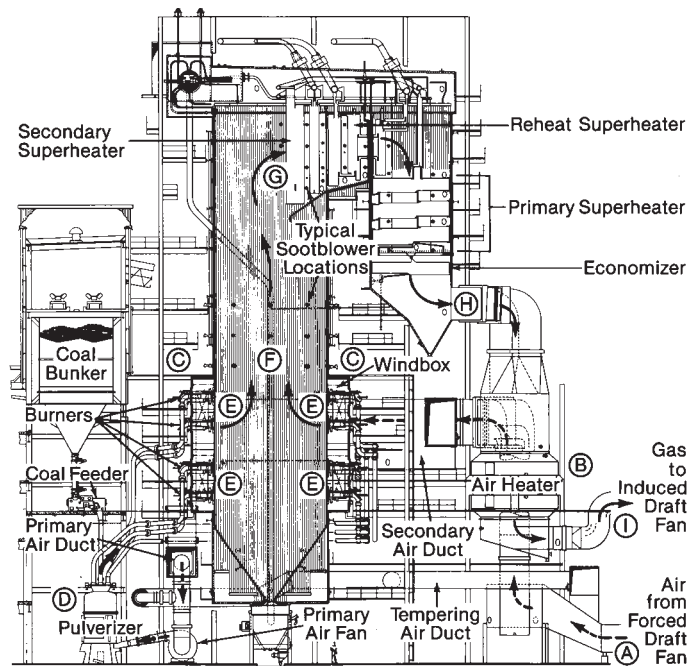

Fig. 17 Coal-fired boiler air/gas flow path.

control of the combustion process, and equipment located downstream of the steam generator. SO_2 emissions may be reduced by using fuels which contain low levels of sulfur, by fluidized-bed combustors, or by using a post-combustion scrubber system. Combustion NO_x emissions are typically controlled by using equipment such as special low NO_x burners or fluidized-bed combustors. Where it is required to significantly reduce NO_x emissions (to levels lower than is practically achieved by combustion techniques alone), back-end or post-combustion techniques, such as selective catalytic reduction (SCR) or selective noncatalytic reduction (SNCR) technologies, are employed. Flyash or airborne particulate is collected by either a fabric filter (baghouse) or electrostatic precipitator (ESP) with removal efficiencies above 99%. The particulate collection equipment and SO_2 scrubbers produce solid byproduct streams which must be safely landfilled or used for some industrial applications.

The water discharges are minimized by installing recirculating cooling systems. An example of this is cooling towers that reject the waste heat from the power cycle to the air, instead of to a water source. These are used on virtually all new fossil and nuclear power plants. Chemical discharges are minimized by specially designed zero discharge systems. A set of emissions rates before and after control for a typical 500 MW power plant is shown in Table 1.

Nuclear steam generating systems

Overview

Nuclear steam generating systems include a series of highly specialized heat exchangers, pressure vessels, pumps and components which use the heat generated by nuclear fission reactions to efficiently and

Table 1
Typical 500 MW Subcritical Coal-Fired Steam Generator Emissions and Byproducts*

** As flyash emissions to the air decline, ash to landfill increases.

safely generate steam. The system is based upon the energy released when atoms within certain materials, such as uranium, break apart or *fission*. Fission occurs when a fissionable atom nucleus captures a free subatomic particle – a neutron. This upsets the internal forces which hold the atom nucleus together. The nucleus splits apart producing new atoms as well as an average of two to three neutrons, gamma radiation and energy.

The nuclear steam supply system (NSSS) is designed to serve a number of functions: 1) house the nuclear fuel, 2) stimulate the controlled fission of the fuel, 3) control the nuclear reaction rate to produce the required amount of thermal energy, 4) collect the heat and generate steam, 5) safely contain the reaction products, and 6) provide backup systems to prevent release of radioactive material to the environment. Various systems have been developed to accomplish these functions. The main power producing system in commercial operation today is the pressurized water reactor (PWR).

A key difference between the nuclear and chemical energy driven systems is the quantity of fuel. The energy released per unit mass of nuclear fuel is many orders of magnitude greater than that for chemical based fuels. For example, 1 lb (0.454 kg) of 3% enriched uranium fuel produces about the same amount of thermal energy in a commercial nuclear system as 100,000 lb (45,360 kg) of coal in a fossil-fired steam system. While a 500 MW power plant must handle approximately one million tons of coal per year, the nuclear plant will handle only 10 tons of fuel. The fossil fuel plant must be designed for a continuous fuel supply process, while most nuclear plants use a batch fuel process, where about one third of the fuel is replaced during periodic outages. However, once the steam is generated, the balance of the power producing system (turbine, condenser, cooling system, etc.) is similar to that used in the fossil fuel plant.

Nuclear steam system components

A typical nuclear steam system from The Babcock & Wilcox Company (B&W) is shown in Fig. 3 and a simplified schematic is shown in Fig. 18. This nuclear system consists of two coolant loops. The primary loop cools the reactor, transports heat to two or more steam generators (only one shown), and returns coolant to the reactor by four or more primary coolant pumps (only one shown). The coolant is high purity, subcooled, single-phase water flowing at very high rates [350,000 to 450,000 GPM (22,100 to 28,400 l/s)] at around 2200 psi (15.17 MPa) and an average temperature of approximately 580F (304C). The primary loop also contains a pressurizer to maintain the loop pressure at design operating levels.

The secondary loop includes the steam generation and interface with the balance of the power plant. High purity water from the last feedwater heater passes through the steam generator and is converted into steam. From the steam generator outlet, the saturated or superheated steam flows out of the containment building to the high pressure turbine. The operating pressure is typically around 1000 psi (6.9 MPa). The balance of the secondary loop resembles fossil fuel-fired systems. (See Figs. 10 and 11.)

The center of the NSSS is the reactor vessel and reactor core (Fig. 19). The fuel consists of compressed pellets [for example, 0.37 in. (9.4 mm) diameter by 0.7 in. (18 mm) long] of 2.5 to 5% enriched uranium oxide. These pellets are placed in zircaloy tubes which are sealed at both ends to protect the fuel and to contain the nuclear reaction products. The tubes are assembled into bundles with spacer and closure devices. These bundles are then assembled into the nuclear fuel core.

The reactor enclosure (Fig. 19) is a low alloy steel pressure vessel lined with stainless steel for corrosion protection. The rest of the reactor includes flow distribution devices, control rods, core support structures,

Fig. 18 Nuclear steam system schematic.

thermal shielding and moderator. The moderator in this case is water which serves a dual purpose. It reduces the velocity of the neutrons thereby making the nuclear reactions more likely. It also serves as the coolant to maintain the core materials within acceptable temperature limits and transports thermal energy to the steam generators. The control rods contain neutron absorbing material and are moved into and out of the nuclear core to control the energy output.

The steam generators can be of two types, once-through (Fig. 20) and recirculating (Fig. 21). In both types, the pressure vessel is a large heat exchanger designed to generate steam for the secondary loop from heat contained in the primary coolant. The primary coolant enters a plenum and passes through several thousand small diameter [approximately 0.625 in. (15.9 mm)] Inconel® tubes. The steam generator is a large, carbon steel pressure vessel. Specially designed tubesheets, support plates, shrouds, and baffles provide effective heat transfer, avoid thermal expansion problems, and avoid flow-induced vibration.

In the once-through steam generator (OTSG), Fig. 20, the secondary loop water flows from the bottom to the top of the shell side of the tube bundle and is continuously converted from water to superheated steam. The superheated steam then passes to the high pressure turbine.

In the recirculating steam generator (RSG), Fig. 21, water moves from the bottom to the top of the shell side of the tube bundle being converted partially into steam. The steam-water mixture passes into the upper shell where steam-water separators supply saturated dry steam to the steam generator outlet. The steam is sent to the high pressure turbine. The water leaving the

steam generator upper shell is mixed with feedwater and is returned to the bottom of the tube bundle.

The pressurizer is a simple cylindrical pressure vessel which contains both water and steam at equilibrium. Electrical heaters and spray systems maintain the pressure in the pressurizer vessel and the primary loop within set limits. The primary loop circulating pumps maintain high flow rates to the reactor core to control its temperature and transfer heat to the steam generators.

A number of support systems are also provided. These include reactor coolant charging systems, makeup water addition, spent fuel storage cooling, and decay heat removal systems for when the reactor is shut down. Other specialized systems protect the reactor system in the case of a loss of coolant event. The key function of these systems is to keep the fuel bundle temperature within safe limits if the primary coolant flow is interrupted.

Nuclear steam system classifications

A variety of reactor systems have been developed to recover thermal energy from nuclear fuel and to generate steam for power generation. These are usually identified by their coolant and moderator types. The principal systems for power generation include:

1. *Pressurized water reactor (PWR)* This is the system discussed above, using water as both reactor coolant and moderator, and enriched uranium oxide as the fuel.
2. *Boiling water reactor (BWR)* The steam generator is eliminated and steam is generated directly in the reactor core. A steam-water mixture cools and moderates the reactor core. Enriched uranium oxide fuel is used.

Fig. 19 Reactor vessel and internals.

3. *CANDU (PHWR)* Heavy water (deuterium) is used as the moderator and primary loop coolant. The reactor configuration is unique but the steam generator is similar to the recirculating steam generator for the PWR. Natural (not enriched) uranium oxide is used as the fuel.
4. *Gas-cooled reactors* These are a variety of gas-cooled reactors which are typically moderated by graphite and cooled by helium or carbon dioxide.
5. *Breeder reactors* These are advanced reactor systems using sodium as the reactor coolant with no moderator. These systems are specially designed to produce more fissionable nuclear fuel than they use.

Engineered safety systems

Safety is a major concern in the design, construction and operation of nuclear power generating facilities. The focus of these efforts is to minimize the likelihood of a release of radioactive materials to the environment. Three approaches are used to accomplish this goal. First, the nuclear power industry has developed one of the most extensive and rigorous quality control programs for the design, construction and maintenance of nuclear facilities. Second, reactor systems are designed with multiple barriers to prevent radioactive material release. These include high temperature ceramic fuel pellets, sealed fuel rods, reactor vessel and primary coolant system, and the contain-

Fig. 20 Once-through steam generator.

Fig. 21 Recirculating steam generator.

ment building including both the carbon steel reactor containment vessel and the reinforced concrete shield building. The third approach includes a series of engineered safety systems to address loss of coolant conditions and maintain the integrity of the multiple barriers. These systems include:

1. emergency reactor trip systems including rapid insertion of control rods and the addition of soluble neutron poisons in the primary coolant to shut down the nuclear reaction,
2. high and low pressure emergency core cooling systems to keep the reactor core temperature within acceptable limits and remove heat from the fuel in the event of a major loss of primary coolant or a small pipe break,
3. a heat removal system for the cooling water and containment building, and
4. spray and filtering systems to collect and remove radioactivity from the containment building.

Because of the high power densities and decay heat generation, the reactor integrity depends upon the continuous cooling of the nuclear fuel rods. Multiple independent components and backup power supplies are provided for all critical systems.

Steam system design

Steam generator interfaces

The steam generator system's primary function is to convert chemical or nuclear energy bound in the fuel to heat and produce high temperature, high pressure steam. The variety of fuel sources, the high temperature nature of these processes, and the large number of subsystem interfaces contribute to the challenging nature of the design process. The initial steps in evaluating the steam generating system include establishing key interfaces with other plant systems and with the power cycle. These are typically set by the end user or consulting engineer after an in-depth evaluation indicates: 1) the need for the expanded power supply or steam source, 2) the most economical fuel selection and type of steam producing system, 3) the plant location, and 4) the desired power cycle or process steam conditions. The key requirements fall into six major areas:

1. Steam minimum, nominal, and maximum flow rates; pressure and temperature; need for one or more steam reheat stages; auxiliary equipment steam usage; and future requirements.
2. Source of the steam flow makeup or replacement water supply, water chemistry and inlet temperature.
3. The type and range of fuels considered, including worst case conditions, and the chemical analyses (proximate and ultimate analyses) for each fuel or mixture of fuels.
4. Elevation above sea level, overall climate history and forecast, earthquake potential and space limitations.
5. Emissions control requirements and applicable government regulations and standards.
6. The types of auxiliary equipment; overall plant and boiler efficiency; access needs; evaluation penalties, e.g., power usage; planned operating modes including expected load cycling requirements, e.g., peaking, intermediate or base load; and likely future plant use.

When these interfaces are established, boiler design and evaluation may begin.

Systematic approach

There are a variety of evaluation approaches that can be used to meet the specific steam generator performance requirements. These include the multiple iterations commonly found in thermal design where real world complexities and nonlinear, noncontinuous interactions prevent a straightforward solution. The process begins by understanding the particular application and system to define conditions such as steam flow requirements, fuel source, operating dynamics, and emissions limits, among others. From these, the designer proceeds to assess the steam generator options, interfaces, and equipment needs to achieve performance. Using a coal-fired boiler as an example, a systematic approach would include the following:

1. Specify the steam supply requirements to define the overall inputs of fuel, air and water, and the steam output conditions.

2. Evaluate the heat balances and heat absorption by type of steam generator surface.
3. Perform combustion calculations to define heat input and gas flow requirements.
4. Configure the combustion system to complete the combustion process while minimizing emissions (fuel preparation, combustion and air handling).
5. Configure the furnace and other heat transfer surfaces to satisfy temperature, material, and performance tradeoffs while meeting the system control needs.
6. Size other water-side and steam-side components.
7. Specify the back-end tradeoffs on the final heat recovery devices such as water heaters (economizers) and air heaters.
8. Check the steam generating system performance to ensure that the design criteria are met.
9. Verify overall unit performance.
10. Repeat steps 2 through 9 until the desired steam mass flow and temperature are achieved over the specified range of load conditions.
11. Use American Society of Mechanical Engineers (ASME) Code rules to design pressure parts to meet the anticipated operating conditions and complete detailed mechanical design.
12. Design and integrate environmental protection equipment to achieve prescribed emissions levels.
13. Incorporate auxiliaries as needed, such as tube surface cleaning equipment, fans, instrumentation and controls, to complete the design and assure safe and continuous operation.

The life cycle and daily operation of the steam generator (and the plant in which it will operate) are important elements to be considered from the beginning of the design and throughout the design process. Today, some steam generators will be required to operate efficiently and reliably for up to 60 years or more. During this time, many components will wear out because of the aggressive environment, so routine inspection of pressure parts is needed to assure continued reliability. Unit operating procedures, such as the permitted severity and magnitude of transients, may be monitored to prevent reduced unit life. Operating practices including water treatment, cycling operation procedures, and preventive maintenance programs, among others, can significantly affect steam generator availability and reliability. Key unit components may be upgraded to improve performance. In each case, decisions made during the design phase and subsequent operation can substantially enhance the life and performance of the unit.

System design example

Now that the basic fossil fuel and nuclear steam generating systems have been described, it is appropriate to explore the general design and engineering process. While each of the many systems requires specialized evaluations, they share many common elements. To illustrate how the design process works, a small industrial B&W PFI gas-fired boiler has been selected for discussion. (See Figs. 22 and 23.)

Basically, the customer has one overriding need: when the valve is turned on, steam is expected to be

supplied at the desired pressure, temperature and flow rate. In this example, the customer specifies 400,000 lb/h (50.4 kg/s) of superheated steam at 600 psi (4.14 MPa) and 850F (454C). The customer has agreed to supply high purity feedwater at 280F (138C) and to supply natural gas as a fuel source. As with all steam generating systems, there are a number of additional constraints and requirements as discussed in *Steam generator interfaces*, but the major job of the steam generator or boiler is to supply steam.

Combustion of the natural gas produces a stream of combustion products or flue gas at perhaps 3600F (1982C). To maximize the steam generator thermal efficiency, it is important to cool these gases as much as possible while generating the steam. The minimum flue gas outlet temperature is established based upon technical and economic factors (discussed below). For now, a 310F (154C) outlet temperature to the exhaust stack is selected. The approximate steam and flue gas temperature curves are shown in Fig. 24 and define the heat transfer process. The heat transfer surface for the furnace, boiler bank, superheater and air heater is approximately 69,000 ft² (6410 m²).

From a design perspective, the PFI boiler can be viewed as either a steam heater or gas cooler. The latter approach is most often selected for design. The design fuel heat input is calculated by dividing the steam heat output by the target steam generator thermal efficiency. Based upon the resulting fuel flow, combustion calculations define the air flow requirements and combustion products gas weight. The heat transfer surface is then configured in the most economical way to cool the flue gas to the temperature necessary for the target steam generator efficiency. Before proceeding to follow the gas through the cooling process, the amount of heat recovery for each of the different boiler surfaces (superheater and boiler) must be established.

Fig. 25 illustrates the water heating process from an inlet temperature of 280F (138C) to the superheater

Fig. 23 Small industrial boiler – sectional view.

steam outlet temperature of 850F (454C). This curve indicates that about 20% of the heat absorbed is used to raise the water from its inlet temperature to the saturation temperature of 490F (254C). 60% of the energy is then used to evaporate the water to produce saturated steam. The remaining 20% of the heat input is used to superheat or raise the steam temperature to the desired outlet temperature of 850F (454C).

The fuel and the combustion process selected set the geometry of the furnace. In this case, simple circular burners are used. The objective of the burners is to mix the fuel and air rapidly to produce a stable flame and complete combustion while minimizing the formation of NO_x emissions. Burners are available in several standardized sizes. The specific size and number are selected from past experience to provide the desired heat input rate while permitting the necessary level of load range control. The windbox, which distributes the air to individual burners, is designed to provide a uniform air flow at low enough velocities to permit the burners to function properly.

The furnace volume is then set to allow complete fuel combustion. The distances between burners and between the burners and the floor, roof, and side walls are determined from the known characteristics of the particular burner flame. Adequate clearances are specified to prevent flame impingement on the furnace surfaces, which could overheat the tubes and cause tube failures.

Once the furnace dimensions are set, this volume is enclosed in a water-cooled membrane panel surface. This construction provides a gas-tight, all steel enclosure which minimizes energy loss, generates some steam and minimizes furnace maintenance. As shown in Fig. 23, the roof and floor tubes are inclined slightly to enhance water flow and prevent steam from collecting on the tube surface. Trapped steam could result in overheating of the tubes. Heat transfer from the flame to the furnace enclosure surfaces occurs primarily by thermal radiation. As a result, the heat input rates per

Fig. 22 Small PFI industrial boiler.

Fig. 24 Industrial boiler – temperature versus heat transfer surface.

unit area of surface are very high and relatively independent of the tubewall temperatures. Boiling water provides an effective means to cool the tubes and keep the tube metal temperatures within acceptable limits as long as the boiling conditions are maintained.

Fig. 26 shows the effect of the furnace on gas temperature. The gas temperature is reduced from 3600 at point A to 2400F at point B (1982 to 1316C), while boiling takes place in the water walls (points 1 to 2). A large amount of heat transfer takes place on a small amount of surface. From the furnace, the gases pass through the furnace screen tubes shown in Fig. 23. The temperature drops a small amount [50F (28C)] from points B to C in Fig. 26, but more importantly, the superheater surface is partially shielded from the furnace thermal radiation. The furnace screen tubes are connected to the drum and contain boiling water. Next, the gas passes through the superheater where the gas temperature drops from 2350 at point C to 1750F at point D (1288 to 954C). Saturated steam from the drum is passed through the superheater tubing to raise its temperature from 490F (254C) saturation temperature to the 850F (454C) desired outlet temperature (points 5 to 4).

The location of the superheater and its configuration are critical in order to keep the steam outlet temperature constant under all load conditions. This involves radiation heat transfer from the furnace with convection heat transfer from the gas passing across the surface. In addition, where dirty gases such as combustion products from coal are used, the spacing of the superheater tubes is also adjusted to accommodate the accumulation of fouling ash deposits and the use of cleaning equipment.

After the superheater, almost half of the energy in the gas stream has been recovered with only a small amount of heat transfer surface [approximately 6400 ft² (595 m²)]. This is possible because of the large temperature difference between the gas and the boiling

water or steam. The gas temperature has now been dramatically reduced, requiring much larger heat transfer surfaces to recover incremental amounts of energy.

The balance of the steam is generated by passing the gas through the boiler bank. (See Figs. 22 and 23.) This bank is composed of a large number of water-containing tubes that connect the steam drum to a lower (mud) drum. The temperature of the boiling water is effectively constant (points 5 to 6 in Fig. 26), while the gas temperature drops by almost 1000F (556C) to an outlet temperature of 760F (404C), between points D and E. The tubes are spaced as closely as possible to increase the gas flow heat transfer rate. If a particulate-laden gas stream were present, the spacing would be set to limit erosion of the tubes, reduce the heat transfer degradation due to ash deposits, and permit removal of the ash. Spacing is also controlled by the allowable pressure drop across the bank. In addition, a baffle can be used in the boiler bank bundle to force the gas to travel at higher velocity through the bundle, increase the heat transfer rate, and thereby reduce the bundle size and cost. To recover this additional percentage of the supplied energy, the boiler bank contains more than 32,000 ft² (3000 m²) of surface, or approximately nine times more surface per unit of energy than in the high temperature furnace and superheater. At this point in the process, the temperature difference between the saturated water and gas is only 270F (150C), between points 6 and E in Fig. 26.

Economics and technical limits dictate the type and arrangement of additional heat transfer surfaces. An economizer or water-cooled heat exchanger could be used to heat the makeup or feedwater and cool the gas. The lowest gas exit temperature possible is the inlet temperature of the feedwater [280F (138C)]. However, the economizer would have to be infinitely large to accomplish this goal. Even if the exit gas temperature is 310F (154C), the temperature difference at this point in the heat exchanger would only be 30F (17C), still making the heat exchanger relatively large. Instead of incorporating an economizer, an air preheater could be used to recover the remaining gas energy and preheat the combustion air. This would reduce the

Fig. 25 Steam-water temperature profile.

natural gas needed to heat the steam generator. Air heaters can be very compact. Also, air preheating can enhance the combustion of many difficult to burn fuels such as coal. All of the parameters are reviewed to select the most economical solution that meets the technical requirements.

In this case, the decision has been made to use an air heater and not an economizer. The air heater is designed to take 80F (27C) ambient air (point 9) and increase the temperature to 570F (299C), at point 8. This hot air is then fed to the burners. At the same time, the gas temperature is dropped from 760F (404C) to the desired 310F (154C) outlet temperature (points E to F). If a much lower gas outlet temperature than 310F (154C) is used, the heat exchanger surfaces may become uneconomically large, although this is a case by case decision. In addition, for fuels such as oil or coal which can produce acid constituents in the gas stream (such as sulfur oxides), lower exit gas temperatures may result in condensation of these constituents onto the heat transfer surfaces, and excessive corrosion damage. The gas is then exhausted through the stack to the atmosphere.

Finally, the feedwater temperature increases from 280F (138C) to saturation temperature of 490F (254C). In the absence of an economizer, the feedwater is supplied directly to the drum where it is mixed with the water flowing through the boiler bank tubes and furnace. The flow rate of this circulating water in industrial units is approximately 25 times higher than the feedwater flow rate. Therefore, when the feedwater is mixed in the drum, it quickly approaches the saturation temperature without appreciably lowering the temperature of the recirculating water in the boiler tubes.

Reviewing the water portion of the system, the feedwater is supplied to the drum where it mixes with the recirculating water after the steam is extracted and sent to the superheater. The drum internals are spe-

cially designed so that the now slightly subcooled water flows down through a portion of the boiler bank tubes to the lower or mud drum. This water is then distributed to the remainder of the boiler bank tubes (also called risers) and the furnace enclosure tubes where it is partially converted to steam (approximately 4% steam by weight). The steam-water mixture is then returned to the steam drum. Here, the steam-water mixture is passed through *separators* where the steam is separated from the water. The steam is then sent to the superheater, and from there to its end use. The remaining water is mixed with the feedwater and is again distributed to the downcomer tubes.

Other steam producing systems

A variety of additional systems also produce steam for power and process applications. These systems usually take advantage of low cost or free fuels, a combination of power cycles and processes, and recovery of waste heat in order to reduce overall costs. Examples of these include:

1. *Gas turbine combined cycle (CC)* Advanced gas turbines with heat recovery steam generators as part of a bottoming cycle to use waste heat recovery and increase thermal efficiency.
2. *Integrated gasification combined cycle (IGCC)* Adds a coal gasifier to the CC to reduce fuel costs and minimize airborne emissions.
3. *Pressurized fluidized-bed combustion (PFBC)* Includes higher pressure combustion with gas cleaning and expansion of the combustion products through a gas turbine.
4. *Blast furnace hood heat recovery* Generates steam using the waste heat from a blast furnace.
5. *Solar steam generator* Uses concentrators to collect and concentrate solar radiation and generate steam.

Common technical elements

The design of steam generating systems involves the combination of scientific and technical fundamentals, empirical data, practical experience and designer insight. While technology has advanced significantly, it is still not possible to base the design of modern systems on fundamentals alone. Instead, the fundamentals provide the basis for combining field data and empirical methods.

Even given the wide variety of shapes, sizes and applications (see Fig. 27), steam generator design involves the application of a common set of technologies. The functional performance of the steam generator is established by combining thermodynamics, heat transfer, fluid mechanics, chemistry, and combustion science or nuclear science with practical knowledge of the fouling of heat transfer surfaces and empirical knowledge of the behavior of boiling water. The design and supply of the hardware are aided by structural design and advanced materials properties research combined with expertise in manufacturing technologies and erection skills to produce a quality, reliable product to meet the highly demanding system requirements.

Fig. 26 Gas and steam temperature schematic.

Fig. 27 This energy complex in the northern U.S. includes four coal-fired steam systems, ranging from 80 to 330 MW, installed over a 25-year period.

The ASME Boiler and Pressure Vessel Code is the firm basis from which steam generator pressure parts can be safely designed. Once built, the operation and maintenance of the steam generator are critical to ensure a long life and reliable service. Water chemistry and chemical cleaning are increasingly recognized as central elements in any ongoing operating program. The impact of fuel and any residual flyash is important in evaluating the corrosion and fouling of heat transfer surfaces. The use of modern techniques to periodically inspect the integrity of the steam generator tubes leads to the ability to extend steam generator life and improve overall performance. These are accomplished by the application of engineered component modification to better meet the changing needs of the steam generating system. Finally, the control systems which monitor and operate many subsystems

to optimize unit performance are important to maintain system reliability and efficiency.

All of these functions – functional performance, mechanical design, manufacture, construction, operation, maintenance, and life extension – must be fully combined to provide the best steam generating system. Long term success depends upon a complete life cycle approach to the steam generating system. Steam generator system operators routinely require their equipment to operate continuously and reliably for more than 60 years in increasingly demanding conditions. Therefore, it is important to consider later boiler life, including component replacement, in the initial phases of boiler specification. Changes in design to reduce initial capital cost must be weighed against their possible impact on future operation.

Chapter 2

Thermodynamics of Steam

Thermodynamics is the science which describes and defines the transformation of one form of energy into another – chemical to thermal, thermal to mechanical, and mechanical to thermal. The basic tenets include: 1) energy in all of its forms must be conserved, and 2) only a portion of *available* energy can be converted to *useful* energy or work. Generally referred to as the first and second laws of thermodynamics, these tenets evolved from the early development of the steam engine and the efforts to formalize the observations of its conversion of heat into mechanical work.

Regardless of the type of work or form of energy under consideration, the terms heat, work, and energy have practical significance only when viewed in terms of systems, processes, cycles, and their surroundings. In the case of expansion work, the *system* is a *fluid* capable of expansion or contraction as a result of pressure, temperature or chemical changes. The way in which these changes take place is referred to as the *process*. A *cycle* is a sequence of processes that is capable of producing net heat flow or work when placed between an energy *source* and an energy *sink*. The *surroundings* represent the sources and sinks which accommodate interchanges of mass, heat and work to or from the system.

Steam may be viewed as a thermodynamic system which is favored for power generation and heat transfer. Its unique combination of high thermal capacity (specific heat), high critical temperature, wide availability, and nontoxic nature has served to maintain this dominant position. High thermal capacity of a working fluid generally results in smaller equipment for a given power output or heat transfer. The useful temperature range of water and its high thermal capacity meet the needs of many industrial processes and the temperature limitations of power conversion equipment.

Properties of steam

Before a process or cycle can be analyzed, reliable properties of the working fluid are needed. Key properties include enthalpy, entropy, and specific volume. While precise definitions are provided later in this chapter, *enthalpy* is a general measure of the internally stored energy per unit mass of a flowing stream,

specific entropy is a measure of the thermodynamic potential of a system in the units of energy per unit mass and absolute temperature, and *specific volume* is the volume per unit mass.

In the case of steam, a worldwide consensus of these and other thermophysical properties has been reached through the International Association for the Properties of Steam. The most frequently used tabulation of steam properties is the American Society of Mechanical Engineers (ASME) Steam Tables.^{1,2} Selected data from this tabulation in English units are summarized in Tables 1, 2 and 3. Corresponding SI tabulations are provided in Appendix 1. These properties are now well described by formulas that have been agreed to by the International Association for the Properties of Water and Steam, and are available from a number of sources on the Internet as add-on functions to spreadsheets and other software products.

The first two columns of Tables 1 and 2 define the unique relationship between pressure and temperature referred to as saturated conditions, where liquid and vapor phases of water can coexist at thermodynamic equilibrium. For a given pressure, steam heated above the saturation temperature is referred to as superheated steam, while water cooled below the saturation temperature is referred to as subcooled or compressed water. Properties for superheated steam and compressed water are provided in Table 3. Reproduced from Reference 1, Fig. 1 shows the values of enthalpy and specific volume for steam and water over a wide range of pressure and temperature.

Under superheated or subcooled conditions, fluid properties, such as enthalpy, entropy and volume per unit mass, are unique functions of temperature and pressure. However, at saturated conditions where mixtures of steam and water coexist, the situation is more complex and requires an additional parameter for definition. For example, the enthalpy of a steam-water mixture will depend upon the relative amounts of steam and water present. This additional parameter is the thermodynamic equilibrium quality or simply quality (x) defined by convention as the mass fraction of steam:

$$x = \frac{m_s}{m_s + m_w} \quad (1)$$

Note: The following steam tables and Fig. 1 have been abstracted from *ASME International Steam Tables for Industrial Use* (copyright 2000 by The American Society of Mechanical Engineers), based on the IAPWS industrial formulation 1997 for the Thermodynamic Properties of Water and Steam (IAPWS-IF97).

1. SI steam tables are provided in Appendix 1.
2. In the balance of *Steam*, enthalpy is denoted by *H* in place of *h* to avoid confusion with heat transfer coefficient.

1. See Notes 1 and 2, Table 1.

Fig. 1 Pressure-enthalpy chart for steam (English units).

where m_s is the mass of steam and m_w is the mass of water. The quality is frequently recorded as a percent steam by weight (% SBW) after multiplying by 100%. The mixture enthalpy (H) (see Note below), entropy (s) and specific volume (v) of a steam-water mixture can then be simply defined as:

$$H = H_f + x(H_g - H_f) \quad (2a)$$

$$s = s_f + x(s_g - s_f) \quad (2b)$$

$$v = v_f + x(v_g - v_f) \quad (2c)$$

where the subscripts f and g refer to properties at saturated liquid and vapor conditions, respectively. The difference in a property between saturated liquid and vapor conditions is frequently denoted by the subscript fg ; for example, $H_{fg} = H_g - H_f$. With these definitions, if the pressure or temperature of a steam-water mixture is known along with one of the mixture properties, the quality can then be calculated. For example, if the mixture enthalpy is known, then:

$$x = (H - H_f) / H_{fg} \quad (3)$$

Engineering problems deal mainly with changes or differences in enthalpy and entropy. It is not necessary to establish an absolute zero for these properties, although this may be done for entropy. The Steam Tables indicate an arbitrary zero internal energy and entropy for the liquid state of water at the triple point corresponding to a temperature of 32.018F (0.01C) and a vapor pressure of 0.08865 psi (0.6112 kPa). The triple point is a unique condition where the three states of water (solid, liquid and vapor) coexist at equilibrium.

Properties of gases

In addition to steam, air is a common working fluid for some thermodynamic cycles. As with steam, well defined properties are important in cycle analysis. Air and many common gases used in power cycle applications can usually be treated as ideal gases. An ideal gas is defined as a substance that obeys the ideal gas law:

$$Pv = RT \quad (4)$$

where R is a constant which varies with gas species; P and T are the pressure and temperature, respectively. R is equal to the universal gas constant, R [1545 ft lb/lb-mole R (8.3143 kJ/kg mole K)], divided by the molecular weight of the gas. For dry air, R is equal to 53.34 lbf ft/lbm R (0.287 kJ/kg K). Values for other gases are summarized in Reference 3. The ideal gas law is commonly used in a first analysis of a process or cycle because it simplifies calculations. Final calcu-

Note: To avoid confusion with the symbol for heat transfer coefficient, enthalpy (Btu/lb or kJ/kg) is denoted by H in this chapter and the balance of *Steam* unless specially noted. Enthalpy is frequently denoted by h in thermodynamic texts.

lations often rely on tabulated gas properties for greater accuracy.

Tabulated gas properties are available from numerous sources. (See References 4 and 5 for examples.) Unfortunately, there is less agreement on gas properties than on those for steam. The United States (U.S.) boiler industry customarily uses 80F (27C) and 14.7 psia (101.35 kPa) as the zero enthalpy of air and combustion products. A more general reference is one atmosphere pressure, 14.696 psia (101.35 kPa), and 77F (25C). This is the standard reference point for heats of formation of compounds from elements in their standard states, latent heats of phase changes and free energy changes. Because of different engineering conventions, considerable care must be exercised when using tabulated properties. Selected properties for air and other gases are provided in Chapter 3, Table 3.

Conservation of mass and energy

Thermodynamic processes are governed by the laws of conservation of mass and conservation of energy except for the special case of nuclear reactions discussed in Chapter 47. These conservation laws basically state that the total mass and total energy (in any of its forms) can neither be created nor destroyed in a process. In an open flowing power system, where mass continually enters and exits a system such as Fig. 2, these laws can take the forms:

Conservation of mass

$$m_1 - m_2 = \Delta m \quad (5)$$

Conservation of energy

$$E_2 - E_1 + \Delta E = Q - W \quad (6)$$

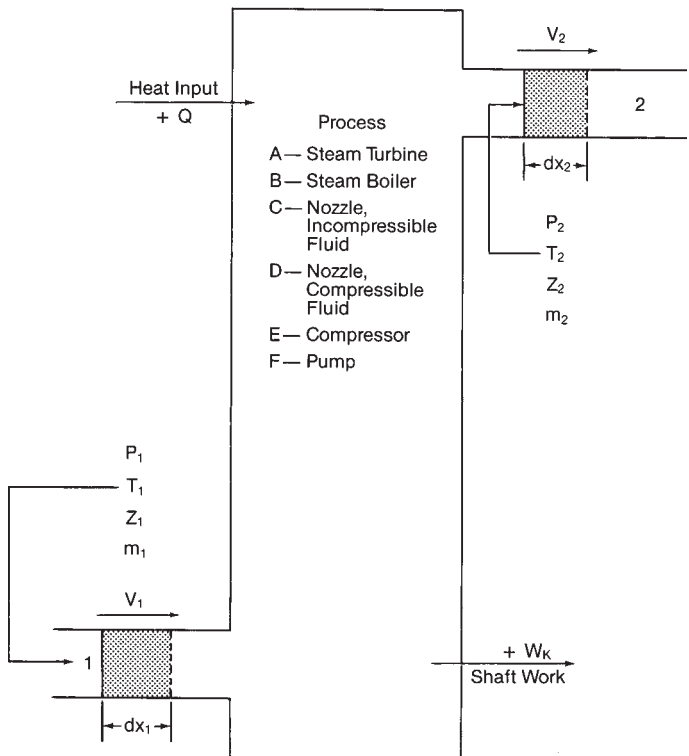

Fig. 2 Diagram illustrating thermodynamic processes.

where m is the mass flow, Δm is the change in internal system mass, E is the total energy flowing into or out of the processes, ΔE is the change in energy stored in the system with time, Q is the heat added to the system, W is the work removed, and the subscripts 1 and 2 refer to inlet and outlet conditions respectively. For steady-state conditions Δm and ΔE are zero.

The conservation of energy states that a balance exists between energy, work, and heat quantities entering and leaving the system. This balance of energy flow is also referred to as the first law of thermodynamics. The terms on the left side of Equation 6 represent stored energy entering or leaving the system as part of the mass flows and the accumulation of total stored energy within the system. The terms on the right side are the heat transferred to the system, Q , and work done by the system, W . The stored energy components, represented by the term E , consist of the internally stored energy and the kinetic and potential energy. In an open system, there is work required to move mass into the system and work done by the system to move mass out. In each case, the total work is equal to the product of the mass, the system pressure, and the specific volume. Separating this work from other work done by the system and including a breakdown of the stored energy, the energy conservation equation becomes:

$$m_2 \left(u + Pv + \frac{V^2}{2g_c} + z \right)_2 - m_1 \left(u + Pv + \frac{V^2}{2g_c} + z \right)_1 + \Delta E = Q - W_k \quad (7)$$

where m is the mass, u is the internal stored energy, P is the system pressure, V is the fluid velocity, v is the specific volume, z is the elevation, and W_k is the sum of the work done by the system.

In this form, the work terms associated with mass moving into and out of the system (Pv) have been grouped with the stored energy crossing the system boundary. W_k represents all other work done by the system.

For many practical power applications, the energy equation can be further simplified for steady-state processes. Because the mass entering and leaving the system over any time interval is the same, dividing Equation 7 by the mass (m_2 or m_1 because they are equal) yields a simple balance between the change in stored energy due to inflow and outflow and the heat and work terms expressed on a unit mass basis. Heat and work expressed on a unit mass basis are denoted q and w , respectively. The unsteady term for system stored energy in Equation 7 is then set to zero. This yields the following form of the energy conservation equation:

$$\Delta u + \Delta(Pv) + \Delta \frac{V^2}{2g_c} + \Delta z \frac{g}{g_c} = q - w_k \quad (8)$$

Each Δ term on the left in Equation 8 represents the difference in the fluid property or system characteristic between the system outlet and inlet. Δu is the difference in internally stored energy associated with molecular and atomic motions and forces. Internally stored energy, or simply internal energy, accounts for

all forms of energy other than the kinetic and potential energies of the collective molecule masses. This is possible because no attempt is made to absolutely define u .

The term $\Delta(Pv)$ can be viewed as externally stored energy in that it reflects the work required to move a unit mass into and out of the system. The remaining terms of externally stored energy, $\Delta(V^2/2g_c)$ and Δz , depend on physical aspects of the system. $\Delta(V^2/2g_c)$ is the difference in total kinetic energy of the fluid between two reference points (system inlet and outlet). $\Delta z g/g_c$ represents the change in potential energy due to elevation, where g is the gravitational constant 32.17 ft/s² (9.8 m/s²) and g_c is a proportionality constant for English units. The value of the constant is obtained from equivalence of force and mass times acceleration:

$$\text{Force} = \frac{\text{mass} \times \text{acceleration}}{g_c} \quad (9)$$

In the English system, by definition, when 1 lb force (lbf) is exerted on a 1 lb mass (lbm), the mass accelerates at the rate of 32.17 ft/s². In the SI system, 1 N of force is exerted by 1 kg of mass accelerating at 1 m/s². Therefore, the values of g_c are:

$$g_c = 32.17 \text{ lbm ft} / \text{lbf s}^2 \quad (10a)$$

$$g_c = 1 \text{ kg m} / \text{N s}^2 \quad (10b)$$

Because of the numerical equivalency between g and g_c in the English system, the potential energy term in Equation 8 is frequently shown simply as Δz . When SI units are used, this term is often expressed simply as $\Delta z g$ because the proportionality constant has a value of 1.

While many texts use the expression lbf to designate lb force and lbm to designate lb mass, this is not done in this text because it is believed that it is generally clear simply by using lb. As examples, the expression Btu/lb always means Btu/lb mass, and the expression ft lb/lb always means ft lb force/lb mass.

Application of the energy equation requires dimensional consistency of all terms and proper conversion constants are inserted as necessary. For example, the terms u and q , usually expressed in Btu/lb or J/kg, may be converted to ft lb/lb or N m/kg when multiplied by J , the mechanical equivalent of heat. This conversion constant, originally obtained by Joule's experiments between 1843 and 1878, is defined as:

$$J = 778.17 \text{ ft lbf} / \text{Btu} \quad (11a)$$

$$J = 1 \text{ Nm} / \text{J} \quad (11b)$$

Particular attention should be given to the sign convention applied to heat and work quantities. Originating with the steam engine analysis, heat quantities are defined as positive when entering the system and work (for example, shaft work) is positive when leaving the system.

Because u and Pv of Equation 8 are system properties, their sum is also a system property. Because these properties of state can not be changed independently of one another and because the combination ($u + Pv$) appears whenever mass enters or leaves the system,

it is customary to consider the sum $(u + Pv)$ as a single property H , called enthalpy.

$$H = u + (Pv/J) \quad (12)$$

where Pv is divided by J to provide consistent units.

In steam applications, H is usually expressed in Btu/lb or J/kg. The examples in the following section illustrate the application of the steady-state open system energy Equation 7 and the usefulness of enthalpy in the energy balance of specific equipment.

Applications of the energy equation

Steam turbine

To apply the energy equation, each plant component is considered to be a system, as depicted in Fig. 2. In many cases, Δz , $\Delta(V^2/2g_c)$ and q from throttle (1) to exhaust (2) of the steam turbine are small compared to $(H_2 - H_1)$. This reduces Equation 8 to:

$$u_2 + (P_2 v_2 / J) - u_1 - (P_1 v_1 / J) = w_k / J \quad (13a)$$

or

$$H_2 - H_1 = w_k / J \quad (13b)$$

Equation 13 indicates that the work done by the steam turbine, w_k / J , is equal to the difference between the enthalpy of the steam entering and leaving. However, H_1 and H_2 are seldom both known and further description of the process is required for a solution of most problems.

Steam boiler

The boiler does no work, therefore $w_k = 0$. Because Δz and $\Delta(V^2/2g_c)$ from the feedwater inlet (1) to the steam outlet (2) are small compared to $(H_2 - H_1)$, the steady-state energy equation becomes:

$$q = H_2 - H_1 \quad (14)$$

Based on Equation 14 the heat added, q (positive), in the boiler per unit mass of flow in is equal to the difference between H_2 of the steam leaving and H_1 of the feedwater entering. Assuming that the pressure varies negligibly through the boiler and the drum pressure is known, Equation 14 can be solved knowing the temperature of the incoming feedwater.

Water flow through a nozzle

For water flowing through a nozzle, the change in specific volume is negligible. Commonly the change in elevation, Δz , the change in internal energy, Δu , the work done, w_k , and the heat added, q , are negligible and the energy equation reduces to:

$$(V_2^2 / 2g_c) - (V_1^2 / 2g_c) = (P_1 - P_2) v \quad (15)$$

The increase in kinetic energy of the water is given by Equation 15 for the pressure drop $(P_1 - P_2)$. If the approach velocity to the nozzle, V_1 , is zero, Equation 15 becomes:

$$V_2 = \sqrt{2g_c (P_1 - P_2) v} \quad (16)$$

The quantity $(P_1 - P_2) v$ is often referred to as the static head.

Flow of a compressible fluid through a nozzle

In contrast to water flow, when steam, air or other compressible fluid flows through a nozzle, the changes in specific volume and internal energy are not negligible. In this case, assuming no change in elevation Δz , Equation 8 becomes:

$$(V_2^2 / 2g_c) - (V_1^2 / 2g_c) = (H_1 - H_2) J \quad (17)$$

If the approach velocity, V_1 , is zero, this further simplifies to:

$$V_2 = \sqrt{2g_c J (H_1 - H_2)} \quad (18)$$

From this, it is evident that the velocity of a compressible fluid leaving a nozzle is a function of its entering and leaving enthalpies. Unfortunately, as with the steam turbine, H_1 and H_2 are seldom both known.

Compressor

If a compressible fluid moves through an adiabatic compressor ($q = 0$, a convenient approximation) and the change in elevation and velocity are small compared to $(H_2 - H_1)$, the energy equation reduces to:

$$-w_k / J = H_2 - H_1 \quad (19)$$

Note that w_k is negative because the compressor does work on the system. Therefore, the net effect of the compressor is expressed as an increase in fluid enthalpy from inlet to outlet.

Pump

The difference between a pump and a compressor is that the fluid is considered to be incompressible for the pumping process; this is a good approximation for water. For an incompressible fluid, the specific volume is the same at the inlet and outlet of the pump. If the fluid friction is negligible, then the internal energy changes, Δu , are set to zero and the energy equation can be expressed as:

$$-w_k = (P_2 - P_1) v \quad (20)$$

Because all real fluids are compressible, it is important to know what is implied by the term incompressible. The meaning here is that the isothermal compressibility, k_T , given by

$$k_T = -\frac{1}{v} \frac{\delta v}{\delta P} \quad (21)$$

is assumed to be arbitrarily small and approaching zero. Because neither v nor P is zero, δv must be zero and v must be a constant. Also, for isothermal conditions (by definition) there can be no change in internal energy, u , due to pressure changes only.

Entropy and its application to processes

The preceding examples illustrate applications of the energy balance in problems where a fluid is used for heat transfer and shaft work. They also demonstrate the usefulness of the enthalpy property. However, as was pointed out, H_1 and H_2 are seldom both known. Additional information is frequently provided by the first and second laws of thermodynamics and their consequences.

The first and second laws of thermodynamics

The first law of thermodynamics is based on the energy conservation expressed by Equation 6 and, by convention, relates the heat and work quantities of this equation to internally stored energy, u . Strictly speaking, Equation 6 is a complete form of the first law of thermodynamics. However, it is frequently useful to use the steady-state formulation provided in Equation 8 and further simplify this for the special case of 1) no change in potential energy due to gravity acting on the mass, and 2) no change in kinetic energy of the mass as a whole. In a closed system where only shaft work is permitted, these simplifying assumptions permit the energy Equation 8 for a unit mass to be reduced to:

$$\Delta u = q - (w_k / J) \quad (22a)$$

or in differential form

$$du = \delta q - (\delta w_k / J) \quad (22b)$$

The first law treats heat and work as being interchangeable, although some qualifications must apply. All forms of energy, including work, can be wholly converted to heat, but the converse is not generally true. Given a source of heat coupled with a heat-work cycle, such as heat released by high temperature combustion in a steam power plant, only a portion of this heat can be converted to work. The rest must be rejected to an energy sink, such as the atmosphere, at a lower temperature. This is essentially the *Kelvin* statement of the second law of thermodynamics. It can also be shown that it is equivalent to the *Clausius* statement wherein heat, in the absence of external assistance, can only flow from a hotter to a colder body.

Concept and definition of entropy

Heat flow is a function of temperature difference. If a quantity of heat is divided by its absolute temperature, the quotient can be considered a type of distribution property complementing the intensity factor of temperature. Such a property, proposed and named entropy by Clausius, is widely used in thermodynamics because of its close relationship to the second law.

Rather than attempt to define entropy (s) in an absolute sense, consider the significance of differences in this property given by:

$$S_2 - S_1 = \Delta S = \int_1^2 \frac{\delta q_{\text{rev}}}{T} \times \text{total system mass} \quad (23)$$

where

ΔS = change in entropy, Btu/R (J/K)

q_{rev} = reversible heat flow between thermodynamic equilibrium states 1 and 2 of the system, Btu/lb (J/kg)

T = absolute temperature, R (K)

Entropy is an extensive property, i.e., a quantity of entropy, S , is associated with a finite quantity of mass, m . If the system is closed and the entire mass undergoes a change from state 1 to 2, an intensive property s is defined by S/m . The property s is also referred to as entropy, although it is actually specific entropy. If the system is open as in Fig. 2, the specific entropy is calculated by dividing by the appropriate mass.

Use of the symbol δ instead of the usual differential operator d is a reminder that q depends on the process and is not a property of the system (steam). δq represents only a small quantity, not a differential. Before Equation 23 can be integrated, q_{rev} must be expressed in terms of properties, and a reversible path between the prescribed initial and final equilibrium states of the system must be specified. For example, when heat flow is reversible and at constant pressure, $q_{\text{rev}} = c_p dT$. This may represent heat added reversibly to the system, as in a boiler, or the equivalent of internal heat flows due to friction or other irreversibilities. In these two cases, Δs is always positive.

The same qualifications for δ hold in the case of thermodynamic work. Small quantities of w similar in magnitude to differentials are expressed as δw .

Application of entropy to a reversible process

Reversible thermodynamic processes exist in theory only; however, they serve an important function of defining limiting cases for heat flow and work processes. The properties of a system undergoing a reversible process are constrained to be homogeneous because there are no variations among subregions of the system. Moreover, during interchanges of heat or work between a system and its surroundings, only corresponding potential gradients of infinitesimal magnitude may exist.

All actual processes are irreversible. To occur, they must be under the influence of a finite potential difference. A temperature difference supplies this drive and direction for heat flow. The work term, on the other hand, is more complicated, because there are as many different potentials (generalized forces) as there are forms of work. However, the main concern here is expansion work for which the potential is clearly a pressure difference.

Regardless of whether a process is to be considered reversible or irreversible, it must have specific beginning and ending points (limits) in order to be evaluated. To apply the first and second laws, the limits must be equilibrium states. Nonequilibrium thermodynamics is beyond the scope of this text. Because the limits of real processes are to be equilibrium states, any process can be approximated by a series of smaller reversible processes starting and ending at the same states as the real processes. In this way, only equilibrium conditions are considered and the substitute processes can be defined in terms of the system properties. The

following lists the reversible processes for heat flow and work:

Reversible Heat Flow	Reversible Work
Constant pressure, $dP = 0$	Constant pressure, $dP = 0$
Constant temperature, $dT = 0$	Constant temperature, $dT = 0$
Constant volume, $dv = 0$	Constant entropy, $ds = 0$
	$w = 0$
	$q = 0$

The qualification of these processes is that each describes a path that has a continuous functional relationship on coordinate systems of thermodynamic properties.

A combined form of the first and second laws is obtained by substituting $\delta q_{\text{rev}} = Tds$ for δq in Equation 22b, yielding:

$$du = Tds - \delta w_k \quad (24)$$

Because only reversible processes are to be used, δw should also be selected with this restriction. Reversible work for the limited case of expansion work can be written:

$$\delta (w_{\text{rev}}) = Pdv \quad (25)$$

In this case, pressure is in complete equilibrium with external forces acting on the system and is related to v through an equation of state.

Substituting Equation 25 in 24, the combined expression for the first and second law becomes:

$$du = Tds - Pdv \quad (26)$$

Equation 26, however, only applies to a system in which the reversible work is entirely shaft work. To modify this expression for an open system in which flow work $d(Pv)$ is also present, the quantity $d(Pv)$ is added to the left side of Equation 25 and added as $(Pdv + vdP)$ on the right side. The result is:

$$du + d(Pv) = Tds - Pdv + Pdv + vdP \quad (27a)$$

or

$$dH = Tds + vdP \quad (27b)$$

The work term vdP in Equation 27 now represents reversible shaft work in an open system, expressed on a unit mass basis.

Because Tds in Equation 26 is equivalent to δq , its value becomes zero under adiabatic or zero heat transfer conditions ($\delta q = 0$). Because T can not be zero, it follows that $ds = 0$ and s is constant. Therefore, the maximum work from stored energy in an open system during a reversible adiabatic expansion is $\int vdP$ at constant entropy. The work done is equal to the decrease in enthalpy. Likewise for the closed system, the maximum expansion work is $-\int Pdv$ at constant entropy and is equal to the decrease in internal energy. These are important cases of an adiabatic isentropic expansion.

Irreversible processes

All real processes are irreversible due to factors such as friction, heat transfer through a finite temperature difference, and expansion through a process with a

finite net force on the boundary. Real processes can be solved approximately, however, by substituting a series of reversible processes. An example of such a substitution is illustrated in Fig. 3, which represents the adiabatic expansion of steam in a turbine or any gas expanded from P_1 to P_2 to produce shaft work. T_1 , P_1 and P_2 are known. The value of H_1 is fixed by T_1 and P_1 for a single-phase condition (vapor) at the inlet. H_1 may be found from the Steam Tables, a T - s diagram (Fig. 3) or, more conveniently, from an H - s (Mollier) diagram, shown in the chapter frontispiece. From the combined first and second laws, the maximum energy available for work in an adiabatic system is $(H_1 - H_3)$, as shown in Fig. 3, where H_3 is found by the adiabatic *isentropic* expansion (expansion at constant entropy) from P_1 to P_2 . A portion of this available energy, usually about 10 to 15%, represents work lost (w_L) due to friction and form loss, limiting ΔH for shaft work to $(H_1 - H_2)$. The two reversible paths used to arrive at point b in Fig. 3 (path a to c at constant entropy, s , and path c to b at constant pressure) yield the following equation:

$$(H_1 - H_3) - (H_2 - H_3) = H_1 - H_2 \quad (28)$$

Point b, identified by solving for H_2 , now fixes T_2 ; v_1 and v_2 are available from separate tabulated values of physical properties.

Note that ΔH_{2-3} can be found from:

$$\Delta H_{2-3} = \int_3^2 Tds \quad (29)$$

or, graphically, the area on the T - s diagram (Fig. 3) under the curve P_2 from points c to b. Areas bounded by reversible paths on the T - s diagram in general rep-

Fig. 3 Irreversible expansion, state a to state b.

resent q (heat flow per unit mass) between the system and its surroundings. However, the path a to b is irreversible and the area under the curve has no significance. The area under path c to b, although it has the form of a reversible quantity q , does not represent heat added to the system but rather its equivalent in internal heat flow. A similar situation applies to the relationship between work and areas under reversible paths in a pressure-volume equation of state diagram. Because of this important distinction between reversible and irreversible paths, care must be exercised in graphically interpreting these areas in cycle analysis.

Returning to Fig. 3 and the path a to b, w_L was considered to be a percentage of the enthalpy change along the path a to c. In general, the evaluation should be handled in several smaller steps (Fig. 4) for the following reason. Point b has a higher entropy than point c and, if expansion to a pressure lower than P_2 (Fig. 3) is possible, the energy available for this additional expansion is greater than that at point c. In other words, a portion of w_L (which has the same effect as heat added to the system) for the first expansion can be recovered in the next expansion or stage. This is the basis of the reheat factor used in analyzing expansions through a multistage turbine. Since the pressure curves are divergent on an H - s or T - s diagram, the sum of the individual ΔH_s values (isentropic ΔH) for individual increments of ΔP (or stages in an irreversible expansion) is greater than that of the reversible ΔH_s between the initial and final pressures (Fig. 4). Therefore the shaft work that can be achieved is greater than that calculated by a simple isentropic expansion between the two pressures.

Principle of entropy increase

Although entropy has been given a quantitative meaning in previous sections, there are qualitative aspects of this property which deserve special emphasis. An increase in entropy is a measure of that portion of process heat which is unavailable for conversion to work. For example, consider the constant pressure reversible addition of heat to a working fluid with the resulting increase in steam entropy. The minimum portion of this heat flow which is unavailable for shaft work is equal to the entropy increase multiplied by the absolute temperature of the sink to which a part of the heat must be rejected (in accordance with the second law). However, because a reversible addition of heat is not possible, incremental entropy increases also occur due to internal fluid heating as a result of temperature gradients and fluid friction.

Even though the net entropy change of any portion of a fluid moving through a cycle of processes is always zero because the cycle requires restoration of all properties to some designated starting point, the sum of all entropy increases has a special significance. These increases in entropy, less any decreases due to recycled heat within a regenerator, multiplied by the appropriate sink absolute temperature (R or K) are equal to the heat flow to the sink. In this case, the net entropy change of the system undergoing the cycle is zero, but there is an entropy increase of the surroundings. Any thermodynamic change that takes place,

Fig. 4 Three-stage irreversible expansion – $\Delta H_{s1} + \Delta H_{s2} + \Delta H_{s3} > \Delta H_{sac}$

whether it is a stand alone process or cycle of processes, results in a net entropy increase when both the system and its surroundings are considered.

Cycles

To this point, only thermodynamic processes have been discussed with minor references to the cycle. The next step is to couple processes so heat may be converted to work on a continuous basis. This is done by selectively arranging a series of thermodynamic processes in a cycle forming a closed curve on any system of thermodynamic coordinates. Because the main interest is steam, the following discussion emphasizes expansion or Pdv work. This relies on the limited differential expression for internal energy, Equation 26, and enthalpy, Equation 27. However, the subject of thermodynamics recognizes work as energy in transit under any potential other than differential temperature and electromagnetic radiation.

Carnot cycle

Sadi Carnot (1796 to 1832) introduced the concept of the cycle and reversible processes. The *Carnot cycle* is used to define heat engine performance as it constitutes a cycle in which all component processes are reversible. This cycle, on a temperature-entropy diagram, is shown in Fig. 5a for a gas and in Fig. 5b for a two-phase saturated fluid. Fig. 5c presents this cycle for a nonideal gas, such as superheated steam, on Mollier coordinates (entropy versus enthalpy).

Referring to Fig. 5, the Carnot cycle consists of the following processes:

1. Heat is added to the working medium at constant temperature ($dT = 0$) resulting in expansion work

Fig. 5 Carnot cycles.

and changes in enthalpy. (For an ideal gas, changes in internal energy and pressure are zero and, therefore, changes in enthalpy are zero.)

2. Adiabatic isentropic expansion ($ds = 0$) occurs with expansion work and an equivalent decrease in enthalpy.
3. Heat is rejected to the surroundings at a constant temperature and is equivalent to the compression work and any changes in enthalpy.
4. Adiabatic isentropic compression occurs back to the starting temperature with compression work and an equivalent increase in enthalpy.

This cycle has no counterpart in practice. The only way to carry out the constant temperature processes in a one-phase system would be to approximate them through a series of isentropic expansions and constant pressure reheats for heat addition, and isentropic compressions with a series of intercoolers for heat rejections. Another serious disadvantage of a Carnot gas engine would be the small ratio of net work to gross work (net work referring to the difference between the expansion work and the compression work, and gross work being expansion work). Even a two-phase cycle, such as Fig. 5b, would be subject to the practical mechanical difficulties of wet compression and, to a lesser extent, wet expansion where a vapor-liquid mixture exists.

Nevertheless, the Carnot cycle illustrates the basic principles of thermodynamics and, because the processes are reversible, the Carnot cycle offers the maximum thermodynamic efficiency attainable between any given temperatures of heat source and sink. The efficiency of the cycle is defined as the ratio of the net work output to the total heat input. Various texts refer to this ratio as either thermodynamic efficiency, thermal efficiency, or simply efficiency. Using the T - s diagram for the Carnot cycle shown in Fig. 5a, the thermodynamic efficiency depends solely on the temperatures at which heat addition and rejection occur:

$$\eta = \frac{T_1 - T_2}{T_1} = 1 - \frac{T_2}{T_1} \quad (30)$$

where

η = thermodynamic efficiency of the conversion from heat into work

T_1 = absolute temperature of heat source, R (K)

T_2 = absolute temperature of heat sink, R (K)

The efficiency statement of Equation 30 can be extended to cover all reversible cycles where T_1 and T_2 are defined as mean temperatures found by dividing the heat added and rejected reversibly by Δs . For this reason, all reversible cycles have the same efficiencies when considered between the same mean temperature limits of heat source and heat sink.

Rankine cycle

Early thermodynamic developments were centered around the performance of the steam engine and, for comparison purposes, it was natural to select a reversible cycle which approximated the processes related to its operation. The *Rankine cycle* shown in Fig. 6, proposed independently by Rankine and Clausius,

meets this objective. All steps are specified for the system only (working medium) and are carried out reversibly as the fluid cycles among liquid, two-phase and vapor states. Liquid is compressed isentropically from points a to b. From points b to c, heat is added reversibly in the compressed liquid, two-phase and finally superheat states. Isentropic expansion with shaft work output takes place from points c to d and unavailable heat is rejected to the atmospheric sink from points d to a.

The main feature of the Rankine cycle is that compression (pumping) is confined to the liquid phase, avoiding the high compression work and mechanical problems of a corresponding Carnot cycle with two-phase compression. This part of the cycle, from points a to b in Fig. 6, is greatly exaggerated, because the difference between the saturated liquid line and point b (where reversible heat addition begins) is too small to show in proper scale. For example, the temperature rise with isentropic compression of water from a saturation temperature of 212F (100C) and one atmosphere to 1000 psi (6.89 MPa) is less than 1F (0.6C).

If the Rankine cycle is closed in the sense that the fluid repeatedly executes the various processes, it is termed a *condensing cycle*. Although the closed, condensing Rankine cycle was developed to improve steam engine efficiency, a closed cycle is essential for any toxic or hazardous working fluid. Steam has the important advantage of being inherently safe. However, the close control of water chemistry required in high pressure, high temperature power cycles also favors using a minimum of makeup water. (Makeup is the water added to the steam cycle to replace leakage and other withdrawals.) Open steam cycles are still found in small units, some special processes, and heating load applications coupled with power. The condensate from process and heating loads is usually returned to the power cycle for economic reasons.

The higher efficiency of the condensing steam cycle is a result of the pressure-temperature relationship between water and its vapor state, steam. The lowest temperature at which an *open*, or *noncondensing*,

Fig. 6 Temperature-entropy diagram of the ideal Rankine cycle.

steam cycle may reject heat is approximately 212F (100C), the saturation temperature corresponding to atmospheric pressure of 14.7 psi (101.35 kPa). The pressure of the condensing fluid can be set at or below atmospheric pressure in a closed cycle. This takes advantage of the much lower sink temperature available for heat rejection in natural bodies of water and the atmosphere. Therefore, the condensing temperature in the closed cycle can be 100F (38C) or lower.

Fig. 7 illustrates the difference between an open and closed Rankine cycle. Both cycles are shown with nonideal expansion processes. Liquid compression takes place from points a to b and heat is added from points b to c. The work and heat quantities involved in each of these processes are the same for both cycles. Expansion and conversion of stored energy to work take place from points c to d' for the open cycle and from c to d for the closed cycle. Because this process is shown for the irreversible case, there is internal fluid heating and an entropy increase. From points d' to a, and d to a, heat is rejected in order to condense the steam. Because this last portion of the two cycles is shown as reversible, the shaded areas are proportional to the rejected heat. The larger amount of rejected heat for the open cycle is evident and is directly related to the lower amount of work that can be done by the expansion process.

Regenerative Rankine cycle

The reversible cycle efficiency given by Equation 30, where T_2 and T_1 are mean absolute temperatures for rejecting and adding heat respectively, indicates only three choices for improving ideal cycle efficiency: decreasing T_2 , increasing T_1 , or both. Little can be done to reduce T_2 in the Rankine cycle because of the limitations imposed by the temperatures of available rejected heat sinks in the general environment. Some T_2 reduction is possible by selecting variable condenser pressures for very large units with two or more exhaust hoods, because the lowest temperature in the condenser is set by the lowest temperature of the cooling water. On the other hand, there are many ways to increase T_1 even though the steam temperature may be limited by high temperature corrosion and allowable stress properties of the material.

One early improvement to the Rankine cycle was the adoption of *regenerative feedwater heating*. This is done by extracting steam from various stages in the turbine to heat the feedwater as it is pumped from the bottom of the condenser (hot well) to the boiler economizer.

Fig. 8 is a diagram of a widely used supercritical pressure steam cycle showing the arrangement of various components including the feedwater heaters. This cycle also contains one stage of steam reheat, which is another method of increasing the mean T_1 . Regardless of whether the cycle is high temperature, high pressure or reheat, regeneration is used in all modern condensing steam power plants. It improves cycle efficiency and has other advantages, including lower volume flow in the final turbine stages and a convenient means of deaerating the feedwater. In the power plant heat balances shown in Fig. 8 and later in Fig. 10, several parameters require definition:

Fig. 7 Rankine cycles.

DC: In the feedwater heater blocks, this parameter is the drain cooler approach temperature or the difference between the shell-side condensate outlet (drain) temperature and the feedwater inlet temperature.

TD: In the feedwater heater blocks, this parameter is the terminal temperature difference or the difference between the shell-side steam inlet temperature and the feedwater outlet temperature.

P: In the feedwater heater blocks, this parameter is the nominal shell-side pressure.

The temperature-entropy diagram of Fig. 9 for the steam cycle of Fig. 8 illustrates the principle of regeneration in which the mean temperature level is increased for heat addition. Instead of heat input starting at the hot well temperature of 101.1F (38.4C), the water entering the boiler economizer has been raised to 502F (261C) by the feedwater heaters.

Fig. 9 also shows that the mean temperature level for heat addition is increased by reheating the steam after a portion of the expansion has taken place. Because maximum temperatures are limited by physical or economic reasons, reheating after partial expansion of the working fluid is also effective in raising the average T_1 . The hypothetical case of an infinite number of reheat and expansion stages approaches a constant temperature heat addition of the Carnot cycle, at least in the superheat region. It would appear beneficial to set the highest temperature in the superheat reheat stage at the temperature limit of the working medium or its containment. However, merely increasing T_1 may not improve efficiency. If the entropy increase accompanying reheat causes the final expansion process to terminate in superheated vapor, the mean temperature for heat rejection, T_2 , has also been increased unless the superheat can be extracted in a regenerative heater, adding heat to the boiler feedwater. Such a regenerative heater would have to operate at the expense of the very effective cycle. All

of these factors, plus component design limitations, must be considered in a cycle analysis where the objective is to optimize the thermodynamic efficiency within the physical and economic constraints of the equipment. In addition, there are constraints imposed by the economics of fuel selection and the environmental impacts of fuel combustion that impact the design of the boiler/turbine regenerative cycle. Overall cycle characteristics, including efficiency, can also be illustrated by plotting the cycle on a Mollier chart. (See chapter frontispiece and Fig. 4.)

The procedure used in preparing Fig. 9 deserves special comment because it illustrates an important function of entropy. All processes on the diagram represent total entropies divided by the high pressure steam flow rate. Total entropies at any point of the cycle are the product of the mass flowing past that point in unit time and the entropy per pound (specific entropy) corresponding to the pressure, temperature, and state of the steam. Specific entropy values are provided by the Steam Tables such as those provided here in Tables 1, 2, and 3. If a point falls in the two-phase region, entropy is calculated in the same manner as enthalpy. That is, the value for evaporation is multiplied by the steam quality (fraction of uncondensed steam) and added to the entropy value of water at saturation conditions corresponding to the pressure at that point in the system.

Because there are different flow rates for the various cycle processes, small sections of individual T -s diagrams are superimposed in Fig. 9 on a base diagram that identifies saturated liquid and vapor parameters. However, the saturation parameters can only be compared to specific points on the T -s diagram. These points correspond to the parts of the cycle representing heat addition to high pressure steam and the expansion of this steam in a high pressure turbine. In these parts of the cycle, the specific entropy of the fluid and the value plotted in the diagram are the same. At each steam bleed point of the intermedi-

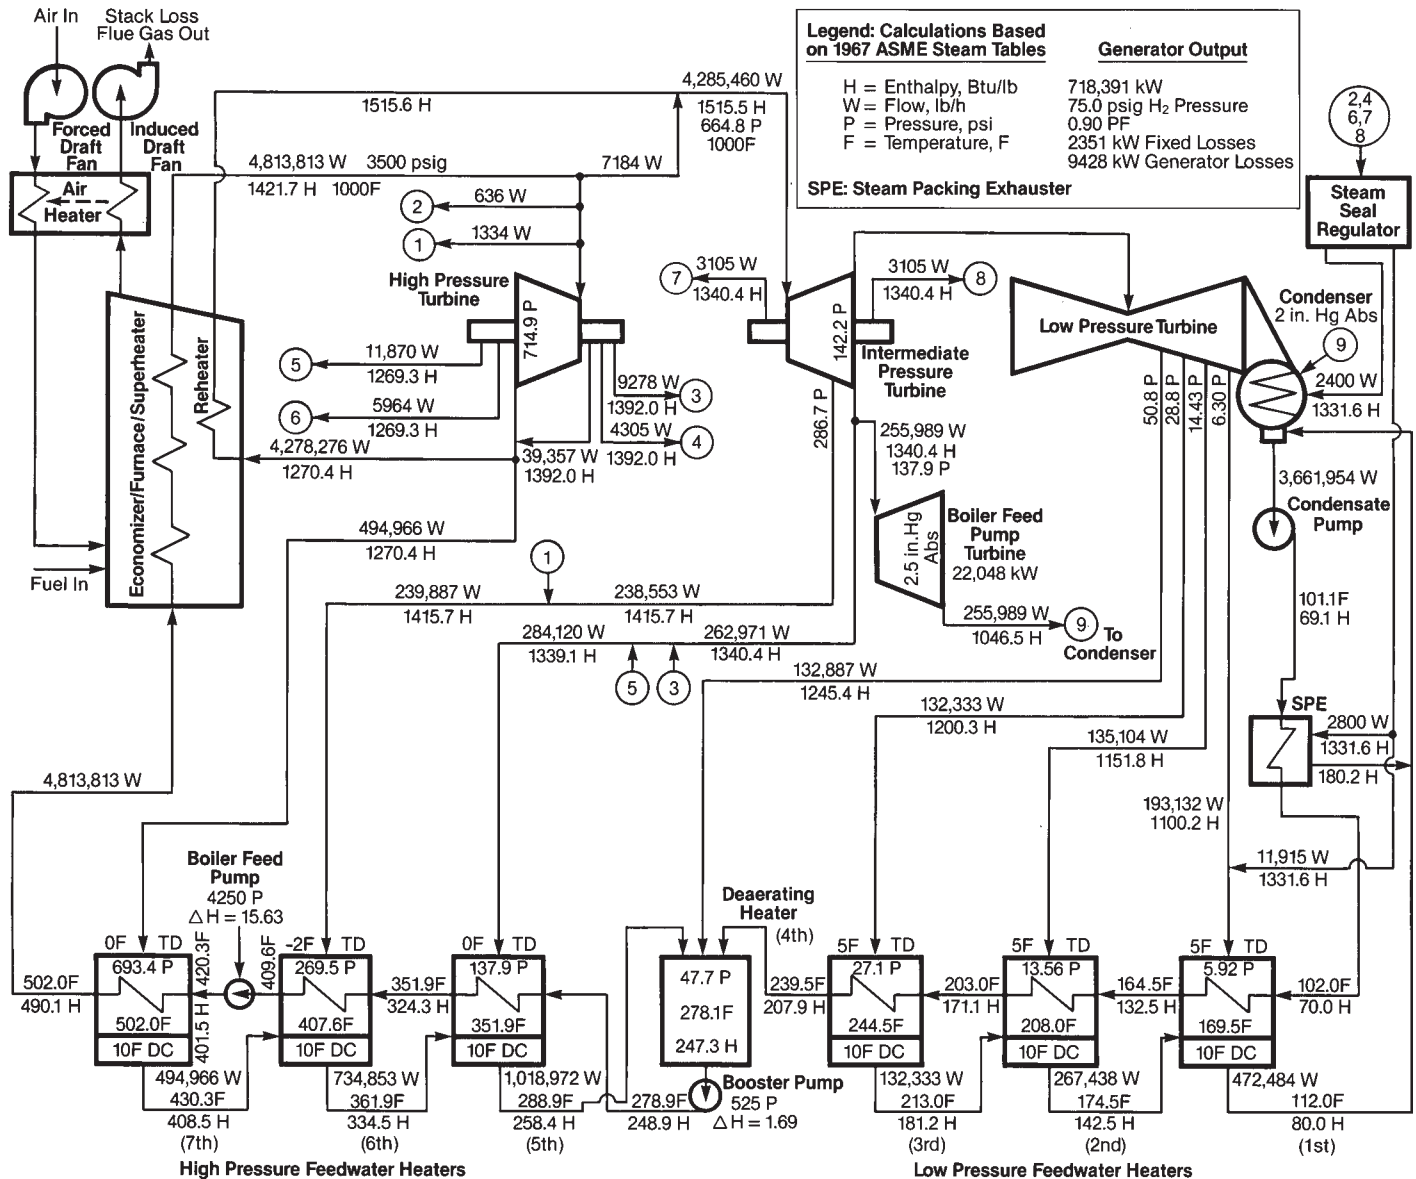

Fig. 8 Supercritical pressure, 3500 psig turbine cycle heat balance (English units).

ate and low pressure turbine, the expansion line should show a decrease in entropy due to reduced flow entering the next turbine stage. However, for convenience, the individual step backs in the expansion lines have been shifted to the right to show the reheated steam expansion as one continuous process.

Feedwater heating through the regenerators and compression by the pumps (represented by the zigzag lines in Fig. 9) result in a net entropy increase. However, two factors are involved in the net increase, an entropy increase from the heat added to the feedwater and a decrease resulting from condensing and cooling the bleed steam and drain flows from higher pressure heaters.

Consider an example in which the feedwater heater just before the deaerating heater increases the temperature of a 3,661,954 lb/h feedwater from 203.0 to 239.5F. From Table 1, this increases the enthalpy, H , of the feedwater from 171.2 to 208.0 and increases the entropy, s , from 0.2985 to 0.3526. The total entropy increase per lb of high pressure steam flowing at 4,813,813 lb/h is:

$$\frac{(s_2 - s_1) \dot{m}_{\text{feedwater}}}{\dot{m}_{\text{HP steam}}} = \frac{(0.3526 - 0.2985) 3,661,954}{4,813,813} = 0.0412 \text{ Btu/lb F} \quad (31)$$

The feedwater temperature rises 36.5F and the total heat absorbed is:

$$(H_2 - H_1) \dot{m}_{\text{feedwater}} = (208.0 - 171.2) 3,661,954 = 134,759,907 \text{ Btu/h} \quad (32)$$

On the heat source side of the balance, 132,333 lb/h of steam are bled from the low pressure turbine at 28.8 psig. This steam has an enthalpy of 1200.3 and

an entropy of 1.7079. The steam is desuperheated and condensed according to the following equation:

$$H_2 = H_1 - \frac{\text{heat absorbed by feedwater}}{\dot{m}_{\text{LP steam}}} \quad (33)$$

$$= 1200.3 - \frac{134,759,907}{132,333} = 182.0 \text{ Btu/lb}$$

Interpolating Table 1, the low pressure steam is cooled to 213.0F at $H_f = 181.2$ Btu/lb. The corresponding entropy of the heater drain is 0.3136 Btu/lb F. Therefore, the entropy decrease is:

$$\frac{(s_1 - s_2) \dot{m}_{\text{LP steam}}}{\dot{m}_{\text{HP steam}}} \quad (34)$$

$$= \frac{(1.7079 - 0.3136) 132,333}{4,813,813}$$

$$= 0.0383 \text{ Btu/lb F}$$

This heater shows a net entropy increase of $0.0412 - 0.0383 = 0.0029$ Btu/lb F.

Recall that an increase in entropy represents heat energy that is unavailable for conversion to work. Therefore, the net entropy increase through the feedwater heater is the loss of available energy that can be attributed to the pressure drop required for flow and temperature difference. These differences are necessary for heat transfer. The quantity of heat rendered unavailable for work is the product of the entropy increase and the absolute temperature of the sink receiving the rejected heat.

Available energy

From the previous feedwater heater example, there is a derived quantity, formed by the product of the corresponding entropy and the absolute temperature of the available heat sink, which has the nature of a property. The difference between H (enthalpy) and $T_o s$ is another derived quantity called available energy.

$$e = H - T_o s \quad (35)$$

where

e = available energy, Btu/lb (kJ/kg)
 H = enthalpy, Btu/lb (kJ/kg)
 T_o = sink temperature, R (K)
 s = entropy, Btu/lb R (kJ/kg K)

Available energy is not a property because it can not be completely defined by an equation of state; rather, it is dependent on the sink temperature. However, a combined statement of the first and second laws of thermodynamics indicates that the difference in the available energy between two points in a reversible process represents the maximum amount of work (on a unit mass basis) that can be extracted from the fluid due to the change of state variables H and s between the two points. Conceptually then, differences in the value of $T_o s$ represent energy that is unavailable for work.

The concept of available energy is useful in cycle

s (Total Entropies \div High Pressure Steam Flow) Btu/lb F (kJ/kg K) (See Text)

Fig. 9 Steam cycle for fossil fuel temperature-entropy diagram – single reheat, seven-stage regenerative feedwater heating – 3500 psig, 1000F/1000F steam.

analysis for optimizing the thermal performance of various components relative to overall cycle efficiency. In this way small, controllable changes in availability may be weighed against larger, fixed unavailable heat quantities which are inherent to the cycle. By comparing actual work to the maximum reversible work calculated from differences in available energy, the potential for improvement is obtained.

Rankine cycle efficiency

As with the Carnot cycle efficiency, the Rankine cycle efficiency (η) is defined as the ratio of the net work ($W_{\text{out}} - W_{\text{in}}$) produced to the energy input (Q_{in}):

$$\eta = \frac{W_{\text{out}} - W_{\text{in}}}{Q_{\text{in}}} \quad (36)$$

For the simple cycle shown in Fig. 7, the work terms and the energy input are defined as:

$$W_{\text{out}} = \eta_t \dot{m}_w (H_c - H_d) \quad (37)$$

$$W_{\text{in}} = \dot{m}_w (H_b - H_a) / \eta_p \quad (38)$$

$$\cong \dot{m}_w v_a (P_b - P_a) / \eta_p$$

$$Q_{\text{in}} = \dot{m}_w (H_c - H_b) \quad (39)$$

where H_{a-d} are the enthalpies defined in Fig. 7, \dot{m}_w is the water flow rate, P_{a-b} are the pressures at points a

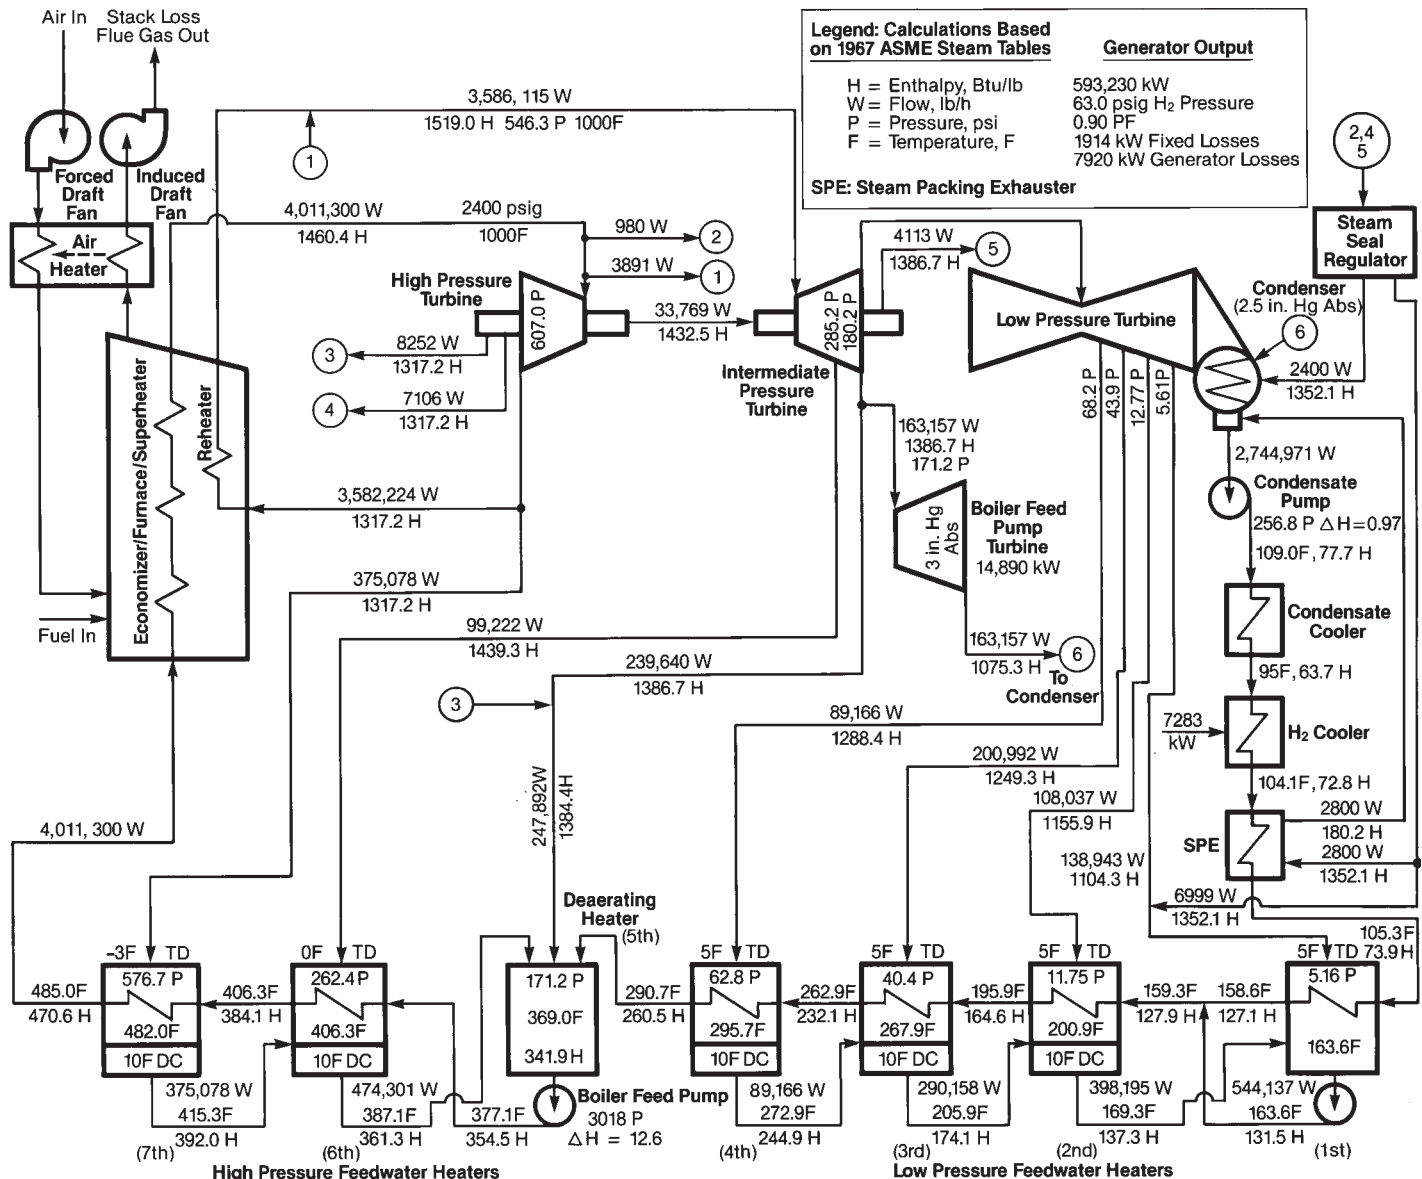

Fig. 10 Subcritical pressure, 2400 psig turbine cycle heat balance (English units).

and b , v_a is the water specific volume at point a , while η_t and η_p are the efficiencies of the turbine and boiler feed pump respectively.

Substituting Equations 37, 38 and 39 into Equation 36 and canceling the mass flow rate, \dot{m}_w , which is the same in all three cases provide the following overall thermodynamic efficiency (η_{th}):

$$\eta_{th} = \frac{\eta_t (H_c - H_d) - v_a (P_b - P_a) / \eta_p}{(H_c - H_b)} \quad (40)$$

In even a simple power producing facility using the Rankine cycle, several other factors must also be considered:

1. Not all of the chemical energy supplied to the boiler from the fuel is absorbed by the steam – typically 80 to 85% of the energy input is absorbed.
2. A variety of auxiliary equipment such as fans, soot-blowers, environmental protection systems, water

treatment equipment, and fuel handling systems, among others use part of the power produced.

3. Electrical generators and motors are not 100% efficient.

Incorporating these general factors into Equation 40 for a simple power cycle yields the net generating efficiency, η_{net} :

$$\eta_{net} = \frac{\eta_g \eta_t (H_c - H_d) - [v_1 (P_b - P_a) / \eta_p \eta_m] - w_{aux}}{(H_c - H_b) / \eta_b} \quad (41)$$

where w_{aux} is the auxiliary power usage, η_b is the boiler efficiency, while η_g and η_m are the electrical generator and motor efficiencies, both typically 0.98 to 0.99. The gross power efficiency can be evaluated from Equation 41 with w_{aux} set at zero.

The evaluation of efficiency in modern high pressure steam power systems is more complex. Provision in the evaluation must be made for steam reheat or

double reheat, and turbine steam extraction for regenerative feedwater heating, among others. This evaluation is based upon a steam turbine heat balance or steam cycle diagram such as that shown in Fig. 8 for a 3500 psig (24.13 MPa) supercritical pressure fossil fuel-fired unit, or Fig. 10 for a 2400 psig (16.55 MPa) subcritical pressure unit. The subcritical pressure unit shown has a single reheat, six closed feedwater heaters and one open feedwater heater.

Rankine cycle heat rate

Heat rate is a term frequently used to define various power plant efficiencies. If the electrical generation used is the net output after subtracting all auxiliary electrical power needs, then Equation 42 defines the *net heat rate* using English units. If the auxiliary electrical usage is not deducted, Equation 42 defines the *gross heat rate*.

$$\text{Heat rate} = \frac{\text{Total fuel heat input (Btu/h)}}{\text{Electrical generation (kW)}} \quad (42)$$

Heat rate is directly related to plant efficiency, η , by the following relationships:

$$\text{Net heat rate} = \frac{3412.14 \text{ Btu/kWh}}{\eta_{\text{net}}} \quad (43a)$$

$$\text{Gross heat rate} = \frac{3412.14 \text{ Btu/kWh}}{\eta_{\text{gross}}} \quad (43b)$$

Steam cycle in a nuclear plant

Fig. 11 illustrates a Rankine cycle whose thermal energy source is a pressurized water nuclear steam system. High pressure cooling water is circulated from a pressurized water reactor to a steam generator. Therefore, heat produced by the fission of enriched uranium in the reactor core is transferred to feedwater supplied to the steam generator which, in turn, supplies steam for the turbine. The steam generators of a nuclear plant are shell and tube heat exchangers in which the high pressure reactor coolant flows inside the tubes and lower pressure feedwater is boiled outside of the tubes. For the pressurized water reactor system, the Rankine cycle for power generation takes place entirely in the nonradioactive water side (*secondary side*) that is boiling and circulating in the steam system; the reactor coolant system is simply the heat source for the power producing Rankine cycle.

The steam pressure at the outlet of the steam generator varies among plants due to design differences and ranges from 700 to 1000 psi (4.83 to 6.90 MPa). Nominally, a nuclear steam system by The Babcock & Wilcox Company (B&W) with a once-through steam generator provides slightly superheated steam at 570F (299C) and 925 psi (6.38 MPa). Steam flow from the once-through generator reaches the high pressure turbine at about 900 psi (6.21 MPa) and 566F (297C). More prevalent are nuclear steam systems that use a recirculating steam generator. In this design, feedwater is mixed with saturated water coming from

the steam generator's separators before entering the tube bundle and boiling to generate steam. This boiling steam-water mixture reaches a quality of 25 to 33% at the end of the heat exchanger and enters the steam generator's internal separators. The separators return the liquid flow to mix with incoming feedwater and direct the saturated steam flow to the outlet of the steam generator. Inevitably, a small amount of moisture is formed by the time the steam flow reaches the high pressure turbine.

Even though the once-through steam generator is capable of providing superheated steam to the turbine, the pressure and temperature limitations of nuclear plant components must be observed. As a result, the expansion lines of the power cycle lie largely in the wet steam region. This is essentially a saturated or nearly saturated steam cycle. The expansion lines for the nuclear steam system shown in Fig. 11 (featuring a once-through steam generator) are plotted on an enthalpy-entropy or *H-s* diagram in Fig. 12.

The superheated steam is delivered to the turbine at a temperature only 34F (19C) above saturation. Although this superheat improves cycle efficiency, large quantities of condensed moisture still exist in the turbine. For example, if expansion from the initial conditions shown in Fig. 12 proceed down one step to the back pressure of 2.0 in. Hg [approximately 1.0 psi (6.9 kPa)] the moisture formed would exceed 20%. At best, steam turbines can accommodate about 15% moisture content. High moisture promotes erosion, especially in the turbine blades, and reduces expansion efficiency.

In addition to mechanical losses from momentum exchanges between slow moving condensate particles, high velocity steam and rotating turbine blades, there is also a thermodynamic loss resulting from the condensate in the turbine. The expansion of the steam is too rapid to permit equilibrium conditions to exist when condensation is occurring. Under this condition, the steam becomes subcooled, retaining a part of the available energy which would be released by condensation.

Fig. 11 indicates two methods of moisture removal used in this cycle and Fig. 12 shows the effect of this moisture removal on the cycle. After expansion in the high pressure turbine, the steam passes through a moisture separator, which is a low pressure drop separator external to the turbine. After passing through this separator, the steam is reheated in two stages, first by bleed steam and then by high pressure steam to 503F (262C), before entering the low pressure turbine. Here a second method of moisture removal, in which grooves on the back of the turbine blades drain the moisture from several stages of the low pressure turbine, is used. The separated moisture is carried off with the bleed steam.

Internal moisture separation reduces erosion and affords a thermodynamic advantage due to the divergence of the constant pressure lines with increasing enthalpy and entropy. This can be shown by the use of available energy, *e*, as follows. Consider the moisture removal stage at 10.8 psi in Fig. 12. After expansion to 10.8 psi, the steam moisture content is 8.9%. Internal separation reduces this to approximately 8.2%. Other properties are as follows:

	End of Expansion	After Moisture Extraction
P	10.8 psi	10.8 psi
H	1057.9 Btu/lb	1064.7 Btu/lb
s	1.6491 Btu/lb F	1.6595 Btu/lb F
T_o (at 2 in. Hg)	560.8 R	560.8 R
T_{os}	924.8 Btu/lb	930.7 Btu/lb
$e = H - T_{os}$	133.1 Btu/lb	134.0 Btu/lb

The values of moisture and enthalpy listed are given for equilibrium conditions without considering the nonequilibrium effects that are likely to exist within the turbine. These effects can be empirically accounted for by the isentropic efficiency of the expansion line. An important point to observe from this example is the need to retain a sufficient number of significant digits in the calculations. Frequently, the evaluation of thermodynamic processes results in working with small differences between large numbers.

As previously pointed out, cycle thermodynamic efficiency is improved by increasing the mean temperature of the heat addition process. This temperature can

The steam cycle of a typical supercritical plant is shown in Fig. 13. In this T - s diagram, point a represents the outlet of the condensate pump. Between points a and b , the condensate is heated in the low pressure feedwater heater using saturated liquid and/or steam extracted from the steam turbines. Point b corresponds to the high pressure feedwater pump inlet. The pump increases the pressure to 4200 psi (28.96 MPa), obtaining conditions of point c . Between points

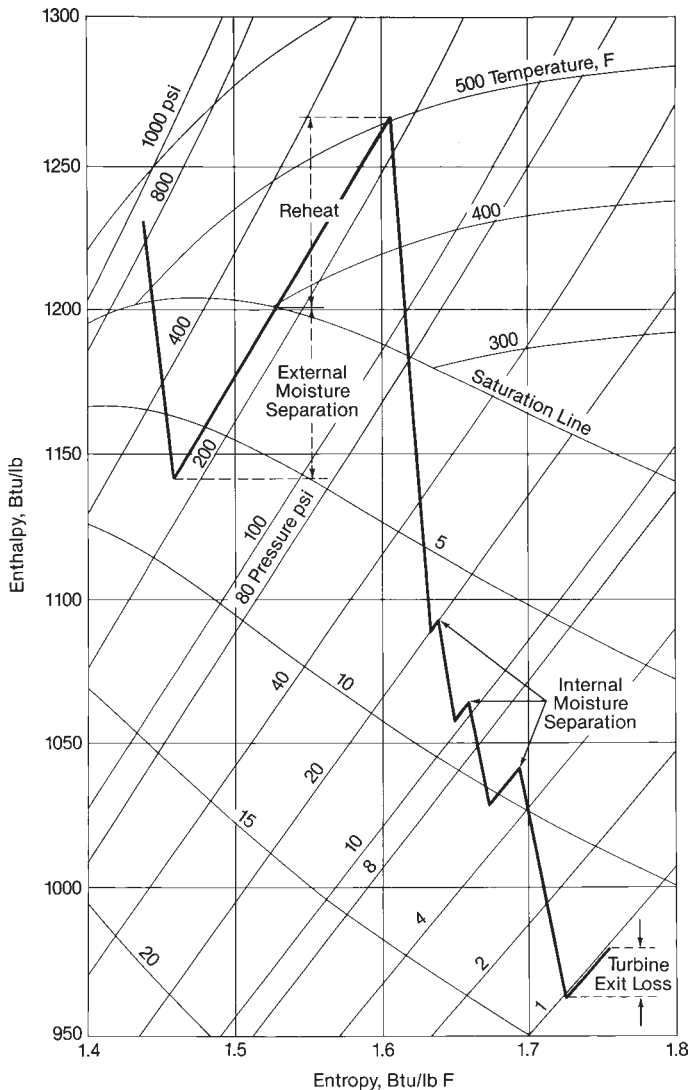

Fig. 12 Steam cycle for nuclear fuel on a Mollier chart: reheat by bleed and high pressure steam, moisture separation and six-stage regenerative feedwater heating – 900 psi, 566F/503F steam (English units).

c and d, additional feedwater heating is provided by steam extracted from the high and low pressure turbines. Point d corresponds to the supercritical boiler inlet. Due to the nature of the fluid, the supercritical boiler is a once-through design, having no need for separation equipment. The Universal Pressure, or UP[®], boiler design used in the supercritical unit is described further in Chapter 26. For the supercritical cycle shown, the steam arrives at the high pressure turbine at 3500 psi (24.1 MPa) and 1050F (566C). Expansion in this turbine is complete at point f, which corresponds to a superheated condition. Steam exhausted from the high pressure turbine is then reheated in the boiler to approximately 1040F (560C), before entering the low pressure turbine at approximately 540 psi (3.7 MPa); this corresponds to point g on the *T-s* diagram. The low pressure turbine expands the steam to point h on the diagram. The cycle is completed by condensing the exhaust from the low pressure turbine to a slightly subcooled liquid, and a condensate pump delivers the liquid to the low pressure feedwater heater, which corresponds to point a in the *T-s* diagram.

The high pressure of the feedwater in the supercritical cycle requires a substantially higher power input to the feedwater pump than that required by the saturated Rankine cycle. In a typical Rankine cycle with a steam pressure of 2400 psi (16.55 MPa), the pump power input requires approximately 2% of the turbine output. This may increase to as much as 3% in the supercritical unit. However, this increase is justified by the improved thermodynamic efficiency of the cycle. In general, with equivalent plant parameters (fuel type, heat sink temperature, etc.), the supercritical steam cycle generates about 4% more net power output than the subcritical pressure regenerative Rankine steam cycle.

Process steam applications

In steam power plants generating only electric power, economically justifiable thermodynamic efficiencies range up to about 42% in fossil fuel plants (higher in combined cycle plants discussed later in this chapter) and 34% in nuclear plants. Therefore, typically more than half of the heat released from the fuel must be transferred to the environment.

Energy resources may be more efficiently used by operating multipurpose steam plants, where steam is exhausted or extracted from the cycle at a sufficient pressure for use in an industrial process or space heating application. With these arrangements, an overall thermal utilization of 65% or greater is possible. Combination power and process installations have been common for many years, but the demand for process steam is not sufficient to permit the use of these combined cycles in most central station electric power generating plants. However, in regions where waste disposal and renewable energy sources have become significant environmental issues, the use of cogeneration, biomass and waste-to-energy installations have been successfully tied together with district heating and

Fig. 13 Supercritical steam cycle with one reheat.

other process steam application projects. In recent years, the most successful of these have been in European municipalities.

Gas turbine cycle

In the thermodynamic cycles previously described, the working fluid has been steam used in a Rankine cycle. The Rankine cycle efficiency limit is dictated by the ratio of the current maximum and minimum cycle temperatures. The current maximum temperature of the steam Rankine cycle is approximately 1200F (649C), which is set primarily by material constraints at the elevated pressures of the steam cycles. One means of extending the efficiency limit is to replace the working fluid with air or gas. The gas turbine system in its simplest form consists of a compressor, combustor and turbine, as shown in Fig. 14. Because of its simplicity, low capital cost and short lead time, gas turbine systems are being used by some utilities to add capacity in smaller increments. Use of the gas turbine system in conjunction with the steam Rankine cycle is also an effective means of recovering some of the heat lost when combustion gases are released to the atmosphere at high temperatures.

In the simple gas turbine system shown in Fig. 14, air is compressed then mixed with fuel and burned in a combustor. The high temperature gaseous combustion products enter the turbine and produce work by expansion. A portion of the work produced by the turbine is used to drive the compressor and the remainder is available to produce power. The turbine exhaust gases are then vented to the atmosphere. To analyze the cycle, several simplifying assumptions are made. First, although the combustion process changes the composition of the working fluid, the fluid is treated as a gas of single composition throughout, and it is considered an ideal gas to obtain simple relationships between points in the system. Second, the combustion process is approximated as a simple heat transfer process in which the heat input to the working fluid is determined by the fuel heating values. A result of this approximation is that the mass flow rate through the system remains constant. The final approximation is to assume that each of the processes is internally reversible.

If the turbine expansion is complete with the exhaust gas at the same pressure as the compressor inlet air, the combination of processes can be viewed as a cycle. The simplifying assumptions above result in the idealized gas turbine cycle referred to as the air-standard *Brayton* cycle. Fig. 15 shows the cycle on *T-s* and *P-v* diagrams, which permit determining the state variables at the various cycle locations.

The idealized cycle assumes an isentropic process between points 1 and 2 (compression) and between 3 and 4 (expansion work). The temperature rise between points 2 and 3 is calculated by assuming the heat addition due to combustion is at a constant pressure. In the analysis, the pressure ratio between points 1 and 2 is given by the compressor design and is assumed to be known. To determine the temperature at point 2, a relationship between the initial and final states of an isentropic ideal gas process is obtained as follows.

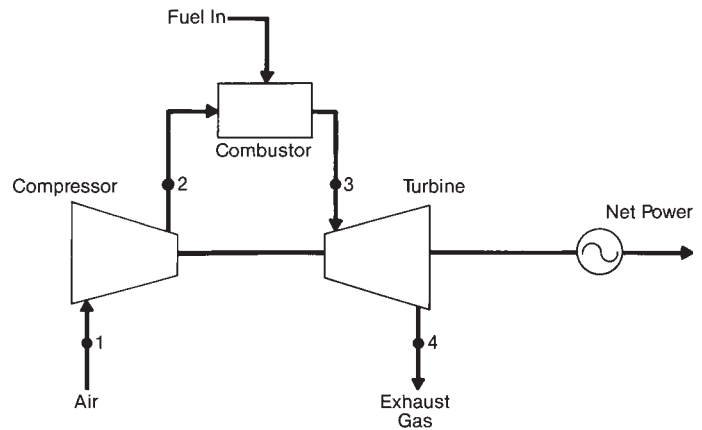

Fig. 14 Simple gas turbine system.

First, the general definitions of constant pressure and constant volume specific heats, respectively, are:

$$c_p = \left(\frac{\partial H}{\partial T} \right)_p \quad (44)$$

$$c_v = \left(\frac{\partial u}{\partial T} \right)_v \quad (45)$$

Strictly speaking, the specific heat values vary with temperature. In practice, however, they are assumed to be constant to facilitate the calculations. The two constants are related in that their difference equals the gas constant in the ideal gas law ($Pv = RT$):

$$c_p - c_v = R \quad (46)$$

The ratio of the constant pressure and constant volume specific heats is designated the specific heat ratio, *k*.

$$k = c_p / c_v \quad (47)$$

From these definitions, changes in enthalpy and internal energy for an ideal gas can be calculated from:

$$dH = c_p dT \quad (48)$$

$$du = c_v dT \quad (49)$$

Although expressed to relate differential changes in enthalpy and temperature, the concept of specific heat can be used to calculate finite enthalpy changes as long as the change in temperature is not excessive. When higher accuracy is required, tabulated enthalpy values should be used.

Recalling Equation 26, the combined expression of the first and second laws of thermodynamics, setting $ds = 0$ for the isentropic process, and inserting the change in internal energy given by Equation 49, the former equation may be written:

$$Tds = du + PdV = c_v dT + PdV = 0 \quad (50)$$

Substituting the ideal gas law (in differential form, $RdT = PdV + VdP$) and using the specific heat ratio definition, Equation 50 becomes:

Fig. 15 Air-standard Brayton cycle.

$$\frac{dP}{P} + \frac{kdv}{v} = 0 \quad (51)$$

Integrating this yields:

$$Pv^k = \text{constant} \quad (52)$$

From Equation 52 and the ideal gas law, the following relationship between pressures and temperatures in an isentropic process is obtained, and the temperatures at points 2 and 4 are determined.

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} = \left(\frac{P_2}{P_1} \right)^{(k-1)/k} \quad (53)$$

With this, the temperature and pressure (state variables) at all points in the cycle are determined. The turbine work output, w_t , required compressor work, w_c , and heat input to the process, q_b , are calculated as:

$$w_t = c_p (T_3 - T_4) \quad (54)$$

$$w_c = c_p (T_2 - T_1) \quad (55)$$

$$q_b = c_v (T_3 - T_2) \quad (56)$$

As in other cycle analyses described to this point, the cycle efficiency η is calculated as the net work produced divided by the total heat input to the cycle and is given by:

$$\eta = \frac{w_t - w_c}{q_b} \quad (57)$$

in which q_b is the heat input in the combustor (burner) per unit mass of gas (the working fluid) flowing through the system. For the ideal cycle, this can also be expressed in terms of gas temperatures by using Equation 48 to express the enthalpy change in the combustor and Equations 54 and 55 for the turbine and compressor work:

$$\eta = \left(1 - \frac{T_4 - T_1}{T_3 - T_2} \right) \frac{c_p}{c_v} \quad (58)$$

The actual gas turbine cycle differs from the ideal cycle due to inefficiencies in the compressor and turbine and pressure losses in the system. The effects of

these irreversible aspects of the real gas turbine cycle are shown in the T - s diagram in Fig. 16. An isentropic compression would attain the point $2s$, whereas the real compressor attains the pressure P_2 , with an entropy corresponding to point 2 on the T - s diagram; likewise the turbine expansion attains point 4 rather than $4s$. Constant-pressure lines on the diagram for pressures P_2 and P_3 illustrate the effect of pressure losses in the combustor and connecting piping, and the deviation of the process between points 4 and 1 from a constant-pressure process illustrates the effect of compressor inlet and turbine exhaust pressure losses on the cycle efficiency.

Points along the real cycle are determined by calculating the temperature T_{2s} from Equation 53 as:

$$T_{2s} = T_1 \left(\frac{P_2}{P_1} \right)^{(k-1)/k} \quad (59)$$

Using the compressor efficiency provided by the manufacturer and solving for enthalpy or temperature at the compressor outlet yields the following:

$$\eta_c = \frac{T_{2s} - T_1}{T_2 - T_1} = \frac{H_{2s} - H_1}{H_2 - H_1} \quad (60)$$

Despite the significant advances in the mechanical efficiency of compressor and turbine designs (both on the order of 80% or greater), the overall cycle efficiency of a real gas turbine system is relatively low (30 to 35%) due to the high exhaust gas temperature and because a significant portion of the turbine output is used for compressor operation. The cycle efficiency may be increased by using a heat exchanger to preheat the air between the compressor and combustor. This heat is supplied by the turbine exhaust gas in a manner similar to that of the Rankine cycle regenerative heat exchangers. However, the higher efficiency is achieved in a system with a lower pressure ratio across the compressor and turbine, which in turn lowers the net work output for a given combustion system. The lower net output and extra hardware cost must be weighed in each case against the thermodynamic efficiency improvement.

One of the key benefits of the gas turbine cycle is its ability to operate at much higher temperatures than the Rankine steam cycle. Gas turbines typically operate with an inlet temperature of 1800 to 2200F (982 to 1204C) and some turbine designs with complex internal cooling systems have been operated as high as 2300F (1260C), raising the thermodynamic efficiency. With the ability to operate at elevated temperatures and to use combustion gases as a working fluid, some gas turbine systems are operated in conjunction with the steam Rankine cycle.

Combined cycles and cogeneration

As seen in the previous discussions of the Rankine and Brayton cycles, the gas turbine Brayton cycle efficiently uses high temperature gases from a combustion process but discharges its exhaust gas at a rela-

Fig. 16 T-s diagram of an actual gas turbine system.

tively high temperature; in the Brayton cycle, this constitutes wasted heat. On the other hand, the steam turbine Rankine cycle is unable to make full use of the highest temperatures. Combined cycles are designed to take advantage of the best features of these two cycles to improve the overall thermodynamic efficiency of the plant. Advanced combined cycles, in which the gas turbine exhaust is used as a heat source for a steam turbine cycle, can achieve overall thermal efficiencies in excess of 50%, generally representing a 15% improvement in the cycle efficiency compared to the gas turbine alone.

Waste heat boilers

In its simplest form, the combined cycle plant is a gas turbine (Brayton cycle) plant enhanced by passing the turbine exhaust through a steam generator, as shown in Fig. 17. The steam generator uses the hot turbine exhaust as a heat source for a steam turbine Rankine cycle. Electric power is generated from the mechanical work provided by the gas turbine and the steam turbine. In concept, the steam generator in the combined cycle is recovering the otherwise wasted heat from the gas turbine exhaust, and therefore it is referred to as a heat recovery steam generator or a waste heat boiler. (See Chapter 27.) More recent applications of the combined cycle have incorporated supplemental firing in the waste heat boiler to elevate

Fig. 17 Simple combined cycle plant.

the steam temperature and, therefore, to improve the steam cycle performance. Thermodynamic efficiency is defined as the work output of the two cycles divided by the total heat supplied (Q_{total}):

$$\eta = \frac{(W_{\text{out}} - W_{\text{in}})_{GT} + (W_{\text{out}} - W_{\text{in}})_{ST}}{Q_{\text{total}}} \quad (61)$$

where the subscripts *GT* and *ST* refer to gas turbine and steam turbine, respectively.

Another approach to combining the gas and steam cycles, in which the steam generator serves as the combustion chamber for the gas turbine cycle, is shown in Fig. 18. In this arrangement, the principal heat source to the gas and steam cycle is the combustion process taking place in the steam generator. The gaseous combustion products are expanded in the gas turbine and the steam generated in the boiler tubes is expanded in the steam turbine. Although not shown in Fig. 18, the heat contained in the gas turbine exhaust may be recovered by using either a regenerative heat exchanger in the gas turbine cycle or a feedwater heater in the steam cycle. A pressurized fluidized-bed combustion combined cycle is a specific example of this approach to combining the gas and steam cycles. (See Chapter 17.)

Cogeneration

In the most general sense, cogeneration is the production of more than one useful form of energy (thermal, mechanical, electrical, etc.) simultaneously from a single fuel. In practice, cogeneration refers to generating electricity while principally performing an industrial function such as space heating, process heating or fuel gasification. Cogeneration systems are divided into two basic arrangements, topping and bottoming cycles.

A topping cycle is shown in Fig. 19. In this system the fuel is used for power generation in a steam boiler or gas turbine cycle combustor, and the waste heat from the power generation cycle supports an industrial process. The most common topping cycle is one in which a boiler generates steam at a higher pressure than that needed for the process or space conditioning application. The high pressure steam is then expanded in a turbine to a pressure that is appropriate for the application, generating electricity in the expansion process. Steam turbines, gas turbines and reciprocating engines are commonly used in topping cycles.

A bottoming cycle is most commonly associated with the recovery or waste heat boiler. In the bottoming cycle, fuel is not supplied directly to the power generating cycle. Rather, steam is generated from a waste

Fig. 18 Pressurized combustion combined cycle plant.

heat source and then expanded in a turbine to produce work or to generate electricity. Steam is frequently used in the bottoming cycle because of its ability to condense at low temperatures in the closed Rankine cycle. The bottoming cycle is shown in Fig. 20. The steam Rankine cycle used as a bottoming cycle has been illustrated previously in the descriptions of combined cycle plants.

Combustion processes

To this point, cycles have been compared based on the thermodynamic efficiency achieved, i.e., the net work produced divided by the total heat input to the cycle. To complete the evaluation of a combustion-based cycle, however, the performance must be expressed in terms of fuel consumption. In addition, the ability of the different machines to make full use of the combustion energy varies with temperatures reached in the combustion chamber and with dissociation of the combustion products.

The energy release during combustion is illustrated by considering the combustion of carbon (C) and oxygen (O₂) to form carbon dioxide (CO₂):

If heat is removed from the combustion chamber and the reactants and products are maintained at 25°C and 0.1 MPa (77°F and 14.5 psi) during the process, the heat transfer from the combustion chamber would be 393,522 kJ per kmole of CO₂ formed. From the first law applied to the process, the heat transfer is equal to the difference in enthalpy between the reactants and products:

$$q - w = H_P - H_R \quad (62)$$

The subscripts *R* and *P* refer to reactants and products, respectively. Assuming that no work is done in the combustion chamber and expressing the enthalpy of reactants and products on a per mole basis, this becomes:

$$Q = \sum n_P H_P - \sum n_R H_R \quad (63)$$

The number of moles of each element or molecular species entering or leaving the chamber, *n_R* or *n_P* re-

spectively, is obtained from the chemical reaction equation. By convention, the enthalpy of elements at 25°C and 0.1 MPa (77°F and 14.5 psi) are assigned the value of zero. Consequently, the enthalpy of CO₂ at these conditions is -393,522 kJ/kmole (the negative sign is due to the convention of denoting heat transferred from a control volume as negative). This is referred to as the enthalpy of formation and is designated by the symbol *H_f^o*. The enthalpy of CO₂ (and other molecular species) at other conditions is found by adding the change in enthalpy between the desired condition and the standard state to the enthalpy of formation. [Note that some tables may not use 25°C and 0.1 MPa (77°F and 14.5 psi) as the standard state when listing the enthalpy of formation.] Ideal gas behavior or tabulated properties are used to determine enthalpy changes from the standard state.

The stoichiometrically balanced chemical reaction equation provides the relative quantities of reactants and products entering and leaving the combustion chamber. The first law analysis is usually performed on a per mole or unit mass of fuel basis. The heat transfer from a combustion process is obtained from a first law analysis of the combustion process, given the pressure and temperature of the reactants and products. Unfortunately, even in the case of complete combustion as assumed in the previous example, the temperature of the combustion products must be determined by additional calculations discussed later in this section.

The combustion of fossil or carbon based fuel is commonly accompanied by the formation of steam or water (H₂O) as in the reaction:

Again, the difference in enthalpy between the reactants and products is equal to the heat transfer from the combustion process. The heat transfer per unit mass of fuel (methane in this example) is referred to as the heating value of the fuel. If the H₂O is present as liquid in the products, the heat transferred is referred to as the *higher heating value* (HHV). The term *lower heating value* (LHV) is used when the H₂O is present as a vapor. The difference between these two values is frequently small (about 4% for most hydrocarbon fuels) but still significant. When the efficiency

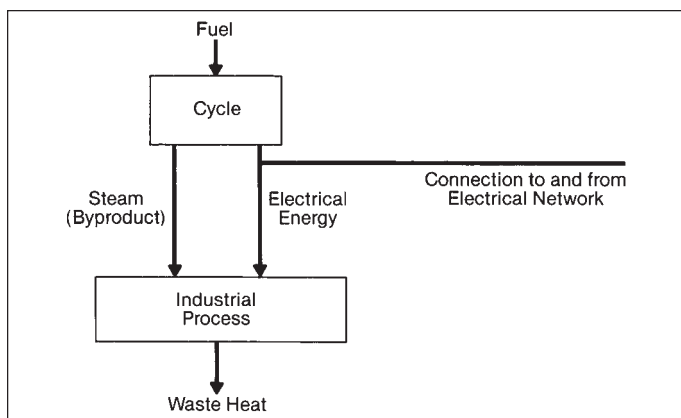

Fig. 19 Topping cycle.

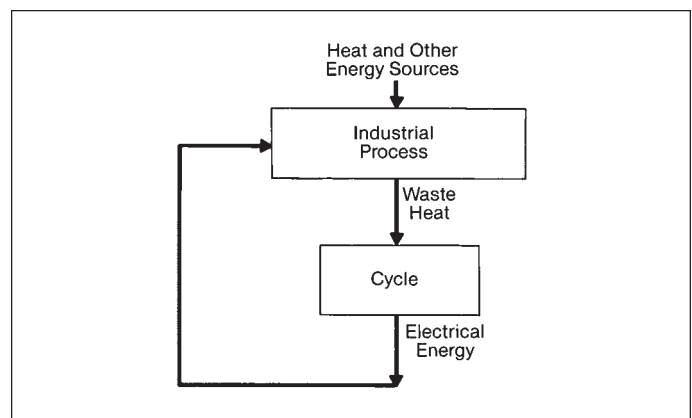

Fig. 20 Bottoming cycle.

of a cycle is expressed as a percentage of the fuel's heating value, it is important to know whether the HHV or LHV is used.

As noted, one of the difficulties in completing the first law analysis of the combustion process is determining the temperature of the products. In some applications an upper limit of the combustion temperature may be estimated. From the first law, this can occur if the combustion process takes place with no change in kinetic or potential energy, with no work and with no heat transfer (adiabatically). Under these assumptions, the first law indicates that the sum of the enthalpies of the reactants equals that of the products. The temperature of the products is then determined iteratively by successively assuming a product temperature and checking the equality of the reactant and product enthalpies. For a given fuel and reactants at the specified inlet temperature and pressure, this procedure determines the highest attainable combustion temperature, referred to as the *adiabatic combustion* or *flame temperature*.

Gibbs free energy

An important thermodynamic property derived from a combination of other properties (just as enthalpy was derived from u , P and v) is Gibbs free energy (g), which is also frequently referred to as *free energy*:

$$g = H - Ts \quad (64)$$

Free energy g is a thermodynamic potential similar to enthalpy and internal energy because in any thermodynamic process, reversible or irreversible, differences in this quantity depend only on initial and final states of the system.

The usefulness of free energy is particularly evident from the following expression of the combined first and second laws, expressed for a reversible process with negligible changes in kinetic and potential energy:

$$W_{\text{rev}} = \sum m_1 (H_1 - T_o s_1) - \sum m_2 (H_2 - T_o s_2) \quad (65)$$

When applied to a combustion process in which the reactants and products are in temperature equilibrium with the surroundings, this becomes:

$$W_{\text{rev}} = \sum n_R g_R - \sum n_P g_P \quad (66)$$

This equation indicates the maximum value of reversible work that can be obtained from the combustion of a given fuel. The reversible work is maximized when the reactants constitute a stoichiometrically balanced mixture (no excess air). The quantities n_R and n_P are obtained from the chemical reaction equation and g is expressed on a per mole basis in Equation 66.

From this, one might expect to express the efficiency of a cycle that extracts energy from a combustion process as a percentage of the Gibbs free energy decrease, rather than in terms of the heating value of the fuel. It is uncommon for this to be done, however, because the difference between the free energy decrease and

the heating value of hydrocarbon fuels is small and because the use of fuel heating value is more widespread.

Free energy is more commonly used to determine the temperature reached in burning fuel, including the effects of dissociation. The problem of dissociation is illustrated by again considering the combustion of carbon and oxygen to form CO_2 . If the temperature of the combustion process is high enough, the CO_2 dissociates to form CO and O_2 according to the reaction:

As the dissociation reaction occurs from left to right (from all CO_2 to none), the sum of the reactant free energies and that of the products vary. Equilibrium of this reaction is reached when the sum of the free energies is a minimum. The equilibrium point (degree of dissociation) varies with the combustion temperature.

While the process of iteratively determining a minimum free energy point is suited for computer calculations, the equilibrium conditions of the dissociation reaction at an assumed temperature can also be determined using tabulated values of a constant relating the species involved in the reaction. This constant is known as the equilibrium constant K_{eq} , which for ideal gases is given by:

$$K_{eq} = \frac{(P_B)^b (P_C)^c}{(P_A)^a} \quad (67)$$

where P_A , P_B and P_C are the partial pressures, i.e., the products of total pressure and mole fractions in the mixture, of the reactants and products. The exponents represent the number of moles present for each species (A , B and C) in the stoichiometric balance equation as follows:

Equations 67 and 68 yield simultaneous equations for the mole fractions a , b and c . For nonideal gas reactions, the partial pressures are replaced by what are known as *fugacities* (the tendencies of a gas to expand or escape). Thermodynamic properties and relationships for the compounds and their elements encountered in the combustion process are available in the literature. One of the best sources for this information is the JANAF Thermochemical Tables, published by the U.S. Department of Commerce.⁶ These tables include \log_{10} values of the equilibrium constants for temperatures from 0 to 6000K.

To continue the carbon-oxygen combustion example, the overall chemical reaction, including dissociation, is now written as:

in which the coefficients a , b and c represent the mole fractions of the product components as determined by the solution to the dissociation reaction at the assumed combustion temperature. The overall reaction equation is now used to check the assumed temperature

by adding the enthalpies of the combustion products at the assumed temperature, noting that the enthalpy per mole must be multiplied by the corresponding mole fraction a , b , or c for each product species. The combustion temperature is determined when the sum of product enthalpies minus that of the reactants equals

the heat transfer to the surroundings of the combustion chamber. The convective and radiative heat transfer from the combustion products to the chamber and eventually to the working fluid of the cycle at the assumed combustion temperature are discussed in Chapter 4.

Mollier diagram (H-s) for steam.

Chapter 3

Fluid Dynamics

In the production and use of steam there are many fluid dynamics considerations. Fluid dynamics addresses steam and water flow through pipes, fittings, valves, tube bundles, nozzles, orifices, pumps and turbines, as well as entire circulating systems. It also considers air and gas flow through ducts, tube banks, fans, compressors and turbines plus convection flow of gases due to draft effect. The fluid may be a liquid or gas but, regardless of its state, the essential property of a fluid is that it yields under the slightest shear stress. This chapter is limited to the discussion of Newtonian liquids, gases and vapors where any shear stress is directly proportional to a velocity gradient normal to the shear force. The ratio of the shear stress to the velocity gradient is the property *viscosity* represented by the symbol μ .

Liquids and gases are recognized as states of matter. In the liquid state, a fluid is relatively incompressible, having a definite volume. It is also capable of forming a free surface interface between itself and its vapor or any other fluid with which it does not mix. On the other hand, a gas is highly compressible. It expands or diffuses indefinitely and is subject only to the limitations of gravitational forces or an enclosing vessel.

The term *vapor* generally implies a gas near saturation conditions where the liquid and the gas phase coexist at essentially the same temperature and pressure, during a process such as vaporization or boiling. In a similar sense the term *gas* denotes a highly superheated steam. Sometimes steam may be treated as an ideal gas and careful judgment is needed when doing so.

Fluid dynamics principles normally consider the fluid to be a continuous region of matter, a continuum, and a molecular model is not required except for rare instances. However, one property is noteworthy to consider due to the effect on steam generation fluid flow and due to intermolecular forces. *Surface tension*, σ , is a liquid property of the vapor-liquid interface and is the energy per unit area required to extend the interface. Surface tension is important in two-phase systems, such as a mixture flowing in a boiler tube, and relates to the shape and flow regime of the bubble interface and also to the heat transfer area of droplets. Vapor bubbles increase the resistance to fluid flow.

The surface tension of water is dependent on temperature and its value goes to zero at the critical temperature (705.47 F, 374.15C). Supercritical water is considered single phase in fluid dynamic analysis due to zero surface tension.

The recommended correlation¹ for the surface tension of water and its vapor, σ , is:

$$\sigma = 235.8 \times 10^{-3} N/m \left[\frac{(T_c - T)}{T} \right]^{1.256} \left[1 - 0.625 \left(\frac{T_c - T}{T} \right) \right] \quad (1)$$

where $T_c = 647.15K$ and T is the fluid temperature in K.

Water in steam generators operating at supercritical pressure (above 3200.1 psia, 22.1 MPa) will behave as a single phase fluid converting from liquid to steam without creating bubbles. At the critical pressure and critical temperature, the density of water and steam are identical and there is no distinguishable interface at equilibrium conditions. Surface tension is also related to the latent heat of vaporization which also decreases to zero at the critical temperature.² This chapter discusses single phase fluid flow. Chapter 5 pertains to two-phase fluid flow that occurs in boiling tube circuits.

Fundamental relationships

Three fundamental laws of conservation apply to fluid dynamic systems: conservation of mass, momentum and energy. With the exception of nuclear reactions where minute quantities of mass are converted into energy, these laws must be satisfied in all flowing systems. Fundamental mathematical relationships for these principles are presented in several different forms that may be applied in particular fluid dynamic situations to provide an appropriate solution method. However, full analytical solutions are frequently too complex without the use of a computer. Simplified forms of the full equations can be derived by applying engineering judgment to drop negligible terms and consider only terms of significant magnitude for cer-

tain classes of problems. Fluid dynamics problems can be classified as compressible or incompressible, viscous or inviscid. Engineering practice is based upon applying various assumptions and empirical relationships in order to obtain a practical method of solution. A more complete discussion of the derivation of these conservation law relationships and vector notation representing three dimensional spaces may be found in References 3, 4, 5 and 6.

Conservation of mass

The *law of conservation of mass* simply states that the rate of change in mass stored in a system must equal the difference in the mass flowing into and out of the system. The *continuity equation* of mass for one dimensional single phase flow in a variable area channel or stream tube is:

$$A \frac{\partial \rho}{\partial t} + AV \frac{\partial \rho}{\partial x} + \rho V \frac{\partial A}{\partial x} + \rho A \frac{\partial V}{\partial x} = 0 \quad (2)$$

In its simplest form in x , y and z three dimensional Cartesian coordinates, conservation of mass for a small fixed control volume is:

$$\frac{\partial}{\partial x} \rho u + \frac{\partial}{\partial y} \rho v + \frac{\partial}{\partial z} \rho w = - \frac{\partial \rho}{\partial t} \quad (3)$$

where u , v and w are the fluid velocities in the x , y and z coordinate directions; t is time and ρ is the fluid density. An important form of this equation is derived by assuming steady-state ($\partial / \partial t = 0$) and incompressible (constant density) flow conditions:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (4)$$

Although no liquid is truly incompressible, the assumption of incompressibility simplifies problem solutions and is frequently acceptable for engineering practice considering water and oils.

Another relationship useful in large scale pipe flow systems involves the integration of Equation 3 around the flow path for constant density, steady-state conditions. For only one inlet (subscript 1) and one outlet (subscript 2):

$$\dot{m} = \rho_1 A_1 V_1 = \rho_2 A_2 V_2 \quad (5)$$

where ρ is the average density, V is the average velocity, A is the cross-sectional area, and \dot{m} is the mass flow rate.

Conservation of momentum

The *law of conservation of momentum* is a representation of Newton's Second Law of Motion – the mass of a particle times its acceleration is equal to the sum of all of the forces acting on the particle. In a flowing system, the equivalent relationship for a fixed (control) volume becomes: the rate of change in momentum entering and leaving the control volume is equal to the sum of the forces acting on the control volume.

The conservation of momentum for one dimensional single phase flow in a variable area channel or stream tube is:

$$\frac{1}{g_c} \left[\frac{\partial G}{\partial t} + \frac{1}{A} \frac{\partial}{\partial x} \left(\frac{G^2 A}{\rho} \right) \right] + \frac{\tau P_f}{A} + \frac{g}{g_c} \rho \sin \theta + \frac{\partial P}{\partial x} = 0 \quad (6)$$

where

- P = pressure, psia (MPa)
- G = mass flux, $G = \rho V$, lb/h ft² (kg/s m²)
- A = flow area of channel ft² (m²)
- ρ = density lb/ft³ (kg/m³)
- τ = wall shear stress, lb/ft² (N/m²) (refer to Equation 26)
- P_f = channel wetted perimeter, ft (m)
- g = 32.17 ft /s² (9.8 m /s²)
- g_c = 32.17 lbf m /lbf s² (1 kg m /N s²)
- θ = angle of channel inclination for x distance

This relationship is useful in calculating steam generator tube circuit pressure drop.

The conservation of momentum is a vector equation and is direction dependent, resulting in one equation for each coordinate direction (x , y and z for Cartesian coordinates), providing three momentum equations for each scalar velocity component, u , v and w .

The full mathematical representation of the momentum equation is complex and is of limited direct use in many engineering applications, except for numerical computational models. As an example, in the x coordinate direction, the full momentum equation becomes:

$$\begin{aligned} & \rho \left(\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right) && \text{Term 1} \\ & = \rho f_x && \text{Term 2} \\ & - \frac{\partial P}{\partial x} && \text{Term 3} \\ & + \frac{\partial}{\partial x} \left[\frac{2}{3} \mu \left(2 \frac{\partial u}{\partial x} - \frac{\partial v}{\partial y} - \frac{\partial w}{\partial z} \right) \right] && \text{Term 4} \\ & + \frac{\partial}{\partial y} \left[\mu \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \right] && \\ & + \frac{\partial}{\partial z} \left[\mu \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right) \right] && \end{aligned} \quad (7)$$

where f_x is the body force in the x direction, P is the pressure, and μ is the viscosity. This equation and the corresponding equations in the y and z Cartesian coordinates represent the Navier-Stokes equations which are valid for all compressible Newtonian fluids with variable viscosity. *Term 1* is the rate of momentum change. *Term 2* accounts for body force effects such as gravity. *Term 3* accounts for the pressure gradient. The balance of the equation accounts for mo-

momentum change due to viscous transfer. *Term 1* is sometimes abbreviated as $\rho(Du/Dt)$ where Du/Dt is defined as the substantial derivative of u . For a function β (scaler or vector), D/Dt is the substantial derivative operator on function β defined as:

$$\begin{aligned} \frac{D\beta}{Dt} &= \frac{\partial\beta}{\partial t} + u \frac{\partial\beta}{\partial x} + v \frac{\partial\beta}{\partial y} \\ &+ w \frac{\partial\beta}{\partial z} = \frac{\partial\beta}{\partial t} + \mathbf{v} \cdot \nabla \beta \end{aligned} \quad (8)$$

where the vector gradient or **grad** or **del** operator on function β is defined as:

$$\nabla\beta \text{ or } \mathbf{grad} \beta \text{ or } \mathbf{del} \beta = \mathbf{i} \partial\beta/\partial x + \mathbf{j} \partial\beta/\partial y + \mathbf{k} \partial\beta/\partial z$$

For the special case of constant density and viscosity, this equation reduces to (for the x coordinate direction):

$$\frac{Du}{Dt} = f_x - \frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{\mu}{\rho} \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) \quad (9)$$

The y and z coordinate equations can be developed by substituting appropriate parameters for velocity u , pressure gradient $\partial P/\partial x$, and body force f_x . Where viscosity effects are negligible ($\mu = 0$), the Euler equation of momentum is produced (x direction only shown):

$$\frac{Du}{Dt} = f_x - \frac{1}{\rho} \frac{\partial P}{\partial x} \quad (10)$$

Energy equation (first law of thermodynamics)

The *law of conservation of energy* for nonreacting fluids states that the energy transferred into a system less the mechanical work done by the system must be equal to the rate of change in stored energy, plus the energy flowing out of the system with a fluid, minus the energy flowing into the system with a fluid. A single scaler equation results. The one dimensional single phase flow energy equation for a variable area channel or stream tube is:

$$\rho \frac{\partial H}{\partial t} + G \frac{\partial H}{\partial x} = q'' \frac{P_H}{A} + q''' + \frac{1}{J} \frac{\partial P}{\partial \tau} \quad (11)$$

where

- P = pressure, psia (MPa)
- G = mass flux, lb/h ft² (kg/s m²)
- A = flow area of channel, ft² (m²)
- ρ = density, lb/ft³ (kg/m³)
- τ = wall shear stress, lb/ft² (N/m²)
- P_H = channel heated area, ft² (m²)
- x = channel distance, ft (m) for x distance
- H = enthalpy, Btu/lb (kJ/kg)
- J = mechanical equivalent of heat = 778.17 ft lbf/Btu (1 N m/J)
- q'' = heat flux at boundary, Btu/h ft² (W/m²)
- q''' = internal heat generation, Btu/h ft³ (W/m)

A general form of the energy equation for a flowing system using an enthalpy based formulation and vector notation is:

$$\rho \frac{DH}{Dt} = \underbrace{q'''}_{\text{Term 1}} + \underbrace{\frac{DP}{Dt}}_{\text{Term 2}} + \underbrace{\nabla \cdot k \nabla T}_{\text{Term 3}} + \underbrace{\frac{\mu}{g_c} \Phi}_{\text{Term 4}} \quad (12)$$

where ρ is the fluid density, H is the enthalpy per unit mass of a fluid, T is the fluid temperature, q''' is the internal heat generation, k is the thermal conductivity, and Φ is the dissipation function for irreversible work.⁶ *Term 1* accounts for net energy convected into the system, *Term 2* accounts for internal heat generation, *Term 3* accounts for work done by the system, *Term 4* addresses heat conduction, and *Term 5* accounts for viscous dissipation.

As with the momentum equations, the full energy equation is too complex for most direct engineering applications except for use in numerical models. (See Chapter 6.) As a result, specialized forms are based upon various assumptions and engineering approximations. As discussed in Chapter 2, the most common form of the energy equation for a simple, inviscid (i.e., frictionless) steady-state flow system with flow in at location 1 and out at location 2 is:

$$\begin{aligned} JQ - W &= J(u_2 - u_1) + (P_2 v_2 - P_1 v_1) \\ &+ \frac{1}{2g_c} (V_2^2 - V_1^2) + (Z_2 - Z_1) \frac{g}{g_c} \end{aligned} \quad (13a)$$

or

$$\begin{aligned} JQ - W &= J(H_2 - H_1) \\ &+ \frac{1}{2g_c} (V_2^2 - V_1^2) + (Z_2 - Z_1) \frac{g}{g_c} \end{aligned} \quad (13b)$$

where

- Q = heat added to the system, Btu/lbm (J/kg) (See Note below)
- W = work done by the system, ft-lbf/lbm (N m/kg)
- J = mechanical equivalent of heat = 778.17 ft lbf/Btu (1 N m/J)
- u = internal energy, Btu/lbm (J/kg)
- P = pressure, lbf/ft² (N/m²)
- v = specific volume, ft³/lbm (m³/kg)
- V = velocity, ft/s (m/s)
- Z = elevation, ft (m)
- H = enthalpy = $u + Pv/J$, Btu/lbm (J/kg)
- g = 32.17 ft/s² (9.8 m/s²)
- g_c = 32.17 lbm ft/lbf s² (1 kg m/N s²)

Note: Where required for clarity, the abbreviation lb is augmented by f (lbf) to indicate pound force and by m (lbm) to indicate pound mass. Otherwise lb is used with force or mass indicated by the context.

Energy equation applied to fluid flow (pressure loss without friction)

The conservation laws of mass and energy, when simplified for steady, frictionless (i.e., inviscid) flow of an incompressible fluid, result in the mechanical energy balance referred to as Bernoulli's equation:

$$P_1 v + Z_1 \frac{g}{g_c} + \frac{V_1^2}{2g_c} = P_2 v + Z_2 \frac{g}{g_c} + \frac{V_2^2}{2g_c} \quad (14)$$

The variables in Equation 14 are defined as follows with the subscripts referring to location 1 and location 2 in the system:

- P = pressure, lbf/ft² (N/m²)
- v = specific volume of fluid, ft³/lbm (m³/kg)
- Z = elevation, ft (m)
- V = fluid velocity, ft/s (m/s)

Briefly, Equation 14 states that the total mechanical energy present in a flowing fluid is made up of pressure energy, gravity energy and velocity or kinetic energy; each is mutually convertible into the other forms. Furthermore, the total mechanical energy is constant along any stream-tube, provided there is no friction, heat transfer or shaft work between the points considered. This stream-tube may be an imaginary closed surface bounded by stream lines or it may be the wall of a flow channel, such as a pipe or duct, in which fluid flows without a free surface.

Applications of Equation 14 are found in flow measurements using the velocity head conversion resulting from flow channel area changes. Examples are the venturi, flow nozzle and various orifices. Also, pitot tube flow measurements depend on being able to compare the total head, $Pv + Z + (V^2/2g_c)$, to the static head, $Pv + Z$, at a specific point in the flow channel. Descriptions of metering instruments are found in Chapter 40. Bernoulli's equation, developed from strictly mechanical energy concepts some 50 years before any precise statement of thermodynamic laws, is a special case of the conservation of energy equation or first law of thermodynamics in Equations 13a and b.

Applications of Equation 13 to fluid flow are given in the examples on water and compressible fluid flow through a nozzle under the *Applications of the Energy Equation* section in Chapter 2. Equation 18, Chapter 2 is:

$$V_2 = \sqrt{2g_c J (H_1 - H_2)} = C \sqrt{H_1 - H_2} \quad (15)$$

where

- V_2 = downstream velocity, ft/s (m/s)
- g_c = 32.17 lbm ft/lbf s² = 1 kg m/Ns²
- J = 778.26 ft lbf/Btu = 1 Nm/J
- H_1 = upstream enthalpy, Btu/lb (J/kg)
- H_2 = downstream enthalpy, Btu/lb (J/kg)
- C = 223.8 $\sqrt{\text{lbm/Btu}} \times \text{ft/s}$ (1.414 $\sqrt{\text{kg/J}} \times \text{m/s}$)

This equation relates fluid velocity to a change in enthalpy under *adiabatic* (no heat transfer), steady, *inviscid* (no friction) flow where no work, local irrevers-

ible flow pressure losses, or change in elevation occurs. The initial velocity is assumed to be zero and compressible flow is permitted. If the temperature (T) and pressure (P) of steam or water are known at points 1 and 2, Equation 15 provides the exit velocity using the enthalpy (H) values provided in Tables 1, 2 and 3 of Chapter 2. If the pressure and temperature at point 1 are known but only the pressure at point 2 is known, the outlet enthalpy (H_2) can be evaluated by assuming constant entropy expansion from points 1 to 2, i.e., $S_1 = S_2$.

Ideal gas relationships

There is another method that can be used to determine velocity changes in a frictionless adiabatic expansion. This method uses the ideal gas equation of state in combination with the pressure-volume relationship for constant entropy.

From the established gas laws, the relationship between pressure, volume and temperature of an ideal gas is expressed by:

$$Pv = RT \quad (16a)$$

or

$$Pv = \frac{R}{M} T \quad (16b)$$

where

- P = absolute pressure, lb/ft² (N/m²)
- v = specific volume, ft³/lb of gas (m³/kg)
- M = molecular weight of the gas, lb/lb-mole (kg/kg-mole)
- T = absolute temperature, R (K)
- R = gas constant for specific gas, ft lbf/lbm R (N m/kg K)
- $MR = R$ = the universal gas constant
= 1545 ft lb/lb-mole R (8.3143 kJ/kg-mole K)

The relationship between pressure and specific volume along an expansion path at constant entropy, i.e., isentropic expansion, is given by:

$$Pv^k = \text{constant} \quad (17)$$

Because P_1 and v_1 in Equation 13 are known, the constant can be evaluated from $P_1 v_1^k$. The exponent k is constant and is evaluated for an ideal gas as:

$$k = c_p / c_v = \text{specific heat ratio} \quad (18)$$

where

- c_p = specific heat at constant pressure, Btu/lb F (J/kg K)
- c_v = specific heat at constant volume, Btu/lb F (J/kg K)
= $(u_1 - u_2) / (T_1 - T_2)$

For a steady, adiabatic flow with no work or change in elevation of an ideal gas, Equations 13, 16, 17 and 18 can be combined to provide the following relationship:

$$V_2^2 - V_1^2 = 2g_c \left(\frac{k}{k-1} \right) P_1 v_1 \left\{ 1 - \left(\frac{P_2}{P_1} \right)^{\frac{k-1}{k}} \right\} \quad (19)$$

When V_1 is set to zero and using English units Equation 19 becomes:

$$V_2 = 8.02 \sqrt{\left(\frac{k}{k-1}\right) P_1 v_1 \left\{1 - \left(\frac{P_2}{P_1}\right)^{\frac{k-1}{k}}\right\}}, \text{ ft/s} \quad (20)$$

Equations 19 and 20 can be used for gases in pressure drop ranges where there is little change in k , provided values of k are known or can be calculated. Equation 20 is widely used in evaluating gas flow through orifices, nozzles and flow meters.

It is sufficiently accurate for most purposes to determine velocity differences caused by changes in flow area by treating a compressible fluid as incompressible. This assumption only applies when the difference in specific volumes at points 1 and 2 is small compared to the final specific volume. The accepted practice is to consider the fluid incompressible when:

$$(v_2 - v_1) / v_2 < 0.05 \quad (21)$$

Because Equation 14 represents the incompressible energy balance for frictionless adiabatic flow, it may be rearranged to solve for the velocity difference as follows:

$$V_2^2 - V_1^2 = 2g_c [\Delta(Pv) + \Delta Zg / g_c] \quad (22)$$

where

$$\begin{aligned} \Delta(Pv) &= \text{pressure head difference between locations} \\ &\quad 1 \text{ and } 2 = (P_1 - P_2) v, \text{ ft (m)} \\ \Delta Z &= \text{head (elevation) difference between loca-} \\ &\quad \text{tions 1 and 2, ft (m)} \\ V &= \text{velocity at locations 1 and 2, ft/s (m/s)} \end{aligned}$$

When the approach velocity is approximately zero, Equation 22 in English units becomes:

$$V_2 = \sqrt{2gh} = 8.02\sqrt{h}, \text{ ft/s} \quad (23)$$

In this equation, h , in ft head of the flowing fluid, replaces $\Delta(Pv) + \Delta Z$. If the pressure difference is measured in psi, it must be converted to lb/ft² to obtain Pv in ft.

Pressure loss from fluid friction

So far, only pressure changes associated with the kinetic energy term, $V^2/2g_c$, and static pressure term, Z , have been discussed. These losses occur at constant flow where there are variations in flow channel cross-sectional area and where the inlet and outlet are at different elevations. Fluid friction and, in some cases heat transfer with the surroundings, also have important effects on pressure and velocity in a flowing fluid. The following discussion applies to fluids flowing in channels without a free surface.

When a fluid flows, molecular diffusion causes momentum interchanges between layers of the fluid that are moving at different velocities. These interchanges are not limited to individual molecules. In

most flow situations there are also bulk fluid interchanges known as eddy diffusion. The net result of all inelastic momentum exchanges is exhibited in shear stresses between adjacent layers of the fluid. If the fluid is contained in a flow channel, these stresses are eventually transmitted to the walls of the channel. To counterbalance this wall shear stress, a pressure gradient proportional to the bulk kinetic energy, $V^2/2g_c$, is established in the fluid in the direction of the bulk flow. The force balance is:

$$\pi \frac{D^2}{4} (dP) = \tau_w \pi D(dx) \quad (24)$$

where

$$\begin{aligned} D &= \text{tube diameter or hydraulic diameter } D_h \text{ ft (m)} \\ D_h &= 4 \times (\text{flow area})/(\text{wetted perimeter}) \text{ for circu-} \\ &\quad \text{lar or noncircular cross-sections, ft (m)} \\ dx &= \text{distance in direction of flow, ft (m)} \\ \tau_w &= \text{shear stress at the tube wall, lb/ft}^2 \text{ (N/m}^2\text{)} \end{aligned}$$

Solving Equation 24 for the pressure gradient (dP/dx):

$$\frac{dP}{dx} = \frac{4}{D} \tau_w \quad (25)$$

This pressure gradient along the length of the flow channel can be expressed in terms of a certain number of velocity heads, f , lost in a length of pipe equivalent to one tube diameter. The symbol f is called the friction factor, which has the following relationship to the shear stress at the tube wall:

$$\tau_w = \frac{f}{4} \frac{1}{v} \frac{V^2}{2g_c} \quad (26)$$

Equation 25 can be rewritten, substituting for τ_w from Equation 26 as follows:

$$\frac{dP}{dx} = \frac{4}{D} \left(\frac{f}{4} \frac{1}{v} \frac{V^2}{2g_c} \right) = \frac{f}{D} \frac{1}{v} \frac{V^2}{2g_c} \quad (27)$$

The general energy equation, Equation 13, expressed as a differential has the form:

$$du + \frac{VdV}{g_c} + d(Pv) = dQ - dW_k \quad (28a)$$

or

$$du + \frac{VdV}{g_c} + Pdv + vdP = dQ - dW_k \quad (28b)$$

Substituting Equation 26 of Chapter 2 ($du = Tds - Pdv$) in Equation 28 yields:

$$Tds + \frac{VdV}{g_c} + vdP = dQ - dW_k \quad (29)$$

The term Tds represents heat transferred to or from the surroundings, dQ , and any heat added internally to the fluid as the result of irreversible processes. These processes include fluid friction or any irrevers-

ible pressure losses resulting from fluid flow. (See Equation 29 and explanation, Chapter 2.) Therefore:

$$Tds = dQ + dQ_F \quad (30)$$

where dQ_F is the heat equivalent of fluid friction and any *local irrecoverable pressure losses* such as those from pipe fittings, bends, expansions or contractions.

Substituting Equation 30 into Equation 29, canceling dQ on both sides of the equation, setting dW_k equal to 0 (no shaft work), and rearranging Equation 29 results in:

$$dP = -\frac{VdV}{vg_c} - \frac{dQ_F}{v} \quad (31)$$

Three significant facts should be noted from Equation 31 and its derivation. First, the general energy equation does not accommodate pressure losses due to fluid friction or geometry changes. To accommodate these losses Equation 31 must be altered based on the first and second laws of thermodynamics (Chapter 2). Second, Equation 31 does not account for heat transfer except as it may change the specific volume, v , along the length of the flow channel. Third, there is also a pressure loss as the result of a velocity change. This loss is independent of any flow area change but is dependent on specific volume changes. The pressure loss is due to acceleration which is always present in compressible fluids. It is generally negligible in incompressible flow without heat transfer because friction heating has little effect on fluid temperature and the accompanying specific volume change.

Equation 27 contains no acceleration term and applies only to friction and local pressure losses. Therefore, dQ_F/v in Equation 31 is equivalent to dP of Equation 27, or:

$$\frac{dQ_F}{v} = f \frac{dx}{D} \frac{V^2}{v2g_c} \quad (32)$$

Substitution of Equation 32 into Equation 31 yields:

$$dP = -\frac{VdV}{vg_c} - f \frac{V^2}{D} \frac{dx}{v2g_c} \quad (33)$$

From Equation 5, the continuity equation permits definition of the mass flux, G , or mass velocity or mass flow rate per unit area [lb/h ft^2 ($\text{kg/m}^2 \text{ s}$)] as:

$$\frac{V}{v} = G = \text{constant} \quad (34)$$

Substituting Equation 34 into Equation 33 for a flow channel of constant area:

$$dP = -2 \frac{G^2}{2g_c} dv - f \frac{G^2}{2g_c} \frac{v}{D} dx \quad (35)$$

Integrating Equation 35 between points 1 and 2, located at $x = 0$ and $x = L$, respectively:

$$P_1 - P_2 = 2 \frac{G^2}{2g_c} (v_2 - v_1) + f \frac{G^2}{2g_c} \frac{1}{D} \int_0^L v dx \quad (36)$$

The second term on the right side of Equation 36 may be integrated provided a functional relationship between v and x can be established. For example, where the heat absorption rate over the length of the flow channel is constant, temperature T is approximately linear in x , or:

$$dx = \frac{L}{T_2 - T_1} dT \quad (37)$$

and

$$\int_0^L v dx = \frac{L}{T_2 - T_1} \int_1^2 v dT = Lv_{av} \quad (38)$$

The term v_{av} is an average specific volume with respect to temperature, T .

$$v_{av} = \phi (v_2 + v_1) = \phi v_1 (v_R + 1) \quad (39)$$

where

$$v_R = v_2/v_1$$

$$\phi = \text{averaging factor}$$

In most engineering evaluations, v is almost linear in T and $\phi \approx 1/2$. Combining Equations 36 and 37, and rewriting $v_2 - v_1$ as $v_1 (v_R - 1)$:

$$P_1 - P_2 = 2 \frac{G^2}{2g_c} v_1 (v_R - 1) + f \frac{L}{D} \frac{G^2}{2g_c} v_1 \phi (v_R + 1) \quad (40)$$

Equation 40 is completely general. It is valid for compressible and incompressible flow in pipes of constant cross-section as long as the function $T = F(x)$ can be assigned. The only limitation is that dP/dx is negative at every point along the pipe. Equation 33 can be solved for dP/dx making use of Equation 34 and the fact that $P_1 v_1$ can be considered equal to $P_2 v_2$ for adiabatic flow over a short section of tube length. The result is:

$$\frac{dP}{dx} = \frac{Pf/2D}{1 - \frac{g_c P v}{V^2}} \quad (41)$$

At any point where $V^2 = g_c P v$, the flow becomes choked because the pressure gradient is positive for velocities greater than $(g_c P v)^{0.5}$. The flow is essentially choked by excessive stream expansion due to the drop in pressure. The minimum downstream pressure that is effective in producing flow in a channel is:

$$P_2 = V^2/v_2 g_c = v_2 G^2/g_c \quad (42)$$

Dividing both sides of Equation 40 by $G^2 v_1 / 2g_c$, the pressure loss is expressed in terms of velocity heads. One velocity head equals:

$$\Delta P \text{ (one velocity head)} = \frac{V^2}{2g_c C v} = \frac{\rho V^2}{2g_c C} \quad (43)$$

where

$$\begin{aligned}\Delta P &= \text{pressure drop equal to one velocity head, lb/in.}^2 \text{ (N/m}^2\text{)} \\ V &= \text{velocity, ft/s (m/s)} \\ v &= \text{specific volume, ft}^3/\text{lb (m}^3/\text{kg)} \\ g_c &= 32.17 \text{ lbf ft/lbf s}^2 = 1 \text{ kg m/N s}^2 \\ C &= 144 \text{ in.}^2/\text{ft}^2 \text{ (1 m}^2/\text{m}^2\text{)} \\ \rho &= \text{density, lb/ft}^3 \text{ (kg/m}^3\text{)}\end{aligned}$$

In either case, f represents the number of velocity heads (N_{vh}) lost in each diameter length of pipe.

The dimensionless parameter defined by the pressure loss divided by twice Equation 43 is referred to as the Euler number:

$$Eu = \Delta P / (\rho V^2 / g_c) \quad (44)$$

where ρ is the density, or $1/v$.

Two other examples of integrating Equation 35 have wide applications in fluid flow. First, adiabatic flow through a pipe is considered. Both H and D are constant and $P_1 v_1^m = P_2 v_2^m$ where m is the exponent for constant enthalpy. Values of m for steam range from 0.98 to 1.0. Therefore, the assumption $Pv = \text{constant} = P_1 v_1$ is sufficiently accurate for pressure drop calculations. This process is sometimes called isothermal pressure drop because a constant temperature ideal gas expansion also requires a constant enthalpy. For $Pv = P_1 v_1$, the integration of Equation 35 reduces to:

$$\begin{aligned}P_1 - P_2 &= 2 \frac{G^2}{2g_c} \frac{2v_1 v_2}{v_1 + v_2} \ell n \left(\frac{v_2}{v_1} \right) \\ &+ f \frac{L}{D} \frac{G^2}{2g_c} \frac{2v_1 v_2}{v_1 + v_2}\end{aligned} \quad (45)$$

Neither P_2 nor v_2 are known in most cases, therefore Equation 45 is solved by iteration. Also, the term $2v_1 v_2 / (v_1 + v_2)$ can usually be replaced by the numerical average of the specific volumes — $v_{av} = 1/2 (v_1 + v_2)$ where $P_R = P_1/P_2 = v_2/v_1$. The maximum high side error at $P_R = 1.10$ is 0.22% and this increases to 1.3% at $P_R = 1.25$. It is common practice to use a numerical average for the specific volume in most fluid friction pressure drop calculations. However, where the lines are long, P_2 should be checked by Equation 42. Also, where heat transfer is taking place, P_2 is seldom constant along the flow channel and appropriate averaging factors should be used. Computation using small zone subdivisions along the length of the tube circuit is recommended to limit errors in widely varying property values.

The second important example considering flow under adiabatic conditions assumes an almost incompressible fluid, i.e., v_1 is approximately equal to v_2 . (See Equation 21.) Substituting v for v_1 and v_2 in Equation 45, the result is:

$$P_1 - P_2 = f \frac{L}{D} \frac{G^2}{2g_c} v \quad (46)$$

All terms in Equations 45 and 46 are expressed in consistent units. However, it is general practice and

often more convenient to use mixed units. For example, a useful form of Equation 46 in English units is:

$$\Delta P = f \frac{L}{D_e} v \left(\frac{G}{10^5} \right)^2 \quad (47)$$

where

$$\begin{aligned}\Delta P &= \text{fluid pressure drop, psi} \\ f &= \text{friction factor from Fig. 1, dimensionless} \\ L &= \text{length, ft} \\ D_e &= \text{equivalent diameter of flow channel, in. (note units)} \\ v &= \text{specific volume of fluid, ft}^3/\text{lb} \\ G &= \text{mass flux of fluid, lb/h ft}^2\end{aligned}$$

Friction factor

The friction factor (f) introduced in Equation 26, is defined as the dimensionless fluid friction loss in velocity heads per diameter length of pipe or equivalent diameter length of flow channel. Earlier correlators in this field, including Fanning, used a friction factor one fourth the magnitude indicated by Equation 26. This is because the shear stress at the wall is proportional to one fourth the velocity head. All references to f in this book combine the factor 4 in Equation 25 with f as has been done by Darcy, Blasius, Moody and others.

The friction factor is plotted in Fig. 1 as a function of the Reynolds number, a dimensionless group of variables defined as the ratio of inertial forces to viscous forces. The Reynolds number (Re) can be written:

$$Re = \frac{\rho V D_e}{\mu} \text{ or } \frac{V D_e}{\nu} \text{ or } \frac{G D_e}{\mu} \quad (48)$$

where

$$\begin{aligned}\rho &= \text{density of fluid, lbm/ft}^3 \text{ (kg/m}^3\text{)} \\ \nu &= \text{kinematic viscosity} = \mu / \rho, \text{ ft}^2/\text{h (m}^2/\text{s)} \\ \mu &= \text{viscosity of fluid, lbm/ft h (kg/m s)} \\ V &= \text{velocity of fluid, ft/h (m/s)} \\ G &= \text{mass flux of fluid, lb/h ft}^2 \text{ (kg/m}^2 \text{ s)} \\ D_e &= \text{equivalent diameter of flow channel, ft (m)}\end{aligned}$$

Fluid flow inside a closed channel occurs in a viscous or laminar manner at low velocity and in a turbulent manner at high velocities. Many experiments on fluid friction pressure drop, examined by dimensional analysis and the laws of similarity, have shown that the Reynolds number can be used to characterize a flow pattern. Examination of Fig. 1 shows that flow is laminar at Reynolds numbers less than 2000, generally turbulent at values exceeding 4000 and completely turbulent at higher values. Indeterminate conditions exist in the critical zone between Reynolds numbers of 2000 and 4000.

Fluid flow can be described by a system of simultaneous partial differential equations. (See earlier *Fundamental relationships* section.) However, due to the complexity of these equations, solutions are generally only available for the case of laminar flow, where the only momentum changes are on a molecular basis. For laminar flow, integration of the Navier-Stokes equa-

tion with velocity in the length direction only gives the following equation for friction factor:

$$f = 64/Re \quad (49)$$

The straight line in the laminar flow region of Fig. 1 is a plot of this equation.

It has been experimentally determined that the friction factor is best evaluated by using the Reynolds number to define the flow pattern. A factor ϵ/D_e is then introduced to define the relative roughness of the channel surface. The coefficient ϵ expresses the average height of roughness protrusions equivalent to the sand grain roughness established by Nikuradse.⁶ The friction factor values in Fig. 1 and the ϵ/D_e values in Fig. 2 are taken from experimental data as correlated by Moody.⁷

Laminar flow

Laminar flow is characterized by the parallel flowing of individual streams like layers sliding over each other. There is no mixing between the streams except for molecular diffusion from one layer to the other. A

small layer of fluid next to the boundary wall has zero velocity as a result of molecular adhesion forces. This establishes a velocity gradient normal to the main body of flow. Because the only interchanges of momentum in laminar flow are between the molecules of the fluid, the condition of the surface has no effect on the velocity gradient and therefore no effect on the friction factor. In commercial equipment, laminar flow is usually encountered only with more viscous liquids such as the heavier oils.

Turbulent flow

When turbulence exists, there are momentum interchanges between masses of fluid. These interchanges are induced through secondary velocities, irregular fluctuations or eddies, that are not parallel to the axis of the mean flow velocity. In this case, the condition of the boundary surface, roughness, does have an effect on the velocity gradient near the wall, which in turn affects the friction factor. Heat transfer is substantially greater with turbulent flow (Chapter 4) and, except for viscous liquids, it is common to induce turbulent flow with steam and water without

Fig. 1 Friction factor/Reynolds number relationship for determining pressure drop of fluids flowing through closed circuits (pipes and ducts).

excessive friction loss. Consequently, it is customary to design for Reynolds numbers above 4000 in steam generating units.

Turbulence fluctuations in the instantaneous velocity introduce additional terms to the momentum conservation equation called Reynolds stresses. These fluctuations influence the mean motion and increase the flow resistance in a manner producing an increase in the *apparent viscosity*. Analysis of turbulent flow must consider the impact of the fluctuating velocity component along with the mean flow velocity or resort to empirical methods that account for the additional momentum dissipation.^{4,6,8}

Velocity ranges

Table 1 lists the velocity ranges generally encountered in the heat transfer equipment as well as in duct and piping systems of steam generating units. These values, plus the specific volumes from the ASME Steam Tables (see Chapter 2) and the densities listed in Tables 2 and 3 in this chapter, are used to establish mass velocities for calculating Reynolds numbers and fluid friction pressure drops. In addition, values of viscosity, also required in calculating the Reynolds

number, are given in Figs. 3, 4 and 5 for selected liquids and gases. Table 4 lists the relationship between various units of viscosity.

Resistance to flow in valves and fittings

Pipelines and duct systems contain many valves and fittings. Unless the lines are used to transport fluids over long distances, as in the distribution of process steam at a factory or the cross country transmission of oil or gas, the straight runs of pipe or duct are relatively short. Water, steam, air and gas lines in a power plant have relatively short runs of straight pipe and many valves and fittings. Consequently, the flow resistance due to valves and fittings is a substantial part of the total resistance.

Methods for estimating the flow resistance in valves and fittings are less exact than those used in establishing the friction factor for straight pipes and ducts. In the latter, pressure drop is considered to be the result of the fluid shear stress at the boundary walls of the flow channel; this leads to relatively simple boundary value evaluations. On the other hand, pressure losses associated with valves, fittings and bends are mainly the result of impacts and inelastic exchanges

Fig. 2 Relative roughness of various conduit surfaces. (SI conversion: mm = 25.4 X in.)

Table 1
Velocities Common in Steam Generating Systems

Nature of Service	Velocity	
	ft/min	m/s
Air:		
Air heater	1000 to 5000	5.1 to 25.4
Coal and air lines, pulverized coal	3000 to 4500	15.2 to 22.9
Compressed air lines	1500 to 2000	7.6 to 10.2
Forced draft air ducts	1500 to 3600	7.6 to 18.3
Forced draft air ducts, entrance to burners	1500 to 2000	7.6 to 10.2
Ventilating ducts	1000 to 3000	5.1 to 15.2
Crude oil lines [6 to 30 in. (152 to 762 mm)]	60 to 3600	0.3 to 18.3
Flue gas:		
Air heater	1000 to 5000	5.1 to 25.4
Boiler gas passes	3000 to 6000	15.2 to 30.5
Induced draft flues and breaching	2000 to 3500	10.2 to 17.8
Stacks and chimneys	2000 to 5000	10.2 to 25.4
Natural gas lines (large interstate)	1000 to 1500	5.1 to 7.6
Steam:		
Steam lines		
High pressure	8000 to 12,000	40.6 to 61.0
Low pressure	12,000 to 15,000	61.0 to 76.2
Vacuum	20,000 to 40,000	101.6 to 203.2
Superheater tubes	2000 to 5000	10.2 to 25.4
Water:		
Boiler circulation	70 to 700	0.4 to 3.6
Economizer tubes	150 to 300	0.8 to 1.5
Pressurized water reactors		
Fuel assembly channels	400 to 1300	2.0 to 6.6
Reactor coolant piping	2400 to 3600	12.2 to 18.3
Water lines, general	500 to 750	2.5 to 3.8

Table 2
Physical Properties of Liquids at 14.7 psi (0.101 MPa)

Liquid	Temperature F (C)	Density lb/ft ³ (kg/m ³)	Specific Heat Btu/lb F (kJ/kg C)
Water	70 (21)	62.4 (999.4)	1.000 (4.187)

Mercury	70 (21)	846 (13,549)	0.033 (0.138)
Fuel oil, #6	70 (21)	60 to 65 (961 to 1041)	0.40 (1.67)
	180 (82)	60 to 65 (961 to 1041)	0.46 (1.93)
Kerosene	70 (21)	50 to 51 (801 to 817)	0.47 (1.97)

of momentum. These losses are frequently referred to as local losses or local nonrecoverable pressure losses. Even though momentum is conserved, kinetic energies are dissipated as heat. This means that pressure losses are influenced mainly by the geometries of valves, fittings and bends. As with turbulent friction factors, pressure losses are determined from empirical correlations of test data. These correlations may

be based on equivalent pipe lengths, but are preferably defined by a multiple of velocity heads based on the connecting pipe or tube sizes. Equivalent pipe length calculations have the disadvantage of being dependent on the relative roughness (ϵ/D) used in the correlation. Because there are many geometries of valves and fittings, it is customary to rely on manufacturers for pressure drop coefficients.

It is also customary for manufacturers to supply valve flow coefficients (C_v) for 60F (16C) water. These are expressed as ratios of weight or volume flow in the fully open position to the square root of the pressure drop. These coefficients can be used to relate velocity head losses to a connecting pipe size by the following expression:

$$N_v = kD^4/C_v^2 \quad (50)$$

Fig. 3 Absolute viscosities of some common liquids (Pa s = 0.000413 X lbm/ft h).

where

- N_v = number of velocity heads, dimensionless
- k = units conversion factor: for C_v based upon gal/min/ $(\Delta p)^{1/2}$, $k = 891$
- D = internal diameter of connecting pipe, in. (mm)
- C_v = flow coefficient in units compatible with k and D : for $k = 891$, $C_v = \text{gal/min}/(\Delta p)^{1/2}$

C_v and corresponding values of N_v for valves apply only to incompressible flow. However, they may be extrapolated for compressible condition using an average specific volume between P_1 and P_2 for ΔP values as high as 20% of P_1 . This corresponds to a maximum pressure ratio of 1.25. The ΔP process for valves, bends and fittings is approximately isothermal and does not require the most stringent limits set by Equation 21.

When pressure drop can be expressed as an equivalent number of velocity heads, it can be calculated by the following formula in English units:

$$\Delta P = N_v \frac{v}{12} \left(\frac{G}{10^5} \right)^2 \quad (51)$$

where

- ΔP = pressure drop, lb/in.²
- N_v = number of equivalent velocity heads, dimensionless
- v = specific volume, ft³/lb
- G = mass flux, lb/ft² h

Another convenient expression, in English units only, for pressure drop in air (or gas) flow evaluations is:

Fig. 4 Absolute viscosities of some common gases at atmospheric pressure.

$$\Delta P = N_v \frac{30}{B} \frac{T + 460}{1.73 \times 10^5} \left(\frac{G}{10^3} \right)^2 \quad (52)$$

where

- ΔP = pressure drop, in. wg
- B = barometric pressure, in. Hg
- T = air (or gas) temperature, F

Equation 52 is based on air, which has a specific volume of 25.2 ft³/lb at 1000R and a pressure equivalent to 30 in. Hg. This equation can be used for other gases by correcting for specific volume.

The range in pressure drop through an assortment of commercial fittings is given in Table 5. This resistance to flow is presented in equivalent velocity heads based on the internal diameter of the connecting pipe. As noted, pressure drop through fittings may also be expressed as the loss in equivalent lengths of straight pipe.

Contraction and enlargement irreversible pressure loss

The simplest sectional changes in a conduit are converging or diverging boundaries. Converging boundaries can stabilize flow during the change from pressure energy to kinetic energy, and local irrecoverable flow losses (inelastic momentum exchanges) can be practically eliminated with proper design. If the included angle of the converging boundaries is 30 deg (0.52 rad) or less and the terminal junctions are smooth and tangent, any losses in mechanical energy are largely due to fluid friction. It is necessary to consider this loss as 0.05 times the velocity head, based on the smaller downstream flow area.

Fig. 5 Absolute viscosities of saturated and superheated steam.

Table 5
Resistance to Flow of Fluids Through
Commercial Fittings*

Fitting	Loss in Velocity Heads
L-shaped, 90 deg (1.57 rad) standard sweep elbow	0.3 to 0.7
L-shaped, 90 deg (1.57 rad) long sweep elbow	0.2 to 0.5
T-shaped, flow through run	0.15 to 0.5
T-shaped, flow through 90 deg (1.57 rad) branch	0.6 to 1.6
Return bend, close	0.6 to 1.7
Gate valve, open	0.1 to 0.2
Check valve, open	2.0 to 10.0
Globe valve, open	5.0 to 16.0
Angle valve, 90 deg (1.57 rad) open	3.0 to 7.0
Boiler nonreturn valve, open	1.0 to 3.0

* See Fig. 9 for loss in velocity heads for flow of fluids through pipe bends.

When the elevation change ($Z_2 - Z_1$) is zero, the mechanical energy balance for converging boundaries becomes:

$$P_1 v + \frac{V_1^2}{2g_c} = P_2 v + \frac{V_2^2}{2g_c} + N_c \frac{V_2^2}{2g_c} \quad (53)$$

Subscripts 1 and 2 identify the upstream and downstream sections. N_c , the contraction loss factor, is the number of velocity heads lost by friction and local non-recoverable pressure loss in contraction. Fig. 6 shows values of this factor.

When there is an enlargement of the conduit section in the direction of flow, the expansion of the flow stream is proportional to the kinetic energy of the flowing fluid and is subject to a pressure loss depending on the geometry. Just as in the case of the contraction loss, this is an irreversible energy conversion to heat resulting from inelastic momentum exchanges. Because it is customary to show these losses as coefficients of the higher kinetic energy term, the mechanical energy balance for enlargement loss is:

$$P_1 v + \frac{V_1^2}{2g_c} = P_2 v + \frac{V_2^2}{2g_c} + N_e \frac{V_1^2}{2g_c} \quad (54)$$

The case of sudden enlargement [angle of divergence $\beta = 180$ deg (π rad)] yields an energy loss of $(V_1 - V_2)^2 / 2g_c$. This can also be expressed as:

$$N_e = \left(1 - \frac{A_1}{A_2}\right)^2 \quad (55)$$

where A_1 and A_2 are the upstream and downstream cross-sectional flow areas, respectively and ($A_1 < A_2$). Even this solution, based on the conservation laws, depends on qualifying assumptions regarding static

Fig. 6 Contraction loss factor for $\beta > 30$ deg ($N_c = 0.05$ for $\beta \leq 30$ deg).

pressures at the upstream and downstream faces of the enlargement.

Experimental values of the enlargement loss factor, based on different area ratios and angles of divergence, are given in Fig. 7. The differences in static pressures caused by sudden and gradual changes in section are shown graphically in Fig. 8. The pressure differences are shown in terms of the velocity head at the smaller area plotted against section area ratios.

Flow through bends

Bends in a pipeline or duct system produce pressure losses caused by both fluid friction and momentum exchanges which result from a change in flow direction. Because the axial length of the bend is normally included in the straight length friction loss of the pipeline or duct system, it is convenient to subtract a calculated equivalent straight length friction loss from experimentally determined bend pressure loss factors. These corrected data form the basis of the empirical bend loss factor, N_b .

The pressure losses for bends in round pipe in excess of straight pipe friction vary slightly with Reynolds numbers below 150,000. For Reynolds numbers above this value, they are reasonably constant and depend solely on the dimensionless ratio r/D , the ratio of the centerline radius of the bend to the internal diameter of the pipe. For commercial pipe, the effect of Reynolds number is negligible. The combined effect of radius ratio and bend angle, in terms of velocity heads, is shown in Fig. 9.

Flow through rectangular ducts

The loss of pressure caused by a direction change in a rectangular duct system is similar to that for cylindrical pipe. However, an additional factor, the shape

Fig. 7 Enlargement loss factor for various included angles.

Fig. 8 Static pressure difference resulting from sudden and gradual changes in section.

of the duct in relation to the direction of bend, must be taken into account. This is called the aspect ratio, which is defined as the ratio of the width to the depth of the duct, i.e., the ratio b/d in Fig. 10. The bend loss for the same radius ratio decreases as the aspect ratio increases, because of the smaller proportionate influence of secondary flows on the stream. The combined effect of radius and aspect ratios on 90 deg (1.57 rad) duct bends is given in terms of velocity heads in Fig. 10.

The loss factors shown in Fig. 10 are average values of test results on ducts. For the given range of aspect ratios, the losses are relatively independent of the Reynolds number. Outside this range, the variation with Reynolds number is erratic. It is therefore recommended that N_b values for $b/d = 0.5$ be used for all aspect ratios less than $b/d = 0.5$, and values for $b/d = 2.0$ be used for ratios greater than $b/d = 2.0$. Losses for bends other than 90 deg (1.57 rad) are customarily considered to be proportional to the bend angle.

Turning vanes

The losses in a rectangular elbow duct can be reduced by rounding or beveling its corners and by in-

Fig. 9 Bend loss for round pipe, in terms of velocity heads.

stalling turning vanes. With rounding or beveling, the overall size of the duct can become large; however, with turning vanes, the compact form of the duct is preserved.

A number of turning vane shapes can be used in a duct. Fig. 11 shows four different arrangements. Segmented shaped vanes are shown in Fig. 11a, simple curved thin vanes are shown in Fig. 11b, and concentric splitter vanes are shown in Fig. 11c. In Fig. 11c, the vanes are concentric with the radius of the duct. Fig. 11d illustrates simple vanes used to minimize flow separation from a square edged duct.

The turning vanes of identical shape and dimension, Fig. 11b, are usually mounted within the bend of an elbow. They are generally installed along a line or section of the duct and are placed from the inner corner to the outside corner of the bend. Concentric turning vanes, Fig. 11c, typically installed within the bend of the turn, are located from one end of the turn to the other end.

The purpose of the turning vanes in an elbow or turn is to deflect the flow around the bend to the inner wall of the duct. When the turning vanes are appropriately designed, the flow distribution is improved by reducing flow separation from the walls and reducing the formation of eddy zones in the downstream section of the bend. The velocity distribution over the downstream cross-section of the turn is improved (see Fig. 12), and the pressure loss of the turn or elbow is decreased.

The main factor in decreasing the pressure losses and obtaining equalization of the velocity field is the elimination of an eddy zone at the inner wall of the turn. For a uniform incoming flow field, the largest effect of decreasing the pressure losses and establishing a uniform outlet flow field for a turn or elbow is achieved by locating the turning vanes closer to the inner curvature of the bend. (See Figs. 11d and 12c.)

For applications requiring a uniform velocity distribution directly after the turn, a full complement or normal arrangement of turning vanes (see Fig. 12b) is required. However, for many applications, it is sufficient to use a reduced number of vanes, as shown in Fig. 12c.

For nonuniform flow fields, the arrangement of turning vanes is more difficult to determine. Many times, numerical modeling (see Chapter 6) and flow testing of the duct system must be done to determine the proper vane locations.

Fig. 10 Loss for 90 deg (1.57 rad) bends in rectangular ducts.

Fig. 11 Turning vanes in elbows and turns: a) segmented, b) thin concentric, c) concentric splitters, and d) slotted (adapted from Idelchik, Reference 12).

Pressure loss

A convenient chart for calculating the pressure loss resulting from impact losses in duct systems conveying air (or flue gas) is shown in Fig. 13. When mass flux and temperature are known, a base velocity head in inches of water at sea level can be obtained.

Flow over tube banks

Bare tube The transverse flow of gases across tube banks is an example of flow over repeated major cross-sectional changes. When the tubes are staggered, sectional and directional changes affect the resistance. Experimental results and the analytical conclusions of extensive research by The Babcock & Wilcox Company (B&W) indicate that three principal variables other than mass flux affect this resistance. The primary variable is the number of major restrictions, i.e., the number of tube rows crossed, N . The second variable is the friction factor f which is related to the Reynolds number (based on tube diameter), the tube spacing diameter ratios, and the arrangement pattern (in-line or staggered). The third variable is the depth factor, F_d (Fig. 14), which is applicable to banks less than ten rows deep. The friction factors f for various in-line tube patterns are given in Fig. 15.

The product of the friction factor, the number of major restrictions (tube rows) and the depth factor is, in effect, the summation of velocity head losses through the tube bank.

$$N_v = f N F_d \quad (56)$$

The N_v value established by Equation 56 may be used in Equations 51 or 52 to find the tube bank pressure loss. Some test correlations indicate f values higher than the isothermal case for cooling gas and lower for heating gas.

Finned tube In some convective boiler design applications, extended surface tube banks are used. Many types of extended surface exist, i.e., solid helical fin, serrated helical fin, longitudinal fin, square fin and different types of pin studs. For furnace applications, the cleanliness of the gas or heat transfer medium dictates whether an extended surface tube bank can be used and also defines the type of extended surface.

Fig. 12 Velocity profiles downstream of an elbow: a) without vanes, b) with typical vanes, and c) with optimum vanes (adapted from Idelchik, Reference 12).

Several different tube bank calculation methods exist for extended surface, and many are directly related to the type of extended surface that is used. Various correlations for extended surface pressure loss can be found in References 9 through 15. In all cases, a larger pressure loss per row of bank exists with an extended surface tube compared to a bare tube. For in-line tube bundles, the finned tube resistance per row of tubes is approximately 1.5 times that of the bare tube row. However, due to the increased heat transfer absorption of the extended surface, a smaller number of tube rows is required. This results in an overall bank pressure loss that can be equivalent to a larger but equally absorptive bare tube bank.

Flow through stacks or chimneys

The flow of gases through stacks or chimneys is established by the natural draft effect of the stack and/or the mechanical draft produced by a fan. The resistance to this flow, or the loss in mechanical energy be-

Fig. 13 Mass flux/velocity head relationship for air.

Fig. 14 Draft loss depth factor for number of tube rows crossed in convection banks.

tween the bottom and the top of the stack, is a result of the friction and stack exit losses. Application examples of these losses are given in Chapter 25.

Pressure loss in two-phase flow

Evaluation of two-phase steam-water flows is much more complex. As with single-phase flow, pressure loss occurs from wall friction, acceleration, and change in elevation. However, the relationships are more complicated. The evaluation of friction requires the assessment of the interaction of the steam and water phases. Acceleration is much more important because of the large changes in specific volume of the mixture as water is converted to steam. Finally, large changes in average mixture density at different locations significantly impact the static head. These factors are presented in detail in Chapter 5.

Entrainment by fluid flow

Collecting or transporting solid particles or a second fluid by the flow of a primary fluid at high velocity is known as entrainment. This is usually accomplished with jets using a small quantity of high pressure fluid to carry large quantities of another fluid or solid particles. The pressure energy of the high pressure fluid is converted into kinetic energy by nozzles, with a consequent reduction of pressure. The material to be transported is drawn in at the low pressure zone, where it meets and mixes with the high velocity jet. The jet is usually followed by a parallel throat section to equalize the velocity profile. The mixture then enters a diverging section where kinetic energy is partially reconverted into pressure energy. In this case, major fluid flow mechanical energy losses are an

example of inelastic momentum exchanges occurring within the fluid streams.

The *injector* is a jet pump that uses condensing steam as the driving fluid to entrain low pressure water for delivery against a back pressure higher than the pressure of the steam supplied. The *ejector*, similar to the injector, is designed to entrain gases, liquids, or mixtures of solids and liquids for delivery against a pressure less than that of the primary fluid. In a water-jet *aspirator*, water is used to entrain air to obtain a partial vacuum. In the Bunsen type burner, a jet of gas entrains air for combustion. In several instances, entrainment may be detrimental to the operation of steam boilers. Particles of ash entrained by the products of combustion, when deposited on heating surfaces, reduce thermal conductance, erode fan blades, and add to pollution when discharged into the atmosphere. Moisture carrying solids, either in suspension or in solution, are entrained in the stream. The solids may be carried through to the turbine and deposited on the blades, decreasing turbine capacity and efficiency. In downcomers or supply tubes, steam bubbles are entrained in the water when the drag on the bubbles is greater than the buoyant force. This reduces the density in the pumping column of natural circulation boilers.

Fig. 15 Friction factor (f) as affected by Reynolds number for various in-line tube patterns; crossflow gas or air.

Boiler circulation

An adequate flow of water and steam-water mixture is necessary for steam generation and control of tube metal temperatures in all circuits of a steam generating unit. At supercritical pressures this flow is produced mechanically by pumps. At subcritical pressures, circulation is produced by the force of gravity

or pumps, or a combination of the two. The elements of single-phase flow discussed in this chapter, two-phase flow discussed in Chapter 5, heat input rates, and selected limiting design criteria are combined to evaluate the circulation in fossil-fired steam generators. The evaluation procedures and key criteria are presented in Chapter 5.

Chapter 4

Heat Transfer

Heat transfer deals with the transmission of thermal energy and plays a central role in most energy conversion processes. Heat transfer is important in fossil fuel combustion, chemical reaction processes, electrical systems, nuclear fission and certain fluid systems. It also occurs during everyday activities including cooking, heating and refrigeration, as well as being an important consideration in choosing clothing for different climates.

Although the fundamentals of heat transfer are simple, practical applications are complex because real systems contain irregular geometries, combined modes of heat transfer and time dependent responses.

Fundamentals

Basic modes of heat transfer

There are three modes of heat transfer: conduction, convection and radiation. One or more of these modes controls the amount of heat transfer in all applications.

Conduction Temperature is a property that indicates the kinetic energy possessed by the molecules of a substance; the higher the temperature the greater the kinetic energy or molecular activity of the substance. Molecular conduction of heat is simply the transfer of energy due to a temperature difference between adjacent molecules in a solid, liquid or gas.

Conduction heat transfer is evaluated using Fourier's law:

$$q_c = -kA \frac{dT}{dx} \quad (1)$$

The flow of heat, q_c , is positive when the temperature gradient, dT/dx , is negative. This result, consistent with the second law of thermodynamics, indicates that heat flows in the direction of decreasing temperature. The heat flow, q_c , is in a direction normal (or perpendicular) to an area, A , and the gradient, dT/dx , is the change of temperature in the direction of heat flow. The thermal conductivity, k , a property of the material, quantifies its ability to conduct heat. A range of thermal conductivities is listed in Table 1. The discrete form of the conduction law is written:

$$q = \frac{kA}{L} (T_1 - T_2) \quad (2)$$

Fig. 1 illustrates positive heat flow described by this equation and shows the effect of variable thermal conductivity on the temperature distribution. The grouping kA/L is known as the thermal conductance, K_c ; the inverse L/kA is known as the thermal resistance, R_c and $K_c = 1/R_c$.

A special case of conduction is the thermal contact resistance across a joint between solid materials. At the interface of two solid materials the surface to surface contact is imperfect from the gap that prevails due to surface roughness. In nuclear applications with fuel pellets and fuel cladding, surface contact resistance can have a major impact on heat transfer. If one dimensional steady heat flow is assumed, the heat transfer across a gap is defined by:

$$q = \frac{T_1 - T_2}{R_{ct}} \quad (3)$$

where the quantity R_{ct} is called the thermal contact resistance, $1/h_{ct}A$, and h_{ct} is called the contact coefficient. T_1 and T_2 are the average surface temperatures on each side of the gap. Tabulated values of the contact coefficient are presented in References 1 and 2.

Table 1
Thermal Conductivity, k , of Common Materials

Material	Btu/h ft F	W/m C
Gases at atmospheric pressure	0.004 to 0.70	0.007 to 1.2
Insulating materials	0.01 to 0.12	0.02 to 0.21
Nonmetallic liquids	0.05 to 0.40	0.09 to 0.70
Nonmetallic solids (brick, stone, concrete)	0.02 to 1.5	0.04 to 2.6
Liquid metals	5.0 to 45	8.6 to 78
Alloys	8.0 to 70	14 to 121
Pure metals	30 to 240	52 to 415

Examples include 300 Btu/h ft² F (1.7 kW/m² K) between two sections of ground 304 stainless steel in air and 25,000 Btu/h ft² F (142 kW/m² K) between two sections of ground copper in air. The factors are usually unknown for specific applications and estimates need to be made. There are two principal contributions across the gap – solid to solid conduction at the points of contact and thermal conduction through the entrapped gases in the void spaces.

Convection Convection heat transfer within a fluid (gas or liquid) occurs by a combination of molecular conduction and macroscopic fluid motion. Convection occurs adjacent to heated surfaces as a result of fluid motion past the surface as shown in Fig. 2.

Natural convection occurs when the fluid motion is due to buoyancy effects caused by local density differences. In the top portion of Fig. 2, the fluid motion is due to heat flow from the surface to the fluid; the fluid density decreases causing the lighter fluid to rise and be replaced by cooler fluid. Forced convection results when mechanical forces from devices such as fans give motion to the fluids. The rate of heat transfer by convection, q_{cv} , is defined:

$$q_{cv} = hA(T_s - T_f) \quad (4)$$

where h is the local heat transfer coefficient, A is the surface area, T_s is the surface temperature and T_f is the fluid temperature. Equation 4 is known as Newton's Law of Cooling and the term hA_s is the convection conductance, K_{cv} . The heat transfer coefficient, h , is also termed the unit conductance, because it is defined as the conductance per unit area. Average heat transfer coefficients over a surface are used in most engineering applications. This convective heat transfer coefficient is a function of the thermal and

Fig. 2 Natural and forced convection. Above, boundary layer on a vertical flat plate. Below, velocity profiles for laminar and turbulent boundary layers in flow over a flat plate. (Vertical scale enlarged for clarity.)

fluid dynamic properties and the surface geometry. Approximate ranges are shown in Table 2.

Radiation Radiation is the transfer of energy between bodies by electromagnetic waves. This transfer, unlike conduction or convection, requires no intervening medium. The electromagnetic radiation, in the wavelength range of 0.1 to 100 micrometers, is produced solely by the temperature of a body. Energy at the body's surface is converted into electromagnetic waves that emanate from the surface and strike another body. Some of the thermal radiation is absorbed by the receiving body and reconverted into internal energy, while the remaining energy is reflected from or transmitted through the body. The fractions of radiation reflected, transmitted and absorbed by a surface are known respectively as the reflectivity, ρ , transmissivity, τ , and absorptivity α . The sum of these fractions equals one:

Table 2
Typical Convective Heat Transfer Coefficients, h

Condition	Btu/h ft ² F	W/m ² C
Air, free convection	1 to 5	6 to 30
Air, forced convection	5 to 50	30 to 300
Steam, forced convection	300 to 800	1800 to 4800
Oil, forced convection	5 to 300	30 to 1800
Water, forced convection	50 to 2000	300 to 12,000
Water, boiling	500 to 20,000	3000 to 120,000

Fig. 1 Temperature-thickness relationships corresponding to different thermal conductivities, k .

$$\rho + \tau + \alpha = 1 \quad (5)$$

All surfaces absorb radiation, and all surfaces whose temperatures are above absolute zero emit thermal radiation. Surfaces in boilers are typically opaque, which do not allow transmission of any radiation ($\tau = 0$).

Thermal radiation generally passes through gases such as dry air with no absorption taking place. These nonabsorbing, or nonparticipating, gases do not affect the radiative transfer. Other gases, like carbon dioxide, water vapor and carbon monoxide, to a lesser degree, affect radiative transfer and are known as participating gases. These gases, prevalent in the flue gases of a boiler, affect the heat transfer to surfaces and the distribution of energy absorbed in the boiler.

All bodies continuously emit radiant energy in amounts which are determined by the temperature and the nature of the surface. A perfect radiator, or *blackbody*, absorbs all of the incident thermal radiation, G , reaching its surface:

$$q_r^+ = A G \quad (6)$$

and emits radiant energy at the maximum theoretical limit according to the Stefan-Boltzmann law:

$$q_r^- = A \sigma T_s^4 \quad (7)$$

σ is the Stefan-Boltzmann constant 0.1713×10^{-8} Btu/h ft² R⁴ (5.669×10^{-8} W/m² K⁴), and T_s is the absolute temperature of the surface, R (K). The product σT_s^4 is also known as the blackbody emissive power, E_b . The net radiative heat transfer of a blackbody is the difference between absorbed and emitted radiant energy:

$$q_r = q_r^+ - q_r^- = A (G - \sigma T_s^4) \quad (8)$$

The radiation from a blackbody extends over the whole range of wavelengths, although the bulk of it in boiler applications is concentrated in a band from 0.1 to 20 micrometers. The wavelength at which the maximum radiation intensity occurs is inversely proportional to the absolute temperature of the body; this is known as Wien's law.

A real radiator absorbs less than 100% of the energy incident on it and emits less than the maximum theoretical limit. The net heat transfer by radiation from a real surface can be expressed by:

$$q_r = A (\alpha G - \varepsilon \sigma T_s^4) \quad (9)$$

where ε is the total emissivity and α is the total absorptivity. If the emissivity and absorptivity are independent of wavelength, the surface is termed a non-selective radiator, or *gray* surface. According to Kirchhoff's law, emissivity and absorptivity are always equal for a gray surface:

$$\varepsilon = \alpha \quad (10)$$

Therefore, α can be eliminated from Equation 9, and emissivity is all that is needed to describe the radiation properties of the surface. Table 3 shows some representative values of emissivity. If all surfaces are assumed to be gray, a simpler treatment of radiation is

Table 3
Representative Values of Emissivity

Polished metals	$0.01 < \varepsilon < 0.08$
Metals, as-received	$0.1 < \varepsilon < 0.2$
Metals oxidized	$0.25 < \varepsilon < 0.7$
Ceramic oxides	$0.4 < \varepsilon < 0.8$
Special paints	$0.9 < \varepsilon < 0.98+$

possible. For two surface enclosures, this treatment involves introducing a total exchange factor, \mathcal{F}_{12} , which depends on the configuration (geometry), the emissivities and the surface areas.³

If the emissivity depends on wavelength, the surface is termed a selective or non-gray radiator. According to Kirchhoff's law, spectral emissivity and spectral absorptivity are always equivalent, $\varepsilon_\lambda = \alpha_\lambda$, for non-gray surfaces. Total emissivity is the integrated average of ε_λ over the spectrum of emitted radiation, and total absorptivity is the integrated average of α_λ over the spectrum of incident radiation. The terms *emissivity* and *emittance* (and corresponding terms *absorptivity* and *absorptance*) are commonly interchanged in the literature. For convenience, the term *emittance* is used here for *total emissivity* and *absorptance* is used for *total absorptivity*, of non-gray surfaces.

For non-gray surfaces, the emittance can be expressed as a function of the surface temperature $\varepsilon(T_s)$, and absorptance as a function of the incident radiation or flame temperature, $\alpha(T_f)$. Based on Kirchhoff's law, plots of ε vs T_s may be interpreted as plots of α vs T_f if the physical state of the surface is unchanged. An analysis of non-gray conditions requires temperature dependent emittance and absorptance, or spectral property calculations which are more complicated. An example of non-gray radiators in a boiler are the ash deposits on waterwall heating surfaces.

The net radiation heat transfer between two blackbody surfaces which are separated by a vacuum or nonparticipating gas is written:

$$q_{12} = A_1 F_{12} \sigma (T_1^4 - T_2^4) \quad (11)$$

A_1 is the surface area; F_{12} is the geometric shape factor and represents the fraction of radiant energy leaving surface 1 that directly strikes surface 2. As will be discussed later for radiation between two surfaces, F_{12} is the exchange factor for two surfaces based on the geometric arrangement only, and \mathcal{F}_{12} is the exchange factor that includes the effects of emissivity for gray surfaces, and participating media between the surfaces. For blackbody surfaces ($\varepsilon_1 = \varepsilon_2 = 1$) and nonparticipating media, $\mathcal{F}_{12} = F_{12}$. T_1 and T_2 are the surface temperatures. Since the net energy at surface 1 must balance the net energy at surface 2, we can write:

$$q_{12} = -q_{21} \quad (12)$$

Using Equations 11 and 12, the following results:

$$A_1 F_{12} = A_2 F_{21} \quad (13)$$

This equation, known as the principle of reciprocity, guarantees conservation of the radiant heat transfer between two surfaces. The following rule applies to the surfaces of an enclosure:

$$\sum_j F_{ij} = 1 \quad (14)$$

stating that the total fraction of energy leaving surface i to all other (j) surfaces must equal 1. Many texts include the calculation of geometric shape factors, commonly named shape factors or configuration factors.^{1,2} Radiation balances for participating and nonparticipating media are presented later in the chapter.

Governing equations

Energy balances The solution of a heat transfer problem requires defining the system which will be analyzed. This usually involves idealizing the actual system by defining a schematic *control volume* of the modeled system. A net energy balance on the control volume reflects the first law of thermodynamics and can be stated:

$$\text{energy in} - \text{energy out} = \text{stored energy} \quad (15)$$

For a steady flow of heat, the balance simplifies to:

$$\text{heat in} = \text{heat out} \quad (16)$$

The laws governing the flow of heat are used to obtain equations in terms of material temperature or fluid enthalpy.

Steady-state conduction The basic laws for each heat transfer mode and the energy balance provide the tools needed to write the governing equations for rectangular and cylindrical heat transfer systems. For example, for the plane wall shown in Fig. 1, the steady flow energy balance for a slice of thickness, dx , is:

$$q_1 - q_2 = q - \left(q + \frac{dq}{dx} dx \right) = 0 \quad (17)$$

After substituting Equation 1, this is rewritten as:

$$\frac{d}{dx} \left(kA \frac{dT}{dx} \right) = 0 \quad (18)$$

The conditions at the boundaries, $T = T_1$ at $x = 0$ and $T = T_2$ at $x = L$, provide closure. The general symbolic form of the equation in three dimensions can be represented, vector notation:

$$\nabla \cdot (k \nabla T) = 0 \quad (19)$$

or in x, y, z Cartesian coordinates:

$$\frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(k \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(k \frac{\partial T}{\partial z} \right) = 0 \quad (20)$$

This assumes there is no net heat storage or heat generation in the wall.

Unsteady-state conduction So far only steady-state conduction, where temperatures vary from point to point but do not change with time, has been discussed. All unsteady-state conduction involves heat storage. For instance, in heating a furnace, enough heat must be supplied to bring the walls to the operating temperature and also to make up for the steady-state losses of normal operation. In large power boilers that run for long periods of time, heat storage in the walls and boiler metal is an insignificant fraction of the total heat input. In small boilers with refractory settings that are operated only part time, or in furnaces that are frequently heated and cooled in batch process work, heat stored in the walls during startup may be a considerable portion of the total heat input.

Unsteady-state conduction is important when equalizing boiler drum temperature during pressure raising and reducing periods. When boiler pressure is raised, the water temperature rises. The inner surface of the steam drum is heated by contact with the water below the water line and by the condensation of steam above the water line. The inside and outside drum temperatures are increased by unsteady-state conduction. During this transient heatup period, temperature differentials across the drum wall (or thermal gradients) will be larger than during steady-state operation. Larger thermal gradients result in higher thermal stresses as discussed in Chapter 8. The rate of temperature and pressure increase must therefore be controlled to maintain the thermal stresses within acceptable levels in order to protect the drum. During pressure reducing periods, the inside of the drum below the water line is cooled by boiler water while the top of the drum is cooled by radiation to the water, by the steam flow to the outlet connections, and by unsteady-state conduction through the drum walls.

Unsteady-state conduction occurs in heating or cooling processes where temperatures change with time. Examples include heating billets, quenching steel, operating regenerative heaters, raising boiler pressure, and heating and cooling steam turbines. By introducing time as an additional variable, conduction analyses become more complicated. For unsteady heat flow, the one dimensional thermal energy equation becomes:

$$\rho c_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) \quad (21)$$

The left side of the equation represents the rate of energy storage. The two boundary temperatures at $x = 0$ and L , and the initial temperature, $T = T^0$, are sufficient to find a solution. Other boundary conditions involving radiation, convection, or specified heat flux at $x = 0$ or L can also be applied.³

A general form of the energy equation for multi-dimensional applications is:

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) \quad (22)$$

where $\nabla \cdot (k \nabla T)$ is defined in Equations 19 and 20. Conditions on the boundary as a function of time, and initial temperature of the system, are sufficient to find a solution.

Electrical analogy The basic laws of conduction, convection and radiation can frequently be rearranged into equations of the form:

$$q = \frac{T_1 - T_2}{R_t} \quad (23)$$

This equation can be compared to Ohm's law for electrical circuits ($I = V/R$). The heat transfer or *heat flow* from point 1 to 2 (q) is analogous with current (I), the temperature difference ($T_1 - T_2$) is analogous with voltage (V), and the thermal resistance (R_t) is analogous with electrical resistance (R). Thermal resistance is defined as the reciprocal of thermal conductance, K_t . Table 4 contains analog thermal resistances used in many applications.

For systems with unsteady-state conduction governed by Equation 21 or 22, an electrical analogy can be written:

$$q = C_t \frac{dT}{dt} \quad (24)$$

where C_t is the thermal capacitance, $\rho c_p V$. This equation can be compared with its electrical equivalent:

$$I = C \frac{dV}{dt} \quad (25)$$

where C is the electrical capacitance. Kirchhoff's law for electrical circuits provides the last analogy needed. In heat transfer notation this would be:

$$\sum q = q_{\text{stored}} \quad (26)$$

Table 4
Summary of Thermal Resistances

	Rectangular Geometries and Surfaces	Cylindrical Geometries and Surfaces

Radiation, R_r from surface	$\frac{T_2 - T_3}{\mathcal{F}_{23} A_2 \sigma (T_2^4 - T_3^4)}$	$\frac{T_2 - T_3}{\mathcal{F}_{23} (2\pi r_2 l) \sigma (T_2^4 - T_3^4)}$

Fig. 3 Temperature distribution in composite wall with fluid films.

This is an expression of the first law of thermodynamics which states that all heat flows into a point equal the rate of energy storage.

Consider the composite system and the equivalent thermal circuit shown in Fig. 3. The concepts of resistance and conductance are particularly useful when more than one mode of heat transfer or more than one material or boundary is involved. When two modes of heat transfer, such as convection and radiation, occur simultaneously and independently, the combined conductance, K , is the sum of the individual conductances, K_{cv} and K_r . These individual conductances are essentially heat flows in parallel. When the heat flows are in series, the resistances, not the conductances, are additive. The total or equivalent thermal resistance can then be substituted into Equation 23 to calculate the total heat flow.

Flowing systems Boilers have complex distributions of flow, temperature and properties. In the basic example depicted in Fig. 4, there is steady flow into and out of the system, which is lumped into a single control volume. This leads to a balance of energy written as:

$$\dot{m}_1 H_1 + \dot{m}_2 H_2 + \dot{m}_3 H_3 = \dot{m}_4 H_4 \quad (27)$$

where \dot{m} is the mass flow rate at each inlet or outlet and H is the fluid enthalpy.

As discussed in Chapter 3, the full energy equation sets the net energy entering a system (from mass flow into and out of the system) equal to the internal heat generation, plus the work done by the system, plus energy conducted into the system, plus a viscous dissipation term (see Chapter 3, Equation 12). Viscous dissipation and work done in the boiler system can both usually be neglected. For steady-state conditions,

Fig. 4 Energy balance for a flowing system.

the energy equation in terms of fluid enthalpy and in vector notation can then be written as:

$$\underbrace{\nabla \cdot (\rho \vec{u} H)}_{\text{Convection}} = \underbrace{\nabla \cdot (\Gamma \nabla H)}_{\text{Conduction}} + \underbrace{S_H}_{\text{Internal heat generation}} \quad (28)$$

The parameter Γ is an effective diffusion coefficient that includes molecular diffusion and turbulent diffusion. S_H is internal heat generation per unit volume. Rearranging Equation 28 and replacing enthalpy with temperature ($dH = c_p dT$) the energy equation becomes:

$$\rho c_p \vec{u} \cdot \nabla T = \nabla \cdot (k_{eff} \nabla T) + S_H \quad (29)$$

The parameter $k_{eff} = c_p \Gamma$ is effective thermal conductivity. Using x, y, z Cartesian coordinates, the equation is expressed:

$$\rho c_p \left(u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} + w \frac{\partial T}{\partial z} \right) = \frac{\partial}{\partial x} \left(k_{eff} \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(k_{eff} \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(k_{eff} \frac{\partial T}{\partial z} \right) + S_H \quad (30)$$

In boiler applications, internal heat generation (S_H) includes radiation absorption and emission from participating gases, and heat release from combustion. The complete velocity field and thermal boundary conditions are necessary to find a solution to the fluid temperature field.

Equations 28 or 29 can be used with single phase flow or can be used with multiple phase flow (gas-solid or steam-water) by using mass averaged enthalpy or temperature. The development and application of the energy equation in rectangular, cylindrical and spherical coordinates are discussed in References 1 and 2.

Most boiler applications are too complex for an algebraic solution of the energy equation. However, the continuity and momentum equations discussed in Chapter 3 (Equations 3 to 10) are combined with the energy equation to form a fundamental part of the computational models discussed in Chapter 6. A numerical solution to this equation can then be readily achieved for many complex problems involving radiation and combustion.

Radiation balances for enclosures

Nonparticipating media Referring to Equation 11, the net radiation between two blackbody surfaces can be written:

$$q_{12} = A_1 F_{12} \sigma (T_1^4 - T_2^4) \quad (31)$$

The term F_{12} is the geometric shape factor and is shown for two common geometries in Fig. 5. Use of the tabulated values for more complex problems is demonstrated in the example problems under *Applications*. Equation 31 has limited value in boilers, because most fireside surfaces are not blackbodies. This equation is better used to obtain estimates of radiation heat transfer, because it describes the maximum theoretical rate of energy transfer between two surfaces.

For the theory of radiation heat transfer in enclosures, see Reference 4. The energy striking a surface, called the *incident energy*, G , is the total energy striking a surface from all other surfaces in the enclosure. The energy leaving a surface, called the *radiosity*, J , is comprised of the energy emitted from the surface (E_b)

Fig. 5 Shape factors, F_{ij} , for calculating surface-to-surface radiation heat transfer.

and the reflected incident energy. These terms are related by:

$$J = \varepsilon E_b + \rho G \quad (32)$$

The net radiation heat transfer from a surface is found as follows:

$$q = A(J - G) \quad (33)$$

Combining Equations 32 and 33 leads to the electrical analogy listed first in Table 5. This circuit equivalent describes the potential difference between the surface at an emissive power, evaluated at T_s , and the surface radiosity. To evaluate the radiative heat transfer, the radiosity must first be determined. The net energy between surface i and surface j is the difference between the outgoing radiosities:

$$q_{ij} = A_i F_{ij} (J_i - J_j) \quad (34)$$

The electrical analogy of the net exchange between two surfaces is listed in Table 5. The sum of similar terms for all surfaces in the enclosure yields the circuit diagram in the table and the equation:

$$q_i = \sum_{j=1}^N A_i F_{ij} (J_i - J_j) \quad (35)$$

The rules for electrical circuits are useful in finding the net radiation heat transfer. Consider the electrical circuit for radiation heat transfer between two gray walls shown in Fig. 6.

The rules for series circuits can be used to determine the net heat transfer:

$$q_{12} = \frac{E_{b2} - E_{b1}}{R_1 + R_2 + R_3} \quad (36)$$

Fig. 6 Electric circuit analogy for thermal radiation.

where

$$R_1 = \frac{1 - \varepsilon_1}{\varepsilon_1 A_1}, R_2 = \frac{1}{A_1 F_{12}}, R_3 = \frac{1 - \varepsilon_2}{\varepsilon_2 A_2}$$

Total radiation exchange factors for common two-surface geometries encountered in boiler design are listed in Table 6.

Participating media On the fire side of the boiler, the mixture of gases and particles absorbs, emits, and scatters radiant energy. When a uniform temperature-bounding surface encloses an isothermal gas volume, the radiant heat transfer can be treated as one zone, with absorption and emission from the participating gas mixture. The incident radiation on the surfaces is made up of the emitted energy from the gas, $\varepsilon_g E_{bg}$, and incoming energy from the surrounding walls, $(1 - \alpha_g) J_s$. Therefore, the incident radiation is defined by:

$$G_s = \varepsilon_g E_{bg} + (1 - \alpha_g) J_s \quad (37)$$

Table 5
Network Equivalents for Radiative Exchange in Enclosures with Gray Surfaces

Description	Circuit Equivalent	Resistance
Net exchange at surface		$R_i = \frac{1 - \varepsilon_i}{A_i \varepsilon_i}$

Net exchange between surface i and all other surfaces		$R_{ik} = \frac{1}{A_i F_{ik}}$

Table 6
Common Gray Two-Surface Enclosures

Large (Infinite) Parallel Planes

$$\begin{array}{l} A_1 = A_2 = A \\ \frac{A_1, T_1, \varepsilon_1}{A_2, T_2, \varepsilon_2} \quad F_{12} = 1 \end{array} \quad \mathcal{F}_{12} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}$$

Long (Infinite) Concentric Cylinders

$$\begin{array}{l} \text{Diagram of concentric cylinders with radii } r_1 \text{ and } r_2 \\ \frac{A_1}{A_2} = \frac{r_1}{r_2} \quad F_{12} = 1 \end{array} \quad \mathcal{F}_{12} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left[\frac{r_1}{r_2} \right]}$$

Concentric Spheres

$$\begin{array}{l} \text{Diagram of concentric spheres with radii } r_1 \text{ and } r_2 \\ \frac{A_1}{A_2} = \frac{r_1^2}{r_2^2} \quad F_{12} = 1 \end{array} \quad \mathcal{F}_{12} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left[\frac{r_1}{r_2} \right]^2}$$

Small Convex Object in a Large Cavity

$$\begin{array}{l} \text{Diagram of a small convex object in a large cavity} \\ \frac{A_1, T_1, \varepsilon_1}{A_2, T_2, \varepsilon_2} \quad F_{12} = 1 \end{array} \quad \mathcal{F}_{12} = \varepsilon_1$$

Note: The net heat flow is calculated from

$$q_{12} = \sigma A_1 \mathcal{F}_{12} (T_1^4 - T_2^4)$$

The energy leaving the surface is made up of direct emission, $\varepsilon_s E_{bs}$, and reflected incident energy, $(1 - \varepsilon_s) G_s$. Therefore, the radiosity is:

$$J_s = \varepsilon_s E_{bs} + (1 - \varepsilon_s) G_s \quad (38)$$

The solution of Equations 37 and 38 yields values for the incoming and the outgoing heat fluxes (q / A_s). The net heat transfer between the surface and gas becomes:

$$q_{sg} = J_s - G_s = \frac{A_s \varepsilon_s (\varepsilon_g E_{bg} - \alpha_g E_{bs})}{1 - (1 - \alpha_g)(1 - \varepsilon_s)} \quad (39)$$

The calculation of absorptivity is described in the examples at the end of the chapter. When the surfaces are radiatively black, $\varepsilon_s = 1$ and Equation 39 becomes:

$$q_{sg} = A_s (\varepsilon_g E_{bg} - \alpha_g E_{bs}) \quad (40)$$

The procedures presented here provide the basis for engineering estimates which are described with examples at the end of the chapter. However, boiler enclosure wall and gas temperatures generally vary from wall to wall and even from point to point. A multi-zone, three-dimensional numerical analysis is then required, because simple expressions of surface heat transfer and participating media can not be solved analytically.

Numerical analysis of radiation heat transfer in multi-dimensional applications with absorption, emission and scattering is routinely applied with commercially available computational fluid dynamics (CFD) software. This involves the solution of an integral-differential equation for radiation intensity as a function of position, direction, and wavelength. The radiative transport equation (RTE) accounts for loss in intensity by absorption and scattering and gain in intensity by emission and scattering. Boundary conditions are applied for absorption, emission, and reflection at the surface. Integration of the equation over the blackbody spectrum simplifies the transport equation by eliminating the dependence on wavelength. The RTE for total (spectrally integrated) radiation intensity uses total radiative properties for gases, particles, and surfaces.

Heat transfer properties and correlations

Thermal conductivity, specific heat and density

Thermal conductivity, k , is a material property that is expressed in Btu/h ft F (W/m K) and is dependent on the chemical composition and physical characteristics of the substance. The relative order of magnitude of values for various substances is shown in Table 7. Thermal conductivities are generally highest for solids, lower for liquids and lower yet for gases. Insulating materials have the lowest conductivities of solid materials.

Thermal conductivities of pure metals generally decrease with an increase in temperature, while alloy conductivities may either increase or decrease. (See Fig. 7.) Conductivities of several steels and alloys are shown in Table 7. Thermal conductivities of various

2. Reference temperature equals 32F (0C) except for steam which is referenced at 212F (100C).

refractory materials are shown in Chapter 23, Fig. 10. For many heat transfer calculations it is sufficiently accurate to assume a constant thermal conductivity that corresponds to the average temperature of the material.

The effective thermal conductivity of ash deposits on water wall heating surfaces varies widely depending on temperature, composition, heating cycle and physical characteristics of the deposits. The lower limit is close to the thermal conductivity of air or lower (0.03 Btu/h ft F or 0.05 W/m K), and the upper limit does not exceed values for refractory materials (1.4 Btu/h ft F or 2.4 W/m K). The effective thermal conductivity of a friable particulate layer is near the lower limit and is fairly independent of temperature below 1650 to 2200F (899 to 1204C) at which sintering usually occurs. Above this temperature, particles fuse together and thermal contact between particles increases, resulting in a sharp increase in thermal conductivity. The highest conductivity is achieved with complete melting. The physical changes caused by fusion and melting are irreversible upon cooling, and thermal conductivity of fused deposits decreases with decreasing temperature.

Fig. 7 Thermal conductivity, k , of some commonly used steels and alloys. (1 Btu/h ft F = 1.7307 W/m K)

Thermal conductance of ash deposits (k/x) is less sensitive to changing conditions than thermal conductivity. As the deposit grows in thickness (x), thermal conductivity (k) also increases due to fusion and slagging. The net effect is that unit thermal conductance may only vary by a factor of four, 25 to 100 Btu/h ft² F (142 to 568 W/m² C), while variations in thermal conductivity are an order of magnitude larger. The thermal effects of coal-ash deposits are further described by Wall et al.⁵

The thermal conductivity of water ranges from 0.33 Btu/h ft F (0.57 W/m K) at room temperature to 0.16 Btu/h ft F (0.28 W/m K) near the critical point. Water properties are relatively insensitive to pressure, particularly at pressures far from the critical point. Most other nonmetallic liquid thermal conductivities range from 0.05 to 0.15 Btu/h ft F (0.09 to 0.26 W/m K). In addition, thermal conductivities of most liquids decrease with temperature.

The thermal conductivities of gases increase with temperature and are independent of pressure at normal boiler conditions. These conductivities generally decrease with increasing molecular weight. The relatively high conductivity of hydrogen (a low molecular weight gas) makes it a good cooling medium for electric generators. The relatively low conductivity of argon (a high molecular weight gas) makes a good insulating medium for thermal pane windows.

When calculating the conductivity of nonhomogeneous materials, the designer must use an apparent thermal conductivity to account for the porous or layered construction materials. In boilers and furnaces with refractory walls, thermal conductivity may vary from site to site due to variations in structure, composition, density, or porosity when the materials were installed. The thermal conductivities of these materials are strongly dependent on their apparent bulk density (mass per unit volume). For higher temperature

insulations, the apparent thermal conductivity of fibrous insulations and insulating firebrick decreases as bulk density increases, because the denser material attenuates the radiation. However, an inflection occurs at some point at which a further increase in density increases the thermal conductivity due to conduction in the solid material.

Theory shows that specific heats of solids and liquids are generally independent of pressure. Table 7 lists specific heats of various metals, alloys and nonhomogeneous materials at 68F (20C). These values may be used at other temperatures without significant error.

The temperature dependence of the specific heat for gases is more pronounced than for solids and liquids. In boiler applications, pressure dependence may generally be neglected. Tables 8a and 8b give specific heat data for air and other gases.

In the case of steam and water, property variations (specific heat and thermal conductivity) can be significant over the ranges of temperature and pressure found in boilers. It is therefore recommended that the properties as compiled in the American Society of Mechanical Engineers (ASME) Steam Tables⁶ be used.

Radiation properties

Bodies that are good radiation absorbers are equally good emitters and Kirchhoff's law states that, for gray surfaces at thermal equilibrium, their emissivities are equal to their absorptivities. A *blackbody* is one which absorbs all incident radiant energy while reflecting or transmitting none of it. The absorptivity and emissivity of a blackbody are, by definition, each equal to one. This terminology does not necessarily mean that the body appears to be black. Snow, for instance, absorbs only a small portion of the incident visible light, but to the longer wavelengths (the bulk of thermal radiation), snow is almost a blackbody. At a temperature of 2000F (1093C) a blackbody glows brightly, because a non-negligible part of its radiation is in the visible range. Bodies are never completely black, but a hole through the wall of a large enclosure can be used to approximate blackbody conditions, because radiation entering the hole undergoes multiple reflections and absorptions. As a result, most of the radiation is retained in the enclosure, and surfaces are treated as gray.

Fortunately, a number of commercial surfaces, particularly at high temperatures, have emissivities of 0.80 to 0.95 and behave much like blackbodies. Typical average emissivity values are noted in Table 9. Although emissivity depends on the surface composition and roughness and wavelength of radiation, the wavelength dependence is often neglected in practical boiler calculations and surfaces are treated as gray.

Ash deposits The emittance and thermal properties of furnace ash deposits have a large effect on boiler heat transfer. The emittance depends on the temperature, chemical composition, structure and porosity of the particulate layer, and whether deposits are partially fused or molten. The same ash at different locations within the same boiler (or the same location in different boilers) may have significantly different values of surface emittance. Reported values in the

literature claim emittances between 0.5 and 0.9 for most ash and slag deposits.

The effect of coal ash composition, structure, and temperature on deposit emittance^{5,7} is shown in Fig. 8. A friable particulate material has low emittance because radiation is scattered (and reflected) from individual particles and does not penetrate beyond a thin layer (~1 mm) near the surface. Emittance of friable ash deposits decreases with increasing surface temperature, until sintering and fusion changes the structure of the deposit. A sharp increase in emittance is associated with ash fusion as particles grow together (pores close) and there are fewer internal surfaces to scatter radiation. Completely molten ash or slag is partially transparent to radiation, and emittance may depend upon substrate conditions. The emittance of completely fused deposits (molten or frozen slag) on oxidized carbon steel is about 0.9. Emittance increases

Iron	0.24	68	Fresh emiered
Iron oxide	0.85 to 0.89	930 to 2190	
Steel	0.79	390 to 1110	Oxidized at 1100F
Steel	0.66	70	Rolled sheet
Steel	0.28	2910 to 3270	Molten
Steel (Cr-Ni)	0.44 to 0.36	420 to 914	18-8 rough, after heating
Steel (Cr-Ni)	0.90 to 0.97	420 to 980	25-20 oxidized in service
Brick, red	0.93	70	Rough
Brick, fireclay	0.75	1832	
Carbon, lamp-black	0.945	100 to 700	0.003 in. or thicker
Water	0.95 to 0.963	32 to 212	

Note:
1. SI conversion: $T(C) = [T(F) - 32]/1.8$; 1 in. = 25.4 mm.

with increasing particle size of friable particulate deposits (Fig. 8a), because larger particles have less capacity to back-scatter incident radiation. Emittance increases with increasing iron oxide (Fe_2O_3) and unburned carbon content of the ash (Fig. 8b) because these components have a greater capacity to absorb radiation. Low emittance of some lignitic ash deposits, known as reflective ash, may be attributed to low Fe_2O_3 content, although this alone is not a reliable indicator of a reflective ash. Emittance is also indirectly dependent upon oxidizing and reducing environment of the flue gas, due to the effect on the melting characteristics and unburned carbon content in the ash. The thermal and radiative effects of coal-ash deposits are further described by Wall et al.⁵

Combustion gases Although many gases, such as oxygen and nitrogen, absorb or emit only insignificant amounts of radiation, others, such as water vapor, carbon dioxide, sulfur dioxide and carbon monoxide, substantially absorb and emit. Water vapor and carbon dioxide are important in boiler calculations because of their presence in the combustion products of hydrocarbon fuels. These gases are selective radiators. They emit and absorb radiation only in certain bands (wavelengths) of the spectrum that lie outside of the visible range and are consequently identified as nonluminous radiators. Whereas the radiation from a furnace wall is a surface phenomenon, a gas radiates and absorbs (within its absorption bands) at every point throughout the furnace. Furthermore, the emissivity of a gas changes with temperature, and the presence of one radiating gas may have characteris-

Fig. 8 Effect of coal ash composition, structure and temperature on deposit emittance.^{5,7}

tics that overlap with the radiating characteristics of another gas when they are mixed. The energy emitted by a radiating gaseous mixture depends on gas temperature, the partial pressures, p , of the constituents and a beam length, L , that depends on the shape and dimensions of the gas volume. An estimate of the mean beam length is $L = 3.6 V/A$ for radiative transfer from the gas to the surface of the enclosure, where V is the enclosure volume and A is the enclosure surface area. The factor 3.6 is approximate, and values between 3.4 to 3.8 have been recommended depending on the actual geometry.⁴

Figs. 9 and 10 show the emissivity for water vapor and carbon dioxide.⁸ The accuracy of these charts has gained greater acceptance than the more widely known charts of Hottel,⁴ particularly at high temperatures and short path lengths. The effective emissivity of a water vapor-carbon dioxide mixture is calculated as follows:

$$\epsilon = \epsilon_{\text{H}_2\text{O}} + \epsilon_{\text{CO}_2} - \Delta\epsilon \quad (41)$$

where $\Delta\epsilon$ is a correction factor that accounts for the effect of overlapping spectral bands. This equation neglects pressure corrections and considers boilers operating at approximately 1 atm. The factors shown in Fig. 11 depend on temperature, the partial pressures, p , of the constituents and the beam length, L . The presence of carbon monoxide and sulfur dioxide can typically be neglected in combustion products, because CO and SO_2 are weakly participating and overlap with the infrared spectrum of H_2O and CO_2 .

When using Figs. 9 to 11 to evaluate absorptivity, α , of a gas, Hottel⁴ recommends modification of the pL product by a surface to gas temperature ratio. This is illustrated in Example 6 at the end of this chapter.

Fig. 9 Emissivity of water vapor at one atmosphere total pressure: $p_w L$ = partial pressure in atmospheres \times mean beam length in feet.⁸ (1 bar-cm = 0.0324 ft-atm; $T(F) = [T(C) \times 1.8] + 32$)

Radiation properties of gases can be calculated more accurately based on fundamental models for spectral gas radiation. The exponential wide band model⁹ predicts spectral absorption and emission properties of single and multi-component gases including H_2O , CO_2 , CO , CH_4 , NO , and SO_2 as a function of temperature and pressure. Diatomic gases N_2 , O_2 and H_2 may contribute to the total gas volume and pressure of the mixture, but are considered transparent to infrared radiation. Radiation properties are conveniently expressed as emission and absorption coefficients that depend on local variations in gas composition, temperature, and pressure. This approach is suitable for numerical modeling of radiation with participating media, which requires frequent evaluation of gas properties at a large number of control volumes.

Entrained particles Combustion usually involves some form of particulate that is entrained in combustion gases. Particles are introduced as the fuel which undergo transformations of combustion and/or are formed by the processes of condensation and agglomeration of aerosol particles. Entrained particles have a significant role in radiation heat transfer because they absorb, emit, and scatter radiation. Scattering effectively extends the beam length of radiation in an enclosure, because the beam changes direction many times before it reaches a wall. Radiation from entrained particles depends on the particle shape, size distribution, chemical composition, concentration, temperature, and the wavelength of incident radiation.

Particulates in boilers are comprised of unreacted fuel (coal, oil, black liquor), char, ash, soot, and other aerosols. Soot is an example of an aerosol that con-

Fig.10 Emissivity of carbon dioxide at one atmosphere total pressure: $p_c L$ = partial pressure in atmospheres \times mean beam length in feet.⁸ (1 bar-cm = 0.0324 ft-atm; $T(F) = [T(C) \times 1.8] + 32$)

Fig. 11 Radiation heat transfer correction factor associated with mixtures of water vapor and carbon dioxide.⁸ (1 bar-cm = 0.0324 ft-atm)

tributes to radiation from gas flames in boilers. Neglecting the effect of soot on radiation heat transfer in the flame could lead to significant errors in the calculated flame temperature, and radiation heat transfer to the furnace walls in the flame zone. Ash is an example of particulate that contributes to radiation in coal-fired boilers. Scattering by ash particles effectively redistributes radiation in the furnace, and smooths out variations in radiation heat flux, analogous to the way a cloud distributes solar radiation on the earth. The absorption and emission characteristics of flyash particles increase, and scattering decreases with the relative amount of iron oxide or residual carbon, which acts as a coloring agent in the ash.

Analytical methods such as Equation 39 that depend upon emissivity and absorptivity of the participating media are inaccurate when particles other than soot are involved, because the effects of scattering are neglected. Numerical methods which solve the general form of the radiative transport equation include the effects of scattering (see *Numerical methods*).

Mie Theory¹⁰ is a general method for calculating the radiation properties of spherical particles as a function of particle composition, concentration, diameter and wavelength. Rigorous calculations by this method can only be performed with the aid of a computer and require that optical properties (complex refractive index as a function of wavelength) of the particle materials are known. The complex refractive index of lignite, bituminous, and anthracite coals, and corresponding properties of char and ash have been measured, as well as other materials that are typically encountered in combustion systems. Radiation properties of particles are conveniently expressed as total emission, absorption, and scattering efficiencies that depend on particle composition, diameter and temperature. Particle properties must be combined with gas properties in an analysis of radiation with participating media.

Working formulas for convection heat transfer

Heat transfer by convection between a fluid (gas or liquid) and a solid is expressed by Equation 4. This equation is a definition of the heat transfer coefficient but is inadequate in describing the details of the convective mechanisms. Only a comprehensive study of the flow and heat transfer would define the dependence of the heat transfer coefficient along the surface. In the literature, simple geometries have been modeled and predictions agree well with experimental data. However, for the more complex geometries encountered in boiler analysis, correlations are used that have been developed principally from experimental data.

Convective heat transfer near a surface takes place by a combination of conduction and mass transport. In the case of heat flowing from a heated surface to a cooler fluid, heat flows from the solid first by conduction into a fluid element, raising its internal energy. The heated element then moves to a cooler zone where heat flows from it by conduction to the cooler surrounding fluid.

Fluid motion can occur in two ways. If the fluid is set in motion due to density differences arising from

temperature variations, free or natural convection occurs. If the motion is externally induced by a pump or fan, the process is referred to as forced convection.

Convective heat transfer can occur in laminar or turbulent flows. For laminar flow, the fluid moves in layers, or lamina, with each element following an orderly path. In turbulent flow, prevalent in boiler passages, the local motion of the fluid is chaotic and statistical treatment is used to establish average velocity and heat transfer values.

Experimental studies have confirmed that a flow field can be divided into two zones: a viscous zone adjacent to the surface and a nonviscous zone removed from the heat transfer surface. The viscous, heated zone is termed the boundary layer region. The hydrodynamic boundary layer is defined as the distance from the wall at which the local velocity reaches 99% of the velocity far from the wall.

At the entrance of a pipe or duct, the boundary layer begins to grow; this flow portion is called the developing region. Downstream, when the viscous region fills the pipe core or grows to a maximum, the flow is termed fully developed. Developing region heat transfer coefficients are larger than the fully developed values. In many applications it is sufficient to assume that the hydrodynamic and thermal boundary layers start to grow at the same location, although this is not always the case.

Flow over a body (around a circular cylinder) is termed external flow, while flow inside a confined region, like a pipe or duct, is termed internal flow.

Natural or free convection

A fluid at rest, exposed to a heated surface, will be at a higher temperature and lower density than the surrounding fluid. The differences in density, because of this difference in temperature, cause the lighter, warmer fluid elements to circulate and carry the heat elsewhere. The complex relationships governing this type of convective heat transfer are covered extensively in other texts.¹ Experimental studies have confirmed that the main dimensionless parameters governing free convection are the Grashof and Prandtl numbers:

$$\text{Gr} = \frac{g \beta (T_s - T_\infty) \rho^2 L^3}{\mu^2} \quad (42)$$

$$\text{Pr} = \frac{c_p \mu}{k} \quad (43)$$

The Grashof number is a ratio of the buoyant to viscous forces. The Prandtl number is the ratio of the diffusion of momentum and heat in the fluid. The product, Gr Pr, is also called the Rayleigh number, Ra.

In boiler system designs, air and flue gases are the important free convection heat transfer media. For these designs, the equation for the convective heat transfer coefficient h is:

$$h = C (T_s - T_\infty)^{1/3} \quad (44)$$

This correlation is applicable when the Rayleigh number, Ra, is greater than 10^9 , which is generally recog-

nized as the transition between laminar and turbulent flow. Values of the constant C in the equation are listed below:

Geometry	$\frac{\text{Btu}}{\text{h ft}^2 \text{ F}^{4/3}}$	$\frac{\text{W}}{\text{m}^2 \text{ K}^{4/3}}$
Horizontal plate facing upward	0.22	1.52
Vertical plates or pipes more than 1 ft (0.3 m) high	0.19	1.31
Horizontal pipes	0.18	1.24

The correlation generally produces convective heat transfer coefficients in the range of 1 to 5 Btu/h ft² F (5.68 to 28.39 W/m² K).

Forced convection

Dimensionless numbers Forced convection implies the use of a fan, pump or natural draft stack to induce fluid motion. Studies of many heat transfer systems and numerical simulation of some simple geometries confirm that fluid flow and heat transfer data may be correlated by dimensionless numbers. Using these principles, scale models enable designers to predict field performance. For simple geometries, a minimum of dimensionless numbers is needed for modeling. More complex scaling requires more dimensionless groups to predict unit performance.

The Reynolds number is used to correlate flow and heat transfer in closed conduits. It is defined as:

$$\text{Re} = \frac{\rho V L}{\mu} = \frac{GL}{\mu} \quad (45)$$

where L is a characteristic length of the conduit or an obstacle in the flow field. This dimensionless group represents the ratio of inertial to viscous forces.

The Reynolds number is only valid for a continuous fluid filling the conduit. The use of this parameter generally assumes that gravitational and intermolecular forces are negligible compared to inertial and viscous forces.

The characteristic length, termed equivalent hydraulic diameter, is different for circular and noncircular conduits. For circular conduits, the inside diameter (ID) is used. For noncircular ducts, the equivalent diameter becomes:

$$D_e = 4 \times \frac{\text{Flow cross-sectional area}}{\text{Wetted perimeter}} \quad (46)$$

This approach, used to compare dynamically similar fluids in geometrically similar conduits of different size, yields equal Reynolds numbers for the flows considered.

At low velocities, the viscous forces are strong and laminar flow predominates, while at higher velocities, the inertial forces dominate and there is turbulent flow. In closed conduits, such as pipes and ducts, the transition to turbulent flow occurs near $\text{Re} = 2000$. The generally accepted range for transition to turbulent flow under common tube flow conditions is $2000 < \text{Re} < 4000$.

For fluid flow over a flat external surface, the characteristic length for the Reynolds number is the surface length in the direction of the flow, x . Transition

to turbulence is generally considered for $\text{Re} \geq 10^5$. In the case of flow over a tube, the outside diameter (OD), D , is the characteristic length. In tube bundles with crossflow, transition generally occurs at $\text{Re} > 100$.

Experimental studies have confirmed that the convective heat transfer coefficient can be functionally characterized by the following dimensionless groups:

$$\text{Nu} = f(\text{Re}, \text{Pr}) \quad (47)$$

where Nu is the Nusselt number, Re is the Reynolds number and Pr is the Prandtl number.

The Nusselt number, a ratio of the wall temperature gradient to reference gradients, is defined as follows:

$$\text{Nu} = \frac{hL}{k} \quad (48)$$

The previously discussed Prandtl number, representing a ratio of the diffusion of momentum and heat in the fluid, is also the ratio of the relative thickness of viscous and thermal boundary layers. For air and flue gases, $\text{Pr} < 1.0$ and the thermal boundary layer is thicker than the viscous boundary layer.

In the literature, correlations are also presented using other dimensionless groups; the Peclet and Stanton numbers are the most common. The Peclet number is defined as follows:

$$\text{Pe} = \text{Re Pr} \quad (49)$$

The Stanton number is defined in terms of the Nusselt, Reynolds and Prandtl numbers:

$$\text{St} = \frac{\text{Nu}}{\text{Re Pr}} \quad (50)$$

Laminar flow inside tubes For heating or cooling of viscous fluids in horizontal or vertical tubes with constant surface temperature and laminar flow conditions ($\text{Re} < 2300$), the heat transfer coefficient, or film conductance, can be determined by the following equation:¹¹

$$\text{Nu} = 1.86 \left(\text{Re Pr} \frac{D}{L} \right)^{1/3} \left(\frac{\mu_b}{\mu_w} \right)^{0.14} \quad (51)$$

or

$$h = 1.86 \frac{k_b}{D} \left(\frac{GD}{\mu} \frac{c_p \mu}{k} \frac{D}{L} \right)_b^{1/3} \left(\frac{\mu_b}{\mu_w} \right)^{0.14} \quad (52)$$

where the parameter $G = \rho V$ is defined as the mass flux or mass flow rate per unit area and tube diameter, D , is the characteristic length used in the evaluation of the Reynolds number. The ratio of viscosities (μ_b/μ_w) is a correction factor that accounts for temperature dependent fluid properties. Properties in Equations 51 and 52 are evaluated at an average bulk fluid temperature, except μ_w which is evaluated at the wall temperature.

For low viscosity fluids, such as water and gases, a more complex equation is required to account for the effects of natural convection at the heat transfer sur-

face. This refinement is of little interest in industrial practice because water and gases in laminar flow are rarely encountered.

Turbulent flow Studies of turbulent flow indicate several well defined regions as shown in Fig. 12. Next to the heat transfer surface is a very thin laminar flow region, less than 0.2% of the characteristic length, where the heat flow to or from the surface is by molecular conduction. The next zone, known as the buffer layer, is less than 1% of the characteristic length and is a mixture of laminar and turbulent flow. Here the heat is transferred by a combination of convection and conduction. In the turbulent core, which comprises roughly 98% of the cross-section, heat is transferred mainly by convection.

In turbulent flow, the local but chaotic motion of the fluid causes axial and radial motion of fluid elements. This combination of motions sets up eddies, or local swirling motions, augmenting the heat transfer from the core to the laminar sublayer. The laminar flow in the sublayer and the laminar component in the buffer layer act as a barrier, or film, to the heat transfer process. Increasing the fluid velocity has been found to decrease this film thickness, reducing the resistance to heat transfer.

Turbulent flow in tubes The distance required to obtain hydrodynamically and thermally fully developed turbulent flow is shorter than that for laminar flow. The flow length needed to achieve hydrodynamically fully developed conditions is variable and depends upon the specific Reynolds number (operating conditions) and surface geometry. It typically varies from 6 to 20 diameters (x/D). Fully developed thermal flow for gases and air, important in boiler analysis, occurs at similar x/D ratios. However, for liquids, the ratio is somewhat higher and increases with the Prandtl number.

Extensive research data using low viscosity gases and liquids have been correlated. The following equation¹² is recommended for fully developed flow with small to moderate temperature differences:

$$Nu_{fd} = 0.023 Re^{0.8} Pr^n \quad (53)$$

with $n = 0.4$ for heating of the fluid and $n = 0.3$ for cooling of the fluid, and properties evaluated at the bulk temperature. Equation 53 applies to gases and liquids in the range $0.7 < Pr < 160$, which covers all fluids in boiler analysis. If the conditions are not fully developed, the correlation is corrected as shown below:¹³

$$Nu = Nu_{fd} \left[1 + (D/x)^{0.7} \right] \quad (54)$$

Fig. 12 Structure of turbulent flow field near a solid boundary.

with the stipulation that $2 \leq x/D \leq 20$. These correlations should only be used for small to moderate temperature differences.

A correlation by Seider and Tate¹¹ is widely used for heating or cooling of a fluid and larger temperature differences. All of the properties are evaluated at the bulk temperature, except μ_w which is evaluated at the wall temperature:

$$Nu_{fd} = 0.027 Re^{0.8} Pr^{1/3} \left(\frac{\mu_b}{\mu_w} \right)^{0.14} \quad (55)$$

The foregoing correlations may be applied for both constant surface temperature and heat flux conditions to a good approximation.

For boiler applications involving turbulent flow in tubes, Equation 53 is rewritten with the temperature ratio added to convert the properties from a bulk to film temperature basis:

$$Nu_{fd} = 0.023 Re_f^{0.8} Pr_f^{0.4} \left(\frac{T_b}{T_f} \right)^{0.8} \quad (56)$$

All properties are evaluated at the film temperature (T_f), which is defined as the arithmetic mean temperature between the wall temperature (T_w) and the bulk fluid temperature (T_b): $T_f = (T_w + T_b)/2$ with all temperatures in absolute units (R or K). Equation 56 is rewritten using parametric groupings:

$$h_l = \left[0.023 \frac{G^{0.8}}{D_e^{0.2}} \right] \left[\frac{c_p^{0.4} k^{0.6}}{\mu^{0.4}} \right]_f \left[\frac{T_b}{T_f} \right]^{0.8} \quad (57)$$

which can be expressed in the form:

$$h_l = h'_l F_{pp} F_T \quad (58)$$

Figs. 13 to 17 display the various factors that make up the right side of Equation 58. Unlike non-dimensional parameters (Nu , Re , Pr), these terms do not have any physical significance and are dependent upon the choice of engineering units. The physical properties factor, F_{pp} , combines all of the properties of the fluid into one term, and is evaluated at the gas film temperature for a particular fluid (gas, air or steam). Note that if F_{pp} for steam can not be obtained from Fig. 16, it can be calculated with values of c_p , k and μ evaluated at the film temperature from the ASME Steam Tables.⁶

Turbulent cross flow around tubes The most important boiler application of convection is heat transfer from the combustion gases to the tubular surfaces in the convection passes. Perhaps the most complete and authoritative research on heat transfer of tubes in crossflow was completed in an extensive program conducted by The Babcock & Wilcox Company (B&W).¹⁴ The following correlation was adapted from this study for different fluids:

Fig. 13 Basic convection velocity and geometry factor, h'_i , for air, gas or steam; turbulent flow inside tubes or longitudinal flow over tubes (English units only).

$$Nu = 0.321 Re_f^{0.61} Pr_f^{0.33} F_a F_d \quad (59)$$

The last terms are an arrangement factor, F_a , and a depth factor F_d , that correct the results from the base configuration ($\ell_{||}/D_0 = 2.0$, $\ell_{\perp}/D_0 = 1.75$, number of rows ≥ 10) which by definition $F_a = F_d = 1$. The equation applies to heating and cooling of fluids for clean tubes in crossflow. Equation 59 is rewritten using parametric groupings shown below:

Fig. 14 Effect of film temperature, T_f , and moisture on the physical properties factor, F_{pp} , for gas; turbulent flow inside tubes or longitudinal flow over tubes (English units only).

Fig. 15 Effect of film temperature, T_f , and moisture on the physical properties factor, F_{pp} , for air; turbulent flow inside tubes or longitudinal flow over tubes (English units only).

$$h_c = \left[\frac{0.321 G^{0.61}}{D^{0.39}} \right] \left[\frac{c_p^{0.33} k^{0.67}}{\mu^{0.28}} \right] F_a F_d \quad (60)$$

which can be expressed in the form:

$$h_c = h'_c F_{pp} F_a F_d \quad (61)$$

Figs. 18 to 23 display the various factors that make up the right side of Equation 61. Unlike non-dimensional parameters (Nu , Re , Pr), these terms do not

Fig. 16 Effect of film temperature, T_f , and pressure on the physical properties factor, F_{pp} , for steam; turbulent flow inside tubes or longitudinal flow over tubes (English units only).

Fig. 17 Temperature factor, F_T , for converting mass velocity from bulk to film basis for air, gas or steam; turbulent flow inside tubes or longitudinal flow over tubes.

have any physical significance and are dependent upon the choice of engineering units. The physical properties factor, F_{pp} , similar to the one previously defined, is evaluated at the gas film temperature for a particular fluid (gas or air). The mass flux or mass flow per unit area, G , and the Reynolds numbers used in Equations 59 and 60 and Figs. 18, 21 and 22 are calculated based on flow conditions at the minimum free area (maximum velocity) between tubes.

The arrangement factor, F_a , depends on the geometric configuration of tubes, the ratio of tube spacing to diameter, Reynolds number, and the presence of ash in the flue gas. Values of F_a for clean tube conditions with air or flue gas without ash are given in Fig. 21. Values of F_a for commercially clean tube conditions with ash-laden flue gas are given in Fig. 22.

The depth factor, F_d , accounts for entrance effects for banks of tubes which are less than ten rows deep in the direction of gas flow. For undisturbed flow [flow that is straight and uninterrupted for at least 4 ft (1.2 m) before entering a tube bank] approaching a bank of less than ten rows, the film conductance must include the correction factor, F_d , shown in Fig. 23. F_d is unity when the tube bank is preceded by a bend, screen, damper or another tube bank in close proximity.

Fig. 18 Basic crossflow convection velocity and geometry factor, h'_c , for gas or air (English units only).

Fig. 19 Effect of film temperature, T_f , and moisture on the physical properties factor, F_{pp} , for gas in turbulent crossflow over tubes (English units only).

Turbulent longitudinal flow around tubes Correlations that were developed based on turbulent flow in tubes (Equations 56 and 57, and Figs. 13 to 17) can also be applied for external flow parallel to tubes. In this case, the equivalent diameter D_e (defined by Equation 46) is used in the evaluation of Reynolds number. For flow parallel to a bank of circular tubes arranged on rectangular spacing, the equivalent diameter becomes:

$$D_e = \frac{4\ell_1 \ell_2}{\pi D_o} - D_o \quad (62)$$

where D_o is the tube outside diameter and ℓ_1 and ℓ_2 are the centerline spacing between tubes. The mass flux or mass flow per unit area, G , in Equations 56 and 57, and Fig. 13 is calculated based on the free area between tubes.

General heat transfer topics

Heat exchangers

Boiler systems contain many heat exchangers. In these devices, the fluid temperature changes as the fluids pass through the equipment. With an energy balance specified between two locations, 1 and 2:

$$q = \dot{m} c_p (T_2 - T_1) \quad (63)$$

the change in fluid temperature can be calculated:

$$T_2 = T_1 + (q / \dot{m} c_p) \quad (64)$$

It is therefore appropriate to define a mean effective temperature difference governing the heat flow. This difference is determined by performing an energy balance on the energy lost by the hot fluid and that energy gained by the cold fluid. An equation of the form:

$$q = UA F \Delta T_{LMTD} \quad (65)$$

is obtained where the parameters U , A and F define the overall heat transfer coefficient, surface area, and ar-

range correction factor, respectively. The term ΔT_{LMTD} , known as the log mean temperature difference, is defined as:

$$\Delta T_{LMTD} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1 / \Delta T_2)} \quad (66)$$

ΔT_1 is the initial temperature difference between the hot and cold fluids (or gases), while ΔT_2 defines the final temperature difference between these media. The pa-

Fig. 23 Heat transfer depth factor for number of tube rows crossed in convection banks. ($F_a = 1.0$ if tube bank is immediately preceded by a bend, screen or damper.)

parameter U in Equation 65 defines the overall heat transfer coefficient for clean surfaces and represents the unit thermal resistance between the hot and cold fluids:

$$\frac{1}{UA_{\text{clean}}} = \frac{1}{h_i A_i} + R_w + \frac{1}{h_o A_o} \quad (67)$$

For surfaces that are fouled, the equation is written:

$$\frac{1}{UA} = \frac{R_{f,i}}{A_i} + \frac{1}{UA_{\text{clean}}} + \frac{R_{f,o}}{A_o} \quad (68)$$

where $R_{f,i}$ is the reciprocal effective heat transfer coefficient of the fouling on the inside surface, $(1/UA)$ is the thermal resistance and $R_{f,o}$ is the reciprocal heat transfer coefficient of the fouling on the outside surface. Estimates of overall heat transfer coefficients and fouling factors are listed in Tables 10 and 11. Actual fouling factors are site specific and depend on water chemistry and other deposition rate factors. Overall heat transfer coefficients can be predicted using: 1) the fluid conditions on each side of the heat transfer surface with either Equation 56 or 59, 2) the known materials of the heat transfer surface, and 3) the fouling factors listed in Table 11. Often the heat exchanger tube wall resistance (R_w) is small compared to the surface resistances and can be neglected, leading to the following equation for a clean surface:

$$U = \frac{h_i h_o}{h_i + (h_o D_o / D_i)} \quad (69)$$

This equation assumes that area, A in product UA , is based on the outside diameter of the tube, D_o .

The difficulty in quantifying fouling factors for gas-, oil- and coal-fired units has led to use of a *cleanliness factor*. This factor provides a practical way to provide extra surface to account for the reduction in heat transfer due to fouling. In gas-fired units, experience indicates that gas-side heat transfer coefficients are higher as a result of the cleanliness of the surface. In oil- and coal-fired units that are kept free of slag and deposits, a

Table 10
Approximate Values of Overall Heat Transfer Coefficients

Physical Situation	Btu/h ft ² F	W/m ² K
Plate glass window	1.10	6.20
Double plate glass window	0.40	2.30
Steam condenser	200 to 1000	1100 to 5700

Steam, non-oil bearing	0.0005	0.0001
Industrial air	0.002	0.0004

lower value is used. For units with difficult to remove deposits, values are reduced further.

There are three general heat transfer arrangements: parallel flow, counterflow and crossflow, as shown in Fig. 24. In parallel flow, both fluids enter at the same relative location with respect to the heat transfer surface and flow in parallel paths over the heating surface. In counterflow, the two fluids enter at opposite ends of the heat transfer surface and flow in opposite directions over the surface. This is the most efficient heat exchanger although it can also lead to the highest tube wall metal temperatures. In crossflow, the paths of the two fluids are, in general, perpendicular to one another.

Fig. 24 shows the flow arrangements and presents Equation 66 written specifically for each case. The arrangement correction factor, F , is 1.0 for parallel and counterflow cases. For crossflow and multi-pass arrangements, the correction factors are shown in Figs. 25 and 26.

Extended surface heat transfer

The heat absorption area in boilers can be increased using longitudinally and circumferentially finned tubes. Finned, or extended, tube surfaces are used on the flue gas side. In regions prone to fouling, the fins must be spaced to permit cleaning. Experimental data on actual finned or extended surfaces are preferred for design purposes; the data should be collected at conditions similar to those expected to be encountered. However, in place of these data, the method by Schmidt¹⁵ generally describes the heat transfer across finned tubes. It is based on heat transfer to the underlying bare tube configuration, and it treats the tube as if it has zero fin height. Schmidt's correlation for the gas-side conductance to tubes with helical, rectangular, circular, or square fins is as follows:

$$h_f = h_c Z \left\{ 1 - (1 - \eta_f) \left(\frac{S_f}{S} \right) \right\} \quad (70)$$

where h_c is the heat transfer coefficient of the bare tubes in crossflow defined by Equations 59 and 60, and Z is the geometry factor defined as:

$$Z = 1 - 0.18 \left(\frac{L_h}{L_t} \right)^{0.63} \quad (71)$$

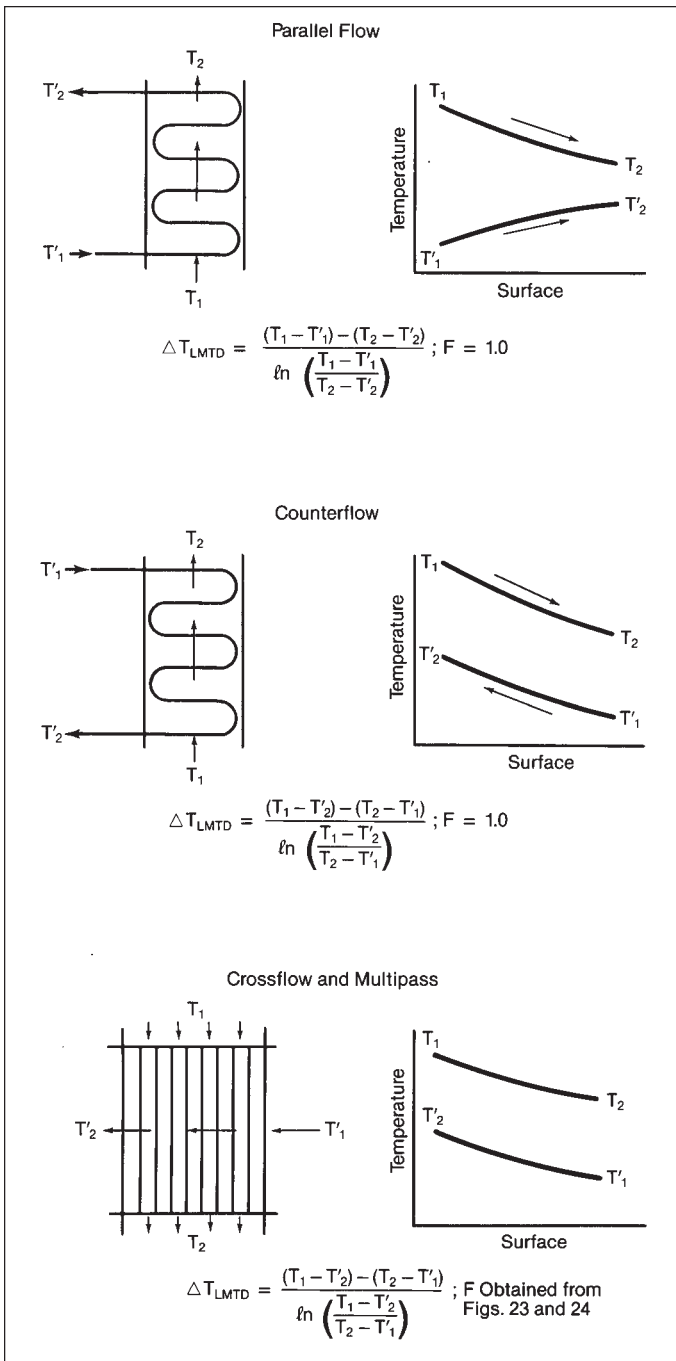

Fig. 24 Mean effective temperature difference.

S_f represents the fin surface area including both sides and the peripheral area, while S represents the exposed bare tube surface between the fins plus the fin surface, S_f . The ratio L_h/L_t is the fin height divided by the clear spacing between fins. Fin efficiency, η_f , is shown in Fig. 27 as a function of the parameter X , defined as:

$$X = L_h \sqrt{2Zh_c / (k_f L_t)} \quad (72)$$

for helical fins, and

$$X = r Y \sqrt{2Zh_c / (k_f L_t)} \quad (73)$$

Fig. 25 Arrangement correction factors for a single-pass, crossflow heat exchanger with both fluids unmixed.

for rectangular, square or circular fins. The parameter Y is defined in Fig. 28.

The overall conductance can be written:

$$\frac{1}{UA} = \frac{1}{C_f A_o h_{f,o}} + R_w + \frac{1}{A_i h_{c,i}} \quad (74)$$

The parameter C_f is the surface cleanliness factor.

NTU method

There are design situations for which the performance of the heat exchanger is known, but the fluid temperatures are not. This occurs when selecting a unit for which operating flow rates are different than those

Fig. 26 Arrangement correction factors for a single-pass, crossflow heat exchanger with one fluid mixed and the other unmixed (typical tubular air heater application).

Fig. 27 Fin efficiency as a function of parameter X .

previously tested. The outlet temperatures can only be found by trial and error using the methods previously presented. These applications are best handled by the net transfer unit (NTU) method that uses the heat exchanger effectiveness (see Reference 16).

Heat transfer in porous materials

Porosity is an important factor in evaluating the effectiveness of insulation materials. In boiler applications, porous materials are backed up by solid walls or casings, so that there is minimal flow through the pores.

Heat flow in porous insulating materials occurs by conduction through the material and by a combination of conduction and radiation through the gas-filled voids. In most refractory materials, the Grashof-Prandtl (Raleigh) number is small enough that negligible convection exists although this is not the case in low density insulations [$< 2 \text{ lb/ft}^3$ (32 kg/m^3)]. The relative magnitudes of the heat transfer mechanisms depend, however, on various factors including porosity of the material, gas density and composition filling the voids, temperature gradient across the material, and absolute temperature of the material.

Analytical evaluation of the separate mechanisms is complex, but recent experimental studies at B&W have shown that the effective conductivity can be approximated by:

$$k_{\text{eff}} = a + bT + cT^3 \quad (75)$$

Experimental data can be correlated through this form, where a , b and c are correlation coefficients. The heat flow is calculated using Equation 1; k is replaced by k_{eff} and T is the local temperature in the insulation.

Fig. 28 Coefficient Y as a function of ratio R/r for fin efficiency.

In high temperature applications, heat transfer across the voids occurs mainly by radiation and the third term of Equation 75 dominates. In low temperature applications, heat flow by conduction dominates and the first two terms of Equation 75 are controlling.

Film condensation

When a pure saturated vapor strikes a surface of lower temperature, the vapor condenses and a liquid film is formed on the surface. If the film flows along the surface because of gravity alone and a condition of laminar flow exists throughout the film thickness, then heat transfer through this film is by conduction only. As a result, the thickness of the condensate film has a direct effect on the quantity of heat transferred. The film thickness, in turn, depends on the flow rate of the condensate. On a vertical surface, because of drainage, the thickness of the film at the bottom will be greater than at the top. Film thickness increases as a plate surface is inclined from the vertical position.

As the film temperature increases, its thickness decreases primarily due to increased drainage velocity. In addition, the film thickness decreases with increasing vapor velocity in the direction of drainage.

Mass diffusion and transfer

Heat transfer can also occur by diffusion and mass transfer. When a mixture of a condensable vapor and a noncondensable gas is in contact with a surface that is below the dew point of the mixture, some condensation occurs and a film of liquid is formed on the surface. An example of this phenomenon is the condensation of water vapor on the outside of a metal container. As vapor from the main body of the mixture diffuses through the vapor-lean layer, it is condensed on the cold surface as shown in Fig. 29. The rate of condensation is therefore governed by the laws of gas diffusion. The heat transfer is controlled by the laws of conduction and convection.

The heat transferred across the liquid layer must equal the heat transferred across the gas film plus the latent heat given up at the gas-liquid interface due to condensation of the mass transferred across the gas film. An equation relating the mass transfer is:

$$h_{\delta}(T_i - T_{\delta}) = h_g(T_g - T_i) + K_y H_{fg}(Y_g - Y_i) \quad (76)$$

where T and Y define the temperatures and concentrations respectively identified in Fig. 29, h_{δ} is the heat transfer coefficient across the liquid film, h_g is the heat transfer coefficient across the gas film, and K_y is the mass transfer coefficient. H_{fg} is the latent heat of vaporization.

Heat transfer due to mass transfer is important in designing cooling towers and humidifiers, where mixtures of vapors and noncondensable gases are encountered.

Evaporation or boiling

The phenomenon of boiling is discussed in Chapters 1 and 5, where the heat transfer advantages of nucleate boiling are noted. Natural-circulation fossil fuel boilers are designed to operate in the boiling range. In this range, the heat transfer coefficient var-

Fig. 29 Simultaneous heat and mass transfer in the dehumidification of air.

ies from 5000 to 20,000 Btu/h ft² F (28,392 to 113,568 W/m² K). This is not a limiting factor in the design of fossil fuel boilers provided scale and other deposits are prevented by proper water treatment, and provided the design avoids critical heat flux (CHF) phenomena. (See Chapter 5.)

In subcritical pressure once-through boilers, water is completely evaporated (dried out) in the furnace wall tubes which are continuous with the superheater tubes. These units must be designed for subcooled nucleate boiling, nucleate boiling, and film boiling, depending on fluid conditions and expected maximum heat absorption rates.

Fluidized-bed heat transfer

The heat transfer in gas-fluidized particle beds used in some combustion systems is complex, involving particle-to-surface contact, general convection and particle-to-surface thermal radiation. Correlations for heat transfer to tube bundles immersed in fluidized beds are summarized in Chapter 17.

Numerical modeling

Advances in computers have enabled B&W to mathematically model complex heat transfer systems. These models provide a tool for analyzing thermal systems inexpensively and rapidly. Although empirical methods and extensive equipment testing continue to provide information to designers, numerical simulation of boiler components, e.g., membrane walls, will become increasingly important as computer technology evolves. (See Chapter 6.)

Conduction

The energy equation for steady-state heat flow was previously defined as Equation 19 and is more generally written as Equation 20. Solutions of these equations for practical geometries are difficult to obtain except in idealized situations. Numerical methods permit the consideration of additional complex effects including irregular geometries, variable properties, and complex boundary conditions. Conduction heat flow through boiler membrane walls, refractory linings with several materials, and steam drum walls are several applications for these methods. The approach is to divide the heat transfer system into subvolumes called control volumes (Fig. 30). (See References 16

and 17.) The governing equation is integrated, or averaged, over the subvolume, leading to an expression of the form:

$$\frac{T_e - T_p}{R_{pe}} + \frac{T_w - T_p}{R_{pw}} + q_p''' V_p = c_p \frac{T_p - T_p^o}{\Delta t} \quad (77)$$

where the subscripts denote the neighbor locations as points on a compass. If the steady-state solution is desired, the right hand side of the equation, $c_p (T_p - T_p^o) / \Delta t$, which accounts for changes in stored energy is set to zero. A solution is then obtained numerically. Equation 77 is a discrete form of the continuous differential equation. The modeled geometry is subdivided and equations of this form are determined for each interior volume. The electrical analogy of the equation is apparent. First, each term is an expression of heat flow into a point using Fourier's law by Equation 1 and, second, Kirchhoff's law for electrical circuits, Equation 26, is used to determine the net flow of heat into any point. The application of the electrical analogy is straightforward for any interior volume once the subvolumes are defined. At the boundaries, temperature or heat flow is defined.

For unsteady-state problems, a sequence of solutions is obtained for the time interval Δt , with T_p^o being the node temperature at the beginning of the interval and T_p being the temperature at the end of the interval. References 16 and 17 explore these models in depth. Various computer codes are commercially available to perform the analysis and display the results.

Radiation

Numerical methods provide accurate estimates of radiative transfer in the absorbing and scattering media that is ubiquitous in the combustion and post-

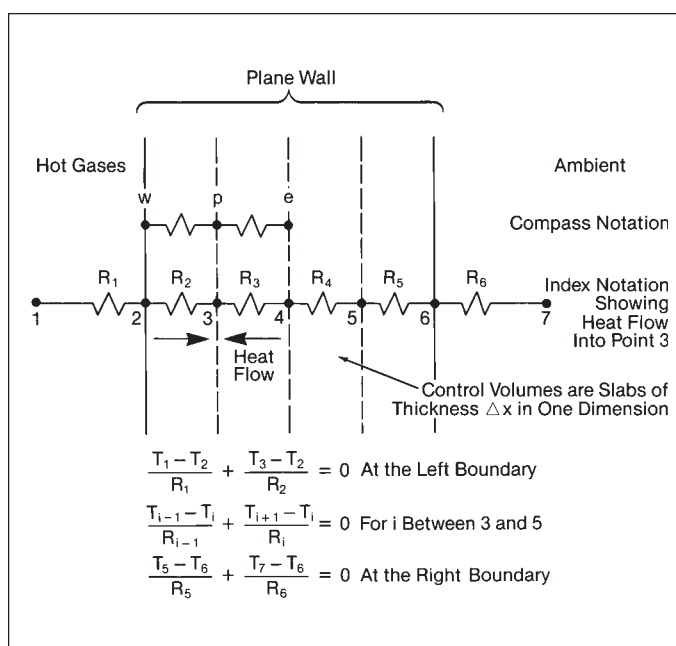

Fig. 30 Control volume layout for a plane wall with notation for heat flow to node 3 and steady-state solution.

combustion zones of a boiler. Many numerical methods have the advantage of incorporating complex geometrical description of the enclosure walls. These methods solve the radiation transport equation (RTE) in two and three dimensions and include the effects of absorption, emission, and scattering media, for gray or non-gray enclosure walls. Numerical models start by dividing the volume and surfaces of an enclosure into multiple control volumes and surface elements (as described in Chapter 6). Radiation properties of gases and particles are evaluated at each control volume, and may vary with local composition and temperature of the combustion mixture. Emissivity and temperature of the walls may also vary with local conditions, for each surface element of the enclosure. The solution of the RTE is generally carried out for the entire radiative spectrum for greatest numerical efficiency. However, if increased accuracy is required, the spectrum can be divided into discrete bands corresponding with the bands of gaseous radiation and the RTE is solved for each band separately.

Radiative heat transfer in furnaces can be calculated by one of several numerical methods, which are described in Reference 10. The simplest of these is the zonal method,⁴ an extension of the network exchange method described previously in this chapter. The enclosure is divided into a finite number of isothermal volume and surface area zones. Exchange factors for all combinations of volume to volume, volume to surface, and surface to surface exchange are precalculated. This analysis leads to a set of simultaneous equations for unknown radiant heat fluxes, which are solved numerically.

The discrete ordinates method is perhaps the most robust approach for numerical analysis of radiation heat transfer in boilers. The angular dependence of radiation is first expressed in spherical coordinates, and is divided into a finite number of discrete directions for solving the RTE. The equations are transformed into a set of simultaneous partial differential equations, one for each direction, that are solved numerically. The accuracy of the method increases with the number of directions that are used in the approximation (typically 12, 24, or 48). Discrete ordinates was developed and optimized for thermal radiation in multi-dimensional geometries by the pioneering work at B&W.¹⁸ Since then, it has gained in popularity, and is now used in many commercial computational fluid dynamics (CFD) codes.

The numerical solution for radiation leads to the distribution of radiant intensity or radiant heat flux, for a given temperature field. This solution is coupled to the energy equation and temperature of the gas-particle mixture. The energy equation (Equation 28 or 29) can be solved numerically for gas-particle temperature field using the methods described in Chapter 6. Radiation absorption and emission is represented by the internal heat generation term, S_H . Wall temperature is determined from an energy balance for convection and radiation heat transfer to the surface, and heat conduction through the wall. Several iterations between radiation, gas-particle energy, and wall temperature will ultimately yield a converged solution in which an overall energy balance is achieved.

Design considerations

Furnaces

Fossil-fuel fired boiler designers need to evaluate furnace wall temperature and heat flux, flue gas temperature, and furnace exit gas temperature. These parameters are required to determine materials and their limits, and to size heat transfer surface.

An analytical solution for heat transfer in a steam generating furnace is extremely complex. It is not possible to calculate furnace outlet temperatures by theoretical methods alone. Nevertheless, this temperature must be correctly predicted because it determines the design of the superheater and other system components.

In a boiler, all of the principal heat transfer mechanisms take place simultaneously. These mechanisms are intersolid radiation between suspended solid particles, tubes, and refractory materials; nonluminous gas radiation from the products of combustion; convection from the gases to the furnace walls; and conduction through ash deposits on tubes.

Fuel variation is significant. Pulverized coal, gas, oil or waste-fuel firing may be used. In addition, different types of the same fuel also cause variations. Coal, for example, may be high volatile or low volatile, and may have high or low ash and moisture contents. The ash fusion temperature may also be high or low, and may vary considerably with the oxidizing properties of the furnace atmosphere.

Furnace geometry is complex. Variations occur in the burner locations and spacing, in the fuel bed size, in the ash deposition, in the type of cooling surface, in the furnace wall tube spacing, and in the arch and hopper arrangements. Flame shape and length also affect the distribution of radiation and heat absorption in the furnace.

High intensity, high mixing burners produce bushy flames and promote large high temperature zones in the lower furnace. Lower intensity, controlled mixing burners frequently have longer flames that delay combustion while controlling pollutant formation.

Surface characteristics vary. The enclosing furnace walls may include any combination of fuel arrangements, refractory material, studded tubes, spaced tubes backed by refractory, close-spaced tubes, membrane construction or tube banks. Emissivities of these surfaces are different. The water-cooled surface may be covered with fluid slag or dry ash in any thickness, or it may be clean.

Temperature varies throughout the furnace. Fuel and air enter at relatively low temperatures, reach high temperatures during combustion, and cool again as the products of combustion lose heat to the furnace enclosure. All temperatures change with load, excess air, burner adjustment and other operating conditions.

Accurate estimates of furnace exit gas temperature are important. For example, high estimates may lead to over-estimating the heat transfer surface, while low estimates may cause operational problems. These are discussed in Chapter 19.

Empirical methods Considering the fuel type, firing rate and furnace configuration, empirical methods as illustrated in Fig. 31 have long been used to

predict local absorption rates in the furnace. These methods, although largely empirical, contain engineering models which are based on fundamentals. Data and operating experience are used to tune the models employed in the design envelope. Fig. 31 shows typical vertical and horizontal heat flux distributions for furnace walls.

Deviations in the heat flux distribution are caused by unbalanced firing, variations in tube surface condition, differences in slagging, load changes, sootblower operation and other variations in unit operation. A typical upset heat flux distribution is shown in Fig. 31. These upset factors are typically a function of vertical/horizontal location, firing method and fuel, and furnace configuration. They are derived from operating experience.

The heat flux applied to the tubes in the furnace wall is also nonuniform in the circumferential direction. As shown in Fig. 32, the membrane wall is exposed to the furnace on one side while the opposite side is typically insulated to minimize heat loss. The resulting heat flux distribution depends upon the tube outside diameter, wall thickness, and spacing, as well as the web thickness and materials. The fluid temperature and inside heat transfer coefficient have secondary effects. This distribution can be evaluated using commercially available computer codes.

Fig. 31 Typical vertical and horizontal heat flux distributions for furnace walls.

Fig. 32 Typical circumferential heat flux distribution for a furnace membrane wall panel tube.

To correlate data and calculations for different furnaces, methods for comparing the relative effectiveness of different furnace wall surfaces are needed. The effectiveness and spacing of tubes compared to a completely water-cooled surface are shown in Fig. 33. A wall of flat-studded tubes is considered completely water-cooled. The effectiveness of expected ash covering, compared with completely water-cooled surfaces, can also be estimated. The entire furnace envelope can then be evaluated in terms of equivalent cold surface.

The heat energy supplied by the fuel and by the preheated combustion air, corrected for unburned combustible loss, radiation loss, and moisture from the fuel, may be combined into a single variable, known as *heat available*. The heat available divided by the equivalent flat projected furnace enclosure plus furnace

Fig. 33 Furnace wall area effectiveness factor (1.0 for completely water-cooled surface). A reduced area (equivalent cold surface) is determined from these curves for walls not completely water cooled. (Adapted from Hottel⁴.)

platen area is called the *furnace heat release rate*. The heat input from fuel divided by the furnace volume is called the *furnace liberation rate*. The *furnace exit plane* defines the boundary of the furnace volume and flat projected furnace enclosure area. The furnace exit plane area and back spacing between the furnace platen tubes are included in the flat projected area calculation. For furnace platens and membrane wall furnace enclosure, the effectiveness factor for all examples given in this and other chapters is equal to 1.00.

Furnace exit gas temperature (FEGT) is primarily a function of heat release rate rather than liberation rate. The *furnace exit* is commercially defined as being located at the face of the first tube bank having a tube spacing of less than 15 in. (38.1 cm) side centers because, as can be inferred from Fig. 39, convection conductance typically becomes the predominant heat transfer mode at this side spacing. The furnace exit plane, generally used for the accurate calculation of overall heat transfer, is normally set at the face of the first tube bank having a tube spacing of 36 in. (91.4 cm) side centers or less in order to include the convection conductance in the heat transfer calculations. At tube side centers of 36 in. (91.4 cm) or less, the convection conductance is too significant to ignore as a portion of total heat transfer. The approximate relation of FEGT to heat release rate at the furnace exit plane for a typical pulverized bituminous coal is given in Fig. 34.

Furnace exit gas temperatures and related heat absorption rates, as functions of furnace heat release rate for most pulverized coal-fired furnaces, lie within

Fig. 34 Approximate relationship of furnace exit gas temperatures to heat release rate for a typical pulverized bituminous coal.

the shaded bands shown in Figs. 35 and 36. The limits indicated serve only as a general guide and may vary due to combustion system type, burner and air port placement, stoichiometry, fuel characteristics and cleaning cycle. The bands for dry ash and for slag-tap furnaces overlap between 100,000 and 150,000 Btu/h ft² (315,460 to 473,190 W/m²), but different types of coal are involved. To be suitable for a slag-tap furnace, a bituminous coal should have an ash viscosity of 250 poises at 2450F (1343C) or lower. In the overlapping range, dry ash and slag-tap both have about the same heat absorption rate, or dirtiness factor, as shown in Fig. 36. Both bands are rather broad, but they cover a wide range of ash characteristics and a considerable diversity in waterwall construction and dirtiness.

The heat leaving the furnace is calculated from the exiting gas flow rate (the gas enthalpy values evaluated at the furnace exit gas temperature) plus the net radiative transfer at the furnace exit. The heat absorbed in the furnace is the difference between the heat available from the fuel, including the preheated combustion air, and heat leaving the furnace.

Numerical methods Empirical design methods are gradually being supplemented with numerical methods, as the level of detail increases and confidence is improved. Radiation heat transfer in furnace enclosures can now be solved on computers, in combination with turbulent flow, energy, and combustion. Radiation properties of gases, particles, and fuel specific properties of ash deposits can be included in the analysis with more advanced engineering models and correlations. The effects of spectral radiation from gases and particles can also be included to improve accuracy of the analysis. Detailed results include the three-dimensional distribution of radiation intensity, gas temperature, and heat flux on the furnace walls. Numerical

Fig. 36 General range of furnace heat absorption rates for dry ash and slag-tap pulverized coal-fired furnaces.

cal methods have the potential for more accurate prediction of heat flux distribution on furnace walls and convective surfaces. However, further validation of results and improvements in computational efficiency are needed to make numerical methods more practical for routine engineering applications.

A numerical model was created for the furnace of a 560 MW supercritical steam pressure boiler firing high volatile eastern United States bituminous coal. A schematic of the furnace is shown in Fig. 37. The sloping furnace walls of the ash hopper, the furnace nose, and

Fig. 37 560 MW utility boiler schematic used for numerical model (see Fig. 38).

the horizontal section of the convection pass were included in the model. Inlet fuel, inlet air and exit streams were properly located around the boundaries. An example of the predicted heat flux distribution is shown in Fig. 38. The predicted furnace exit gas temperature for this case was 2242F (1228C), while the observed average value was 2276F (1247C). Relative magnitudes of convective and radiative heat transfer at various locations are shown in Fig. 39 for a 650 MW boiler. The furnace area is dominated by radiation while the back-end heat transfer surfaces in the direction of flow are increasingly dominated by convection.

Convection banks

Tube spacing and arrangement In addition to heat absorption and resistance to gas flow, other important factors must be considered in establishing the optimum tube spacing and arrangement for a convection surface. These are slagging or fouling of surfaces, accessibility for cleaning, and space occupied. A large longitudinal spacing relative to the transverse spacing is usually undesirable because it increases the space requirement without improving performance. These are discussed further in Chapter 21.

Tube diameter For turbulent flow, the heat transfer coefficient is inversely proportional to a power of the tube diameter. In Equations 57 and 60 the exponent for longitudinal flow is 0.20; for cross flow it is 0.39. These equations indicate that the tube diameter should be minimized for the most effective heat transfer. However, this optimum tube diameter may require

Fig. 38 Numerical model - predicted furnace wall flat projected heat flux distribution. (1 W/m² = 0.317 Btu/h ft²)

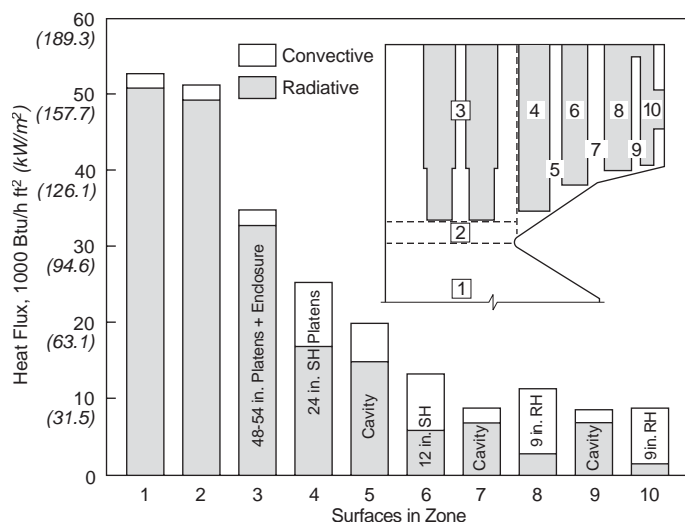

Fig. 39 Comparison of radiative and convective heat transfer contributions to absorption in various locations within a large utility boiler (SH = superheater; RH = reheater; 1 in. = 2.54 cm).

an arrangement that is expensive to fabricate, difficult to install, or costly to maintain. A compromise between heat transfer effectiveness and manufacturing, erection, and service limitations is therefore necessary in selecting tube diameter.

Penetration of radiation A convection bank of tubes bordering a furnace or a cavity acts as a blackbody radiant heat absorber. Some of the impinging heat, however, radiates through the spaces between the tubes of the first row and may penetrate as far as the fourth row. The quantity of heat penetration can be established by geometric or analytical methods. The effect of this penetration is especially important in establishing tube temperatures for superheaters located close to a furnace or high temperature cavity. Consider 2.0 in. (50.8 mm) OD tubes placed in an array of tubes on a 6.0 in. (152.4 mm) pitch. Fig. 33, curve 1 can be used to estimate the remaining radiation. For a given radiant heat flux, 45% is absorbed in the first tube row, and 55% passes to the second row. 45% of this reduced amount is again absorbed in the second tube row. After the fourth row, less than 10% of the initial radiation remains.

Effect of lanes Lanes in tube banks, formed by the omission of rows of tubes, may decrease the heat absorption considerably. These passages act as bypasses for flowing hot gases and radiation losses. Although the overall efficiency decreases, the high mass flow through the lanes increases the absorption rate of the adjacent tubes. Critical tube temperatures in superheaters or steaming conditions in economizers may develop. Whenever possible, lanes should be avoided within tube banks and between tube banks and walls; however, this is not always possible. A calculation accounting for the lanes is necessary in such cases.

Heat transfer to water

Water heat transfer coefficient The heat transfer coefficient for water in economizers is so much higher than the gas-side heat transfer coefficient that it can be neglected in determining economizer surface.

Boiling water heat transfer coefficient The combined gas-side heat transfer coefficient (convection plus

intertube radiation) seldom exceeds 30 Btu/h ft² F (170 W/m² K) in boiler design practice. The heat transfer coefficient for boiling water [10,000 Btu/h ft² F (56,784 W/m² K)] is so much larger that it is generally neglected in calculating the resistance to heat flow, although Equation 4 in Chapter 5 can be used to calculate this value.

Effect of scale Water-side and steam-side scale deposits provide high resistance to heat flow. As scale thickness increases, additional heat is required to maintain a given temperature inside a furnace tube. This leads to high metal temperatures and can cause tube failure. Deposition of scale and other contaminants is prevented by good feedwater treatment and proper operating practices.

Heat transfer to steam In superheaters, the steam-side convection constitutes a significant resistance to heat flow. Although this resistance is much lower than the gas-side resistance, it can not be neglected in computing the overall heat flow resistance or the heat transfer rate. It is particularly significant in calculating superheater tube temperatures, because the mean tube wall temperature is equal to the steam temperature plus the temperature drop through the steam film plus half of the metal temperature drop.

The steam-side heat transfer coefficient is calculated from Equation 58 using information from Figs. 13, 16 and 17. If the steam heat transfer coefficient is designated as h , the film temperature drop, ΔT_f , is $q/(hA)$, using the outside surface area of the tube as the base in each expression.

It is imperative to prevent scale deposits in superheater tubes. Because of its high resistance to heat flow and due to the elevated temperatures, even a thin layer of scale may be sufficient to overheat and fail a tube.

Cavities

Cavities are necessary between tube banks of steam generating units for access, for sootblowers, and for possible surface addition. Hot flue gas radiates heat to the boundary surfaces while passing through the cavity. The factors involved in calculating heat transfer in cavities are as follows.

Temperature level Radiation from nonluminous gases to boundary surfaces and radiation to the gas by the surroundings increase approximately by the fourth power of their respective absolute temperatures. Remembering that $E_b = \sigma T^4$, Equations 39 and 40 illustrate this relationship.

Gas composition Carbon dioxide and water vapor are the normal constituents of flue gases which emit nonluminous radiation in steam generating units. The concentrations of these constituents depend on the fuel burned and the amount of excess air.

Particles in the gas The particles carried by flue gases receive heat from the gas by radiation, convection, and conduction, and emit heat by radiation to the furnace enclosure.

Size of cavity The heat transfer rate increases with cavity size. Thick layers of gas radiate more vigorously than thin layers. The shape of the cavity can also complicate heat transfer calculations.

Receiving surface A refractory surface forming part of a cavity boundary reaches a high temperature by convection and radiation from the flue gas. It also reradiates heat to the gas and to the other walls of the enclosure. Reradiation from a clean, heat-absorbing surface is small unless the receiving surface temperature is high, as is the case with superheaters and reheaters. Ash or slag deposits on the tube reduce heat absorption and increase reradiation.

In boiler design, there are two significant effects of cavity radiation: 1) the temperature of flue gas drops, from several degrees up to 40F (22C), in passing across a cavity, and 2) gas radiation increases the heat absorption rates for the tubes forming the cavity boundaries. The second effect influences superheater tube temperatures and the selection of alloys.

Insulation

The calculation of heat transfer through insulation follows the principles outlined for conduction through a composite wall. Refer to Chapter 23 for more information regarding insulating materials.

Hot face temperature In a furnace with tube-to-tube walls, the hot face temperature of the insulation is the saturation temperature of the water in the tubes. If the inner face of the furnace wall is refractory, the hot face insulation temperature must be calculated using radiation and convection heat transfer principles on the gas side of the furnace wall, or estimated using empirical data.

Heat loss and cold face temperature The heat loss to the surroundings and the cold face temperature decrease as the insulation thickness increases. However, once an acceptable layer of insulation is applied, additional amounts are not cost effective. Standard commercial insulation thicknesses should be used in the composite wall.

The detailed calculation of overall heat loss by radiation and convection from the surfaces of a steam generating unit (usually called radiation loss) is tedious and time consuming. A simple approximate method is provided by the chart prepared from the American Boiler Manufacturers Association (ABMA) original. (See Chapter 23, Fig. 12.)

Ambient air conditions Low ambient air temperature and high air velocities reduce the cold face temperature. However, they have only a small effect on total heat loss, because surface film resistance is a minor part of the total insulation resistance. Combined heat loss rates (radiation plus convection) are given in Chapter 23, Fig. 11, for various temperature differences and air velocities. The effect of surface film resistance on casing temperature and on heat loss through casings is shown in Chapter 23, Fig. 15.

Temperature limits and conductivities Refractory or insulating material suitable for high temperature applications is usually more expensive and less effective than low temperature materials. It is therefore customary to use several layers of insulation. The lower cost, more effective insulation is used in the cool zones; the higher cost materials are used only where demanded by high operating temperatures. Thermal conductivities for refractory and insulating materials, and temperatures for which they are suitable, are shown in Chapter 23, Fig. 10.

Applications

Example 1 – Conduction through a plane wall

If a flat plate is heated on one side and cooled on the other, the heat flow rate in the wall, shown in Fig. 1, is given by Equation 2. The rate of heat flow through a 0.25 in. thick steel plate with 1 ft² surface area and $\Delta T = 25^\circ\text{F}$ may be evaluated with Equation 2 as follows:

$$q = kA \frac{\Delta T}{L} = \frac{30 \times 1 \times 25}{0.25/12} = 36,000 \text{ Btu/h} \quad (78)$$

where the thermal conductivity, k , for steel is 30 Btu/h ft F.

Example 2 – Heat flow in a composite wall with convection

The heat flow through a steel wall which is insulated on both sides is shown in Fig. 3. This example demonstrates the procedure for combining thermal resistances. In addition to the thermal resistance of the firebrick, steel, and insulation, the heat flow is impeded by the surface resistances. Consider a 600 ft² surface with gases at 1080F or 1540R on the inside exposed to an ambient temperature of 80F on the outside. The thermal conductivities of the firebrick, steel flue and insulation are assumed to be $k_1 = 0.09$, $k_2 = 25$, and $k_3 = 0.042$ Btu/h ft F, respectively. These assumptions are verified later. The layer thicknesses are $\Delta x_1 = 4$ in., $\Delta x_2 = 0.25$ in., and $\Delta x_3 = 3$ in. The heat transfer coefficients for convection are $h_{cv,i} = 5.0$ Btu/h ft² F on the inside surface $h_{cv,o} = 2.0$ Btu/h ft² F on the outside surface. Where the temperature difference between the radiating gas, T_g , and a surface, T_s , is small, the radiation heat transfer coefficient can be estimated by:

$$h_r \cong 4.0 \sigma \varepsilon F \left[(T_g + T_s)/2 \right]^3 \approx 4 \sigma \varepsilon F T_g^3 \quad (79a)$$

where T_g and T_s are the absolute temperatures, R (K). In this example, the surface emissivity is assumed close to 1.0 and $F = 1.0$ resulting in:

$$h_r = 4.0 (0.1713 \times 10^{-8}) (1080 + 460)^3 = 25 \text{ Btu/h ft}^2 \text{ F} \quad (79b)$$

Using the R_{eq} shown in Fig. 3 and values of R evaluated using Table 4:

$$\begin{aligned} R_{eq} A &= \frac{\left(\frac{1}{5} \right) \left(\frac{1}{25} \right)}{\frac{1}{5} + \frac{1}{25}} + \frac{4}{0.09} + \frac{0.25}{25} + \frac{3}{0.042} + \frac{1}{2} \\ &= 0.033 + 3.70 + 0.000833 + 5.95 + 0.5 \quad (80) \\ &= 10.18 \frac{\text{h ft}^2 \text{ F}}{\text{Btu}} \end{aligned}$$

It is clear that the firebrick and insulation control the overall resistance; the steel resistance can be ne-

glected. If the successive material layers do not make good thermal contact with each other, there will be interface resistances due to the air space or film. These resistances may be neglected in composite walls of insulating materials. However, they must be included in calculations if the layer resistances are small compared to the interface resistances. An example of this is heat transfer through a boiler tube with internal oxide deposits.

The heat flow can be computed using Equation 23:

$$q = \frac{T_f - T_\infty}{R_{eq}} = A \frac{T_f - T_\infty}{R_{eq} A} = 600 \left(\frac{1080 - 80}{10.18} \right) = 58,939 \frac{\text{Btu}}{\text{h}} \quad (81)$$

To determine if the correct thermal conductivities were assumed and if the temperature levels are within allowable operating limits of the material, it is necessary to calculate the temperatures at the material interfaces. Solving Equation 81 for temperature and substituting individual resistances and local temperatures:

$$T_1 = T_f - \frac{q}{A} (R A)_f = 1080 - \frac{(58,939)(0.033)}{600} = 1077\text{F} \quad (82)$$

$$T_2 = T_1 - \frac{q}{A} (R A)_1 = 1077 - \frac{(58,939)(3.70)}{600} = 713\text{F} \quad (83)$$

$$T_3 = T_2 - \frac{q}{A} (R A)_2 = 713 - \frac{(58,939)(0.000833)}{600} = 713\text{F} \quad (84)$$

$$T_4 = T_3 - \frac{q}{A} (R A)_3 = 713 - \frac{(58,939)(5.95)}{600} = 129\text{F} \quad (85)$$

$$T_\infty = T_4 - \frac{q}{A} (R A)_\infty = 129 - \frac{(58,939)(0.5)}{600} = 80\text{F} \quad (86)$$

The small temperature difference between the radiating gas and the surface ($T_f - T_1 = 3\text{F}$) verifies the assumption for using Equation 79a. Had the temperature difference been larger, then the full equation for the radiation resistance in Table 4 may have been required.

The negligible resistance of the steel flue is reflected in the temperature drop $T_2 - T_3 = 0$. If the calculated interface temperatures indicate the conductivity was chosen improperly, new conductivities are defined using the mean temperature of each material. For example, a new firebrick conductivity is determined using $0.5 (T_1 + T_2)$.

Example 3 – Heat flow in an insulated pipe

Heat flow in cylindrical geometries is important in evaluating boiler heat transfer. Refer to the example steam line shown in Fig. 40. The resistances in Table 4 for cylindrical geometries must be used. The thermal analogy for the pipe in Fig. 40 can be written:

$$R_{eq} = \frac{1}{h_i (2\pi r_1 l)} + \frac{\ln(r_2/r_1)}{2\pi k_2 l} + \frac{\ln(r_3/r_2)}{2\pi k_3 l} + \frac{1}{h_o (2\pi r_3 l)} \quad (87)$$

A 3 in. Schedule 40 steel pipe ($k = 25 \text{ Btu/h ft F}$) is covered with 0.75 in. insulation of $k = 0.10 \text{ Btu/h ft F}$. This pipe has a 3.07 in. ID and a 3.50 in. OD. The pipe transports fluid at 300F and is exposed to an ambient temperature of 80F. With an inside heat transfer coefficient of $50 \text{ Btu/h ft}^2 \text{ F}$ and an outside heat transfer coefficient of $4 \text{ Btu/h ft}^2 \text{ F}$, the thermal resistance and heat flow per unit length are:

$$R_{eq} l = \frac{1}{50(2\pi) \left(\frac{3.07/2}{12} \right)} + \frac{\ln \left(\frac{3.50}{3.07} \right)}{2\pi(25)} + \frac{\ln \left(\frac{5.0}{3.5} \right)}{2\pi(0.1)} + \frac{1}{4(2\pi) \left(\frac{5.0/2}{12} \right)} \quad (88)$$

$$R_{eq} l = 0.0249 + 0.000834 + 0.568 + 0.191 = 0.785 \frac{\text{h ft F}}{\text{Btu}} \quad (89)$$

The overall resistance is dominated by the insulation resistance and that of the outer film boundary layer. The resistance of the metal pipe is negligible.

$$\frac{q}{l} = \frac{300 - 80}{0.785} = 280 \text{ Btu/h ft} \quad (90)$$

Fig. 40 Example of heat flow in an insulated pipe.

Example 4 – Heat flow between a small object and a large cavity

Consider an unshielded thermocouple probe with an emissivity of 0.8 inserted in a duct at 240F carrying combustion air. If the thermocouple indicates a temperature of 540F and the surface heat transfer coefficient, h , between the thermocouple and gas is 20 Btu/h ft² F, the true gas temperature can be estimated. The thermocouple temperature must be below the gas temperature because heat is lost to the walls. Under steady-state conditions, an energy balance equates the radiant heat loss from the thermocouple to the wall and the rate of heat flow from the gas to the thermocouple.

Using Table 6, the heat flow between the thermocouple and the cavity becomes:

$$\begin{aligned} \frac{q}{A} &= 0.8 (0.1713 \times 10^{-8}) \\ &\times \left[(540 + 460)^4 - (240 + 460)^4 \right] \quad (91) \\ &= 1041.4 \text{ Btu/h ft}^2 \end{aligned}$$

The true gas temperatures becomes:

$$T_g = \frac{q/A}{h} + T_t = \frac{1041.4}{20} + 540 = 592\text{F} \quad (92)$$

Similar analyses can be performed for thermocouples shielded with reflective foils in high temperature environments. This practice prevents thermocouple heat losses and incorrect temperature readings. The heat flow from a shielded thermocouple is calculated as follows:

$$q_{\text{shielded}} = \frac{1}{(N + 1)} q_{\text{no shield}} \quad (93)$$

where N is the number of concentric layers of material.

Example 5 – Heat flow between two surfaces

An estimate of the maximum radiant heat transfer between two surfaces can be determined using Equation 11. This approximation is valid when the walls are considered black and any intervening absorbing gases are neglected. If two 5 × 10 ft black rectangles, directly opposed, are spaced 10 ft apart with temperatures of 940 and 1040F, the energy exchange is estimated as follows.

The energy from surface 1 directly striking surface 2 is defined by the shape factor F_{12} . Referring to Fig. 5, this factor F_{12} is 0.125, indicating that 87.5% of the energy leaving surface 1 strikes a surface other than surface 2. The net heat flow is:

$$\begin{aligned} q_{12} &= A_1 F_{12} \sigma (T_1^4 - T_2^4) \\ &= 50(0.125)(0.1713 \times 10^{-8}) \\ &\times \left[(1040 + 460)^4 - (940 + 460)^4 \right] \quad (94) \\ q_{12} &= 13,071 \text{ Btu/h} \end{aligned}$$

Intervening gases and/or gray walls further reduce the net heat flow.

Example 6 – Radiation from a hot gas to furnace walls

Consider a furnace with a volume of 160,000 ft³ and a heat transfer surface area of 19,860 ft². The gas traversing the furnace (T_g) is at 2540F (1393C) and the furnace walls (T_s) are at 1040F (560C). The radiant heat transfer rate can be estimated using Equation 40, assuming the walls are radiatively black ($\epsilon_s = 1$). If the products of combustion at one atmosphere consist of 10% carbon dioxide, 5% water vapor, and 85% nitrogen, Figs. 9 to 11 can be used to estimate the gas emissivity and absorptivity. The beam length is $L = 3.6 \text{ V/A} = 29.0 \text{ ft}$. Then for H₂O, $p_w L = (29.0)(0.05) = 1.45 \text{ ft-atm (45 bar-cm)}$ and from Fig. 9 at 1393C the emissivity is found to be 0.22. For CO₂, $p_c L = (29.0)(0.10) = 2.90 \text{ ft-atm (89 bar-cm)}$ and from Fig. 10, at 1393C, the emissivity is found to be 0.16. The correction $\Delta\epsilon$ is determined from Fig. 11. The total gas emissivity is then found from Equation 41:

$$\epsilon_g = \epsilon_{\text{H}_2\text{O}} + \epsilon_{\text{CO}_2} - \Delta\epsilon_g \quad (95)$$

$$\epsilon_g = 0.22 + 0.16 - 0.06 = 0.32 \quad (96)$$

Hottel⁴ suggests calculating the absorptivity of the gas using modified pressure length parameters:

$$\begin{aligned} F_w &= p_w L \frac{T_s}{T_g} = (0.05)(29) \frac{1040 + 460}{2540 + 460} \\ &= 0.73 \text{ ft-atm (or 22 bar-cm)} \quad (97) \end{aligned}$$

$$\begin{aligned} F_c &= p_c L \frac{T_s}{T_g} = (0.10)(29) \frac{1040 + 460}{2540 + 460} \\ &= 1.45 \text{ ft-atm (or 45 bar-cm)} \quad (98) \end{aligned}$$

$$\begin{aligned} \alpha_{\text{H}_2\text{O}} &= \epsilon_{\text{H}_2\text{O}} (F_w, T_s) \times \left(\frac{T_g}{T_s} \right)^{0.45} \\ &= 0.21 \left(\frac{2540 + 460}{1040 + 460} \right)^{0.45} = 0.29 \quad (99) \end{aligned}$$

$$\begin{aligned} \alpha_{\text{CO}_2} &= \epsilon_{\text{CO}_2} (F_c, T_s) \times \left(\frac{T_g}{T_s} \right)^{0.65} \\ &= 0.15 \left(\frac{2540 + 460}{1040 + 460} \right)^{0.65} = 0.24 \quad (100) \end{aligned}$$

$$\Delta\alpha_g = \Delta\epsilon(T_s) = 0.04 \quad (101)$$

$$\alpha_g = \alpha_{\text{H}_2\text{O}} + \alpha_{\text{CO}_2} - \Delta\alpha_g = 0.49 \quad (102)$$

The net rate of heat flow calculated from Equation 40:

$$\begin{aligned} q_{sg} &= A (\epsilon_g E_{bg} - \alpha_g E_{bs}) \\ &= 19,860 (0.32 \sigma 3000^4 - 0.49 \sigma 1500^4) \quad (103) \\ &= 797 \times 10^6 \text{ Btu/h} \end{aligned}$$

In estimating boiler heat transfer, the beam lengths are large, effecting large pL values. Proprietary data are used to estimate the heat transfer for these values, and extrapolation of the curves in Figs. 9 to 11 is not recommended.

Example 7 – Radiation in a cavity

Radiation in a cavity containing absorbing gases can be analyzed with the concepts previously presented. These concepts are useful in analyzing surface to surface heat transfer. Examples include boiler wall to boiler wall, platen to platen, and boiler wall to boiler enclosure heat exchanges. Table 5 (and Reference 4) contains the thermal resistances used in constructing the thermal circuit in Fig. 41. Note the resistance between surface 1 and 2 decreases as the transmission in the gas, τ_{12} , increases to a transparent condition $\tau_{12} = 1$. At τ_{12} near zero, the gases are opaque, and the resistance is very large. As the gas emissivity decreases, the thermal circuit reduces to Fig. 6 and Equation 36. The solution of the circuit in Fig. 41 is found using Kirchhoff's rule for nodes J_1 and J_2 . The equations are solved simultaneously for J_1 and J_2 :

$$\frac{E_{b1} - J_1}{\frac{1 - \epsilon_1}{\epsilon_1 A_1}} + \frac{J_2 - J_1}{\frac{1}{A_1 F_{12} \tau_{12}}} + \frac{E_{bg} - J_1}{\frac{1}{A_1 \epsilon_{g1}}} = 0 \quad (104)$$

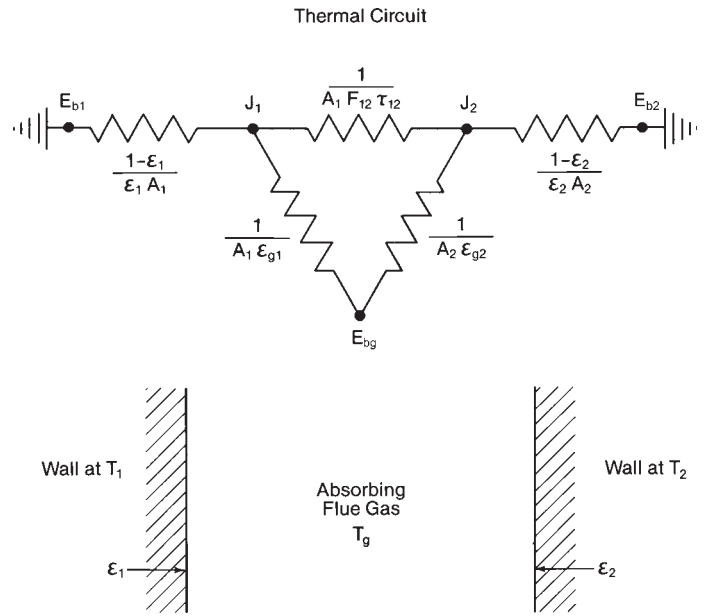

Fig. 41 Example of radiation in a cavity.

$$\frac{E_{b2} - J_2}{\frac{1 - \epsilon_2}{\epsilon_2 A_2}} + \frac{J_1 - J_2}{\frac{1}{A_1 F_{12} \tau_{12}}} + \frac{E_{bg} - J_2}{\frac{1}{A_1 \epsilon_{g2}}} = 0 \quad (105)$$

The net heat flow between the surfaces is:

$$q_{12} = A_1 F_{12} \tau_{12} (J_1 - J_2) \quad (106)$$

Hottel⁴ demonstrates the procedures for finding the beam length to determine F_{12} , ϵ_{g1} , and ϵ_{g2} .

Chapter 5

Boiling Heat Transfer, Two-Phase Flow and Circulation

A case of heat transfer and flow of particular interest in steam generation is the process of boiling and steam-water flow. The boiling or evaporation of water is a familiar phenomenon. In general terms, boiling is the heat transfer process where heat addition to a liquid no longer raises its temperature under constant pressure conditions; the heat is absorbed as the liquid becomes a gas. The heat transfer rates are high, making this an ideal cooling method for surfaces exposed to the high heat input rates found in fossil fuel boilers, concentrated solar energy collectors and the nuclear reactor fuel bundles. However, the boiling phenomenon poses special challenges such as: 1) the sudden breakdown of the boiling behavior at very high heat input rates, 2) the potential flow rate fluctuations which may occur in steam-water flows, and 3) the efficient separation of steam from water. An additional feature of boiling and two-phase flow is the creation of significant density differences between heated and unheated tubes. These density differences result in water flowing to the heated tubes in a well designed boiler natural circulation loop.

Most fossil fuel steam generators and all commercial nuclear steam supply systems operate in the pressure range where boiling is a key element of the heat transfer process. Therefore, a comprehensive understanding of boiling and its various related phenomena is essential in the design of these units. Even at operating conditions above the critical pressure, where water no longer boils but experiences a continuous transition from a liquid-like to a gas-like fluid, boiling type behavior and special heat transfer characteristics occur.

Boiling process and fundamentals

Boiling point and thermophysical properties

The boiling point, or saturation temperature, of a liquid can be defined as the temperature at which its vapor pressure is equal to the total local pressure. The saturation temperature for water at atmospheric pressure is 212F (100C). This is the point at which net vapor generation occurs and free steam bubbles are formed from a liquid undergoing continuous heating. As discussed in Chapter 2, this saturation tempera-

ture (T_{sat}) is a unique function of pressure. The American Society of Mechanical Engineers (ASME) and the International Association for the Properties of Steam (IAPS) have compiled extensive correlations of thermophysical characteristics of water. These characteristics include the enthalpy (or heat content) of water, the enthalpy of evaporation (also referred to as the latent heat of vaporization), and the enthalpy of steam. As the pressure is increased to the critical pressure [3200 psi (22.1 MPa)], the latent heat of vaporization declines to zero and the bubble formation associated with boiling no longer occurs. Instead, a smooth transition from liquid to gaseous behavior occurs with a continuous increase in temperature as energy is applied.

Two other definitions are also helpful in discussing boiling heat transfer:

1. **Subcooling** For water below the local saturation temperature, this is the difference between the saturation temperature and the local water temperature ($T_{sat} - T$).
2. **Quality** This is the flowing mass fraction of steam (frequently stated as percent steam by weight or %SBW after multiplying by 100%):

$$x = \frac{\dot{m}_{\text{steam}}}{\dot{m}_{\text{water}} + \dot{m}_{\text{steam}}} \quad (1)$$

where

\dot{m}_{steam} = steam flow rate, lb/h (kg/s)

\dot{m}_{water} = water flow rate, lb/h (kg/s)

Thermodynamically, this can also be defined as:

$$x = \frac{H - H_f}{H_g - H_f} \text{ or } \frac{H - H_f}{H_g - H_f} \quad (2)$$

where

H = local average fluid enthalpy, Btu/lb (J/kg)

H_f = enthalpy of water at saturation, Btu/lb (J/kg)

H_g = enthalpy of steam at saturation, Btu/lb (J/kg)

H_{fg} = latent heat of vaporization, Btu/lb (J/kg)

When boiling is occurring at saturated, thermal equilibrium conditions, Equation 2 provides the fractional steam flow rate by mass. For subcooled condi-

tions where $H < H_g$, quality (x) can be negative and is an indication of liquid subcooling. For conditions where $H > H_g$, this value can be greater than 100% and represents the amount of average superheat of the steam.

Boiling curve

Fig. 1 illustrates a boiling curve which summarizes the results of many investigators. This curve provides the results of a heated wire in a pool, although the characteristics are similar for most situations. The heat transfer rate per unit area, or *heat flux*, is plotted versus the temperature differential between the metal surface and the bulk fluid. From points A to B, convection heat transfer cools the wire and boiling on the surface is suppressed. Moving beyond point B, which is also referred to as the *incipient boiling point*, the temperature of the fluid immediately adjacent to the heated surface slightly exceeds the local saturation temperature of the fluid while the bulk fluid remains subcooled. Bubbles, initially very small, begin to form adjacent to the wire. The bubbles then periodically collapse as they come into contact with the cooler bulk fluid. This phenomenon, referred to as *subcooled boiling*, occurs between points B and S on the curve. The heat transfer rate is quite high, but no net steam generation occurs. From points S to C, the temperature of the bulk fluid has reached the local saturation temperature. Bubbles are no longer confined to the area immediately adjacent to the surface, but move into the bulk fluid. This region is usually referred to as the *nucleate boiling* region, and as with subcooled boiling, the heat transfer rates are quite high and the metal surface is only slightly above the saturation temperature.

As point C is approached, increasingly large surface evaporation rates occur. Eventually, the vapor generation rate becomes so large that it restricts the liquid return flow to the surface. The surface eventually becomes covered (blanketed) with an insulating layer of steam and the ability of the surface to transfer heat drops. This transition is referred to as the

critical heat flux (CHF), *departure from nucleate boiling (DNB)*, *burnout*, *dryout*, *peak heat flux*, or *boiling crisis*. The temperature response of the surface under this condition depends upon how the surface is being heated. In fossil fuel boiler furnaces and nuclear reactor cores, the heat input is effectively independent of surface temperature. Therefore, a reduction in the heat transfer rate results in a corresponding increase in surface temperature from point D to D' in Fig. 1. In some cases, the elevated surface temperature is so high that the metal surface may melt. If, on the other hand, the heat input or heat transfer rate is dependent upon the surface temperature, typical of a nuclear steam generator, the average local temperature of the surface increases as the local heat transfer rate declines. This region, illustrated in Fig. 1 from points D to E, is typically referred to as *unstable film boiling* or *transition boiling*. Because a large surface temperature increase does not occur, the main consequences are a decline in heat transfer performance per unit surface area and less overall energy transfer. The actual local phenomenon in this region is quite complex and unstable as discrete areas of surface fluctuate between a wetted boiling condition and a steam blanketed, or dry patch, condition. From position E through D' to F, the surface is effectively blanketed by an insulating layer of steam or vapor. Energy is transferred from the solid surface through this layer by radiation, conduction and microconvection to the liquid-vapor interface. From this interface, evaporation occurs and bubbles depart. This heat transfer region is frequently referred to as *stable film boiling*.

In designing steam generating systems, care must be exercised to control which of these phenomena occur. In high heat input locations, such as the furnace area of fossil fuel boilers or nuclear reactor cores, it is important to maintain nucleate or subcooled boiling to adequately cool the surface and prevent material failures. However, in low heat flux areas or in areas where the heat transfer rate is controlled by the boiling side heat transfer coefficient, stable or unstable film boiling may be acceptable. In these areas, the resultant heat transfer rate must be evaluated, any temperature limitations maintained and only allowable temperature fluctuations accepted.

Flow boiling

Flow or forced convective boiling, which is found in virtually all steam generating systems, is a more complex phenomenon involving the intimate interaction of two-phase fluid flow, gravity, material phenomena and boiling heat transfer mechanisms. Fig. 2 is a classic picture of boiling water in a long, uniformly heated, circular tube. The water enters the tube as a subcooled liquid and convection heat transfer cools the tube. The point of incipient boiling is reached (point 1 in Fig. 2). This results in the beginning of subcooled boiling and bubbly flow. The fluid temperature continues to rise until the entire bulk fluid reaches the saturation temperature and nucleate boiling occurs, point 2. At this location, flow boiling departs somewhat from the simple pool boiling model previously discussed. The steam-water mixture progresses through a series of

Fig. 1 Boiling curve – heat flux versus applied temperature difference.

flow structures or patterns: bubbly, intermediate and annular. This is a result of the complex interaction of surface tension forces, interfacial phenomena, pressure drop, steam-water densities and momentum effects coupled with the surface boiling behavior. While boiling heat transfer continues throughout, a point is reached in the annular flow regime where the liquid film on the wall becomes so thin that nucleation in the film is suppressed, point 3. Heat transfer then occurs through conduction and convection across the thin annular film with surface evaporation at the steam-water interface. This heat transfer mechanism, called *convective boiling*, also results in high heat transfer rates. It should also be noted that not all of the liquid is on the tube wall. A portion is entrained in the steam core as dispersed droplets.

Eventually, an axial location, point 4, is reached where the tube surface is no longer wetted and CHF or dryout occurs. This is typically associated with a temperature rise. The exact tube location and magnitude of this temperature, however, depend upon a variety of parameters, such as the heat flux, mass flux, geometry and steam quality. Fig. 3 illustrates the effect of heat input rate, or heat flux, on CHF location and the associated temperature increase. From points 4 to 5 in Fig. 2, post-CHF heat transfer, which is quite complex, occurs. Beyond point 5, all of the liquid is evaporated and simple convection to steam occurs.

Boiling heat transfer evaluation

Engineering design of steam generators requires the evaluation of water and steam heat transfer rates under boiling and nonboiling conditions. In addition, the

Fig. 2 Simplified flow boiling in a vertical tube (adapted from Collier¹).

identification of the location of critical heat flux (CHF) is important where a dramatic reduction in the heat transfer rate could lead to: 1) excessive metal temperatures potentially resulting in tube failures, 2) an unacceptable loss of thermal performance, or 3) unacceptable temperature fluctuations leading to thermal fa-

Fig. 3 Tube wall temperatures under different heat input conditions.

tigue failures. Data must also be available to predict the rate of heat transfer downstream of the dryout point. CHF phenomena are less important than the heat transfer rates for performance evaluation, but are more important in defining acceptable operating conditions. As discussed in Chapter 4, the heat transfer rate per unit area or heat flux is equal to the product of temperature difference and a heat transfer coefficient.

Heat transfer coefficients

Heat transfer correlations are application (surface and geometry) specific and The Babcock & Wilcox Company (B&W) has developed extensive data for its applications through experimental testing and field experience. These detailed correlations remain proprietary to B&W. However, the following generally available correlations are provided here as representative of the heat transfer relationships.

Single-phase convection Several correlations for forced convection heat transfer are presented in Chapter 4. Forced convection is assumed to occur as long as the calculated forced convection heat flux is greater than the calculated boiling heat flux (point 1 in Fig. 2):

$$q''_{\text{Forced Convection}} > q''_{\text{Boiling}} \quad (3)$$

While not critical in most steam generator applications, correlations are available which explicitly define this onset of subcooled boiling and more accurately define the transition region.¹

Subcooled boiling In areas where subcooled boiling occurs, several correlations are available to characterize the heat transfer process. Typical of these is the Jens and Lottes² correlation for water. For inputs with English units:

$$\Delta T_{\text{sat}} = 60 (q''/10^6)^{1/4} e^{-P/900} \quad (4a)$$

and for inputs with SI units:

$$\Delta T_{\text{sat}} = 25 (q'')^{1/4} e^{-P/6.2} \quad (4b)$$

where

$$\begin{aligned} \Delta T_{\text{sat}} &= T_w - T_{\text{sat}}, \text{ F (C)} \\ T_w &= \text{wall temperature, F (C)} \\ T_{\text{sat}} &= \text{saturated water temperature, F (C)} \\ q'' &= \text{heat flux, Btu/h ft}^2 \text{ (MW/m}^2\text{)} \\ P &= \text{pressure, psi (MPa)} \end{aligned}$$

Another relationship frequently used is that developed by Thom.³

Nucleate and convective boiling Heat transfer in the saturated boiling region occurs by a complex combination of bubble nucleation at the tube surface (nucleate boiling) and direct evaporation at the steam-water interface in annular flow (convective boiling). At low steam qualities, nucleate boiling dominates while at higher qualities convective boiling dominates. While separate correlations are available for each range, the most useful relationships cover the entire saturated boiling regime. They typically involve the summation of appropriately weighted nucleate and convective

boiling components as exemplified by the correlation developed by J.C. Chen and his colleagues.⁴ While such correlations are frequently recommended for use in saturated boiling systems, their additional precision is not usually required in many boiler or reactor applications. For general evaluation purposes, the subcooled boiling relationship provided in Equation 4 is usually sufficient.

Post-CHF heat transfer As shown in Fig. 3, substantial increases in tube wall metal temperatures are possible if boiling is interrupted by the CHF phenomenon. The maximum temperature rise is of particular importance in establishing whether tube wall overheating may occur. In addition, the reliable estimation of the heat transfer rate may be important for an accurate assessment of thermal performance. Once the metal surface is no longer wetted and water droplets are carried along in the steam flow, the heat transfer process becomes more complex and includes: 1) convective heat transfer to the steam which becomes superheated, 2) heat transfer to droplets impinging on the surface from the core of the flow, 3) radiation directly from the surface to the droplets in the core flow, and 4) heat transfer from the steam to the droplets. This process results in a nonequilibrium flow featuring superheated steam mixed with water droplets. Current correlations do not provide a good estimate of the heat transfer in this region, but computer models show promise. Accurate prediction requires the use of experimental data for similar flow conditions.

Reflooding A key concept in evaluating emergency core coolant systems for nuclear power applications is *reflooding*. In a loss of coolant event, the reactor core can pass through critical heat flux conditions and can become completely dry. Reflooding is the term for the complex thermal-hydraulic phenomena involved in rewetting the fuel bundle surfaces as flow is returned to the reactor core. The fuel elements may be at very elevated temperatures so that the post-CHF, or steam blanketed, condition may continue even in the presence of returned water flow. Eventually, the surface temperature drops enough to permit a rewetting front to wash over the fuel element surface. Analysis includes transient conduction of the fuel elements and the interaction with the steam-water heat transfer processes.

Critical heat flux phenomena

Critical heat flux is one of the most important parameters in steam generator design. CHF denotes the set of operating conditions (mass flux, pressure, heat flux and steam quality) covering the transition from the relatively high heat transfer rates associated with nucleate or forced convective boiling to the lower rates resulting from transition or film boiling (Figs. 1 and 2). These operating conditions have been found to be geometry specific. CHF encompasses the phenomena of departure from nucleate boiling (DNB), burnout, dryout and boiling crisis. One objective in recirculating boiler and nuclear reactor designs is to avoid CHF conditions. In once-through steam generators, the objective is to design to accommodate the temperature increase at the CHF locations. In this process, the heat flux profile, flow passage geometry, operating pressure

and inlet enthalpy are usually fixed, leaving mass flux, local quality, diameter and some surface effects as the more easily adjusted variables.

Factors affecting CHF Critical heat flux phenomena under flowing conditions found in fossil fuel and nuclear steam generators are affected by a variety of parameters.⁵ The primary parameters are the operating conditions and the design geometries. The operating conditions affecting CHF are pressure, mass flux and steam quality. Numerous design geometry factors include flow passage dimensions and shape, flow path obstructions, heat flux profile, inclination and wall surface configuration. Several of these effects are illustrated in Figs. 3 through 7.

Fig. 3 illustrates the effect of increasing the heat input on the location of the temperature excursion in a uniformly heated vertical tube cooled by upward flowing water. At low heat fluxes, the water flow can be almost completely evaporated to steam before any temperature rise is observed. At moderate and high heat fluxes, the CHF location moves progressively towards the tube inlet and the maximum temperature excursion increases. At very high heat fluxes, CHF occurs at a low steam quality and the metal temperature excursion can be high enough to melt the tube. At extremely high heat input rates, CHF can occur in subcooled water. Avoiding this type of CHF is an important design criterion for pressurized water nuclear reactors.

Many large fossil fuel boilers are designed to operate between 2000 and 3000 psi (13.8 and 20.7 MPa). In this range, pressure has a very important effect, shown in Fig. 4, with the steam quality limit for CHF

Fig. 4 Steam quality limit for CHF as a function of pressure.

falling rapidly near the critical pressure; i.e., at constant heat flux, CHF occurs at lower steam qualities as pressure rises.

Many CHF correlations have been proposed and are satisfactory within certain limits of pressure, mass velocity and heat flux. Fig. 5 is an example of a correlation which is useful in the design of fossil fuel natural circulation boilers. This correlation defines safe and unsafe regimes for two heat flux levels at a given pressure in terms of steam quality and mass velocity. Additional factors must be introduced when tubes are used in membrane or tangent wall construction, are inclined from the vertical, or have different inside diameter or surface configuration. The inclination of the flow passage can have a particularly dramatic effect on the CHF conditions as illustrated in Fig. 6.⁶

Ribbed tubes Since the 1930s, B&W has investigated a large number of devices, including internal twistors, springs and grooved, ribbed and corrugated tubes to delay the onset of CHF. The most satisfactory overall performance was obtained with tubes having helical ribs on the inside surface.

Two general types of rib configurations have been developed:

1. single-lead ribbed (SLR) tubes (Fig. 8a) for small internal diameters used in once-through subcritical pressure boilers, and
2. multi-lead ribbed (MLR) tubes (Fig. 8b) for larger internal diameters used in natural circulation boilers.

Both of these ribbed tubes have shown a remarkable ability to delay the breakdown of boiling. Fig. 7

Fig. 5 Steam quality limit for CHF as a function of mass flux.

Fig. 6 Effect of inclination on CHF at 700,000 lb/h ft² (950 kg/m² s).⁶

compares the effectiveness of a ribbed tube to that of a smooth tube in a membrane wall configuration. This plot is different from Fig. 5 in that heat flux is given as an average over the flat projected surface. This is more meaningful in discussing membrane wall heat absorption.

The ribbed bore tubes provide a balance of improved CHF performance at an acceptable increase in pressure drop without other detrimental effects. The ribs generate a swirl flow resulting in a centrifugal action which forces the water to the tube wall and retards entrainment of the liquid. The steam blanketing and film dryout are therefore prevented until substantially higher steam qualities or heat fluxes are reached.

Fig. 7 Steam quality limit for CHF in smooth and ribbed bore tubes.

Fig. 8a Single-lead ribbed tube.

Fig. 8b Multi-lead ribbed tube.

Because the ribbed bore tube is more expensive than a smooth bore tube, its use involves an economic balance of several design factors. In most instances, there is less incentive to use ribbed tubes below 2200 psi (15.2 MPa).

Evaluation CHF is a complex combination of thermal-hydraulic phenomena for which a comprehensive theoretical basis is not yet available. As a result, experimental data are likely to continue to be the basis for CHF evaluations. Many data and correlations define CHF well over *limited* ranges of conditions and geometries. However, progress is being made in developing more general evaluation procedures for at least the most studied case – a uniformly heated smooth bore tube with upward flowing water.

To address this complex but critical phenomenon in the design of reliable steam generating equipment, B&W has developed an extensive proprietary database and associated correlations. A graphical example is shown in Fig. 5 for a fossil fuel boiler tube. A B&W correlation⁷ for nuclear reactor fuel rod bundle subchannel analysis is shown in Table 1.

CHF criteria A number of criteria are used to assess the CHF margins in a particular tube or tube bundle geometry.⁸ These include the CHF ratio, flow ratio and quality margin, defined as follows:

1. CHF ratio = minimum value of $\frac{\text{CHF heat flux}}{\text{upset heat flux}}$
2. flow ratio = minimum value of $\frac{\text{min. design mass flux}}{\text{mass flux at CHF}}$
3. quality margin = CHF quality – max. design quality

The CHF ratios for a sample fossil fuel boiler are illustrated in Fig. 9 for a smooth bore tube (q''_B/q''_A) and a ribbed bore tube (q''_C/q''_A). The graph indicates the relative increase in local heat input which can be tolerated before the onset of CHF conditions. A similar relationship for a nuclear reactor fuel rod application is shown in Fig. 10.

Supercritical heat transfer

Unlike subcritical pressure conditions, fluids at supercritical pressures experience a continuous transition from water-like to steam-like characteristics. As a result, CHF conditions and boiling behavior would not be expected. However, at supercritical pressures, especially in the range of $1 < P/P_c < 1.15$ where P_c is the critical pressure, two types of boiling-like behavior have been observed: pseudo-boiling and pseudo-film boiling. Pseudo-boiling is an increase in heat transfer coefficient not accounted for by traditional convection relationships. In pseudo-film boiling, a dramatic reduction in the heat transfer coefficient is observed at high heat fluxes. This is similar to the critical heat flux condition at subcritical pressures.

These behaviors have been attributed to the sharp changes in fluid properties as the transition from water-like to steam-like behavior occurs.

Fluid properties In the supercritical region, the thermophysical properties important to the heat transfer process, i.e., conductivity, viscosity, density and specific heat, experience radical changes as a certain pressure-dependent temperature is approached and exceeded. This is illustrated in Fig. 11. The transition temperature, referred to as the pseudo-critical temperature, is defined as the temperature where the specific heat, c_p , reaches its maximum. As the operating pressure is increased, the pseudo-critical temperature increases and the dramatic change in the thermophysical properties declines as this temperature is approached and exceeded.

Heat transfer rates Because of the significant changes in thermophysical properties (especially in specific heat) near the pseudo-critical temperature, a

Fig. 9 Fossil boiler CHF ratio = minimum value of critical heat flux divided by upset heat flux.

Table 1
B&W2 Reactor Rod Bundle Critical Heat Flux (CHF) Correlation⁷

$$q''_{CHF} = \frac{(a - bD_i) \left[A_1 (A_2 G)^{A_3 + A_4(P-2000)} - A_9 G x_{CHF} H_{fg} \right]}{A_5 (A_6 G)^{A_7 + A_8(P-2000)}}$$

where

$a = 1.15509$	A = area, in. ²
$b = 0.40703$	D_i = equivalent diameter = $4A/Per$
$A_1 = 0.37020 \times 10^8$	G = mass flux, lb/h ft ²
$A_2 = 0.59137 \times 10^{-6}$	H_{fg} = latent heat of vaporization, Btu/lb
$A_3 = 0.83040$	P = pressure, psi
$A_4 = 0.68479 \times 10^{-3}$	Per = wetted perimeter, in.
$A_5 = 12.710$	x_{CHF} = steam quality at CHF conditions, fraction steam by weight
$A_6 = 0.30545 \times 10^{-5}$	q''_{CHF} = heat flux at CHF conditions, Btu/h ft ²
$A_7 = 0.71186$	
$A_8 = 0.20729 \times 10^{-3}$	
$A_9 = 0.15208$	

modified approach to evaluating convective heat transfer is needed. A number of correlations have been developed and a representative relationship for smooth bore tubes is:⁹

$$\frac{hD_i}{k_w} = 0.00459 \left[\frac{D_i G}{\mu_w} \right]^{0.923} \times \left[\left(\frac{H_w - H_b}{T_w - T_b} \right) \left(\frac{\mu_w}{k_w} \right) \right]^{0.613} \left[\frac{v_b}{v_w} \right]^{0.231} \quad (5)$$

Fig. 10 Nuclear reactor CHF ratio = minimum value of critical heat flux divided by design heat flux.

Fig. 11 Thermophysical properties of water (English units).

where

- h = heat transfer coefficient, Btu/h ft² F (W/m² K)
- k = thermal conductivity, Btu/h ft F (W/m K)
- D_i = inside tube diameter, ft (m)
- G = mass flux, lb/h ft² (kg/m² s)
- μ = viscosity, lb/ft h (kg/m s)
- H = enthalpy, Btu/lb (J/kg)
- T = temperature, F (C)
- v = specific volume, ft³/lb (m³/kg)

The subscripts b and w refer to properties evaluated at the bulk fluid and wall temperatures respectively.

This correlation has demonstrated reasonable agreement with experimental data from tubes of 0.37 to 1.5 in. (9.4 to 38.1 mm) inside diameter and at low heat fluxes.

Pseudo-boiling For low heat fluxes and bulk fluid temperatures approaching the pseudo-critical temperature, an improvement in the heat transfer rate takes place. The enhanced heat transfer rate observed is sometimes referred to as pseudo-boiling. It has been attributed to the increased turbulence resulting from the interaction of the water-like and steam-like fluids near the tube wall.

Pseudo-film boiling Potentially damaging temperature excursions associated with a sharp reduction in heat transfer can be observed at high heat fluxes. This temperature behavior is similar to the CHF phenomenon observed at subcritical conditions and is referred to as pseudo-film boiling. This phenomenon has been attributed to a limited ability of the available

turbulence to move the higher temperature steam-like fluid away from the tube wall into the colder, higher density (water-like) fluid in the bulk stream. A phenomenon similar to steam blanketing occurs and the wall temperature increases in response to the relatively constant applied heat flux.

Single-lead ribbed (SLR) bore tubes are very effective in suppressing the temperature peaks encountered in smooth bore tubes.¹⁰

Two-phase flow

Flow patterns

As illustrated in Fig. 2, two-phase steam-water flow may occur in many regimes or structures. The transition from one structure to another is continuous rather than abrupt, especially under heated conditions, and is strongly influenced by gravity, i.e., flow orientation. Because of the qualitative nature of flow pattern identification, there are probably as many flow pattern descriptions as there are observers. However, for vertical, heated, upward, co-current steam-water flow in a tube, four general flow patterns are generally recognized (see Fig. 12):

1. **Bubbly flow** Relatively discrete steam bubbles are dispersed in a continuous liquid water phase. Bubble size, shape and distribution are dependent upon the flow rate, local enthalpy, heat input rate and pressure.
2. **Intermediate flow** This is a range of patterns between bubbly and annular flows; the patterns are also referred to as slug or churn flow. They range from: a) large bubbles, approaching the tube size in diameter, separated from the tube wall by thin annular films and separated from each other by slugs of liquid which may also contain smaller bubbles, to b) chaotic mixtures of large nonsymmetric bubbles and small bubbles.
3. **Annular flow** A liquid layer is formed on the tube wall with a continuous steam core; most of the liq-

Fig. 12 Flow pattern – upward, co-current steam-water flow in a heated vertical tube.

uid is flowing in the annular film. At lower steam qualities, the liquid film may have larger amplitude waves adding to the liquid droplet entrainment and transport in the continuous steam core. At high qualities, the annular film becomes very thin, bubble generation is suppressed and the large amplitude waves disappear.

4. **Mist flow** A continuous steam core transports entrained water droplets which slowly evaporate until a single-phase steam flow occurs. This is also referred to as droplet or dispersed flow.

In the case of inclined and horizontal co-current steam-water flow in heated tubes, the flow patterns are further complicated by stratification effects. At high flow rates, the flow patterns approach those of vertical tubes. At lower rates, additional distinct flow patterns (wavy, stratified and modified plug) emerge as gravity stratifies the flow with steam concentrated in the upper portion of the tube. This can be a problem where inclined tubes are heated from the top. CHF or dryout conditions occur at much lower steam qualities and lower heat input rates in such inclined or horizontal tubes.

Additional complexity in patterns is observed when two-phase flow occurs in parallel or crossflow tube bundles. The tubes, baffles, support plates and mixing devices further disrupt the flow pattern formation.

Flow maps The transitions from one flow regime to another are quite complex, with each transition representing a combination of factors. However, two dimensional flow maps provide at least a general indication of which flow pattern is likely under given operating conditions. The maps generally are functions of superficial gas and liquid velocities. An example for vertical, upward, steam-water co-current flow is provided in Fig. 13.¹¹ The axes in this figure represent the superficial momentum fluxes of the steam (y-axis) and water (x-axis). A sample flow line is shown beginning with nearly saturated water conditions and ending with saturated steam conditions. The tube experiences bubbly flow only near its inlet. This is followed by a brief change to intermediate flow before annular flow dominates the heated length.

Other flow maps are available for arrangements such as downflow tubes, inclined tubes and bundles. Flow maps, however, are only approximations providing guidance in determining the relevant flow structure for a given situation.

Pressure loss

The local pressure loss, ΔP [lb/ft² (Pa)] or gradient $\delta P / \delta l$ [lb/ft²/ft (Pa/m)] in a two-phase steam-water system may be represented by:

$$\Delta P = \Delta P_f + \Delta P_a + \Delta P_g + \Delta P_l \quad (6a)$$

or

$$-\frac{\delta P}{\delta l} = -\left(\frac{\delta P}{\delta l}\right)_f - \left(\frac{\delta P}{\delta l}\right)_a - \left(\frac{\delta P}{\delta l}\right)_g + \Delta P_l \quad (6b)$$

The ΔP_f and $-(\delta P / \delta l)_f$ terms account for local wall friction losses. The ΔP_a and $-(\delta P / \delta l)_a$ terms address

Fig. 13 Flow pattern map for vertical upward flow of water.¹¹

the momentum or acceleration loss incurred as the volume increases due to evaporation. The hydraulic or static head loss is accounted for by ΔP_g and $-(\delta P / \delta l)_g$. Finally, all of the local losses due to fittings, contractions, expansions, bends, or orifices are included in ΔP_l . The evaluation of these parameters is usually made using one of two models: homogeneous flow or separated flow.

A parameter of particular importance when evaluating the pressure loss in steam-water flows is void fraction. The void fraction can be defined by time-averaged flow area ratios or local-volume ratios of steam to the total flow. The area-based void fraction, α , can be defined as the ratio of the time-averaged steam flow cross-sectional area (A_{steam}) to the total flow area ($A_{\text{steam}} + A_{\text{water}}$):

$$\alpha = \frac{A_{\text{steam}}}{A_{\text{steam}} + A_{\text{water}}} \quad (7)$$

Using the simple continuity equation, the relationship between quality, x , and void fraction is:

$$\alpha = \frac{x}{x + (1-x) \frac{\rho_g}{\rho_f} S} \quad (8)$$

where

S = ratio of the average cross-sectional velocities of steam and water (referred to as *slip*)

ρ_g = saturated steam density, lb/ft³ (kg/m³)

ρ_f = saturated water density, lb/ft³ (kg/m³)

If the steam and water are moving at the same velocity, $S = 1$ (no slip). Obviously, the relationship between void fraction and quality is also a strong function of system pressure. This relationship is illustrated in Fig. 14. The difference between the homogeneous and separated flow models is illustrated by the shaded band. The upper bound is established by the homogeneous model and the lower bound by the separated flow model.

Homogeneous model The homogeneous model is the simpler approach and is based upon the premise that the two-phase flow behavior can be directly modeled after single-phase behavior (see Chapter 3) if appropriate average properties are determined. The temperature and velocities of steam and water are assumed equal. The mixed weight averaged specific volume (v) or the inverse of the homogeneous density ($1/\rho_{\text{hom}}$) is used:

$$v = v_f (1-x) + v_g x \quad (9a)$$

or

$$\frac{1}{\rho_{\text{hom}}} = \frac{(1-x)}{\rho_f} + \frac{x}{\rho_g} \quad (9b)$$

where

- v_f = saturated water specific volume, ft³/lb (m³/kg)
- v_g = saturated steam specific volume, ft³/lb (m³/kg)
- ρ_f = saturated water density, lb/ft³ (kg/m³)
- ρ_g = saturated steam density, lb/ft³ (kg/m³)
- x = steam quality

This model provides reasonable results when high or low steam qualities exist, when high flow rates are present, or at higher pressures. In these cases, the flow is reasonably well mixed.

Fig. 14 Void fraction – quality relationship (homogeneous model, upper bound; separated flow model, lower bound).

The friction pressure drop (ΔP_f) can be evaluated by the equations provided in Chapter 3 using the mixture thermophysical properties. The pressure difference due to elevation (ΔP_g) can be evaluated as:

$$\Delta P_g = \pm \rho_{\text{hom}} \left(\frac{g}{g_c} \right) L \sin \theta \quad (10)$$

where

- g = acceleration of gravity, ft/s² (m/s²)
- g_c = 32.17 lbm ft/lbf s² (1 kg m/N s²)
- L = length, ft (m)
- θ = angle from the horizontal

The constant g_c is discussed in Chapter 2. A pressure gain occurs in downflow and a pressure loss occurs in upflow. The acceleration loss can be evaluated by:

$$\Delta P_a = \frac{G^2}{g_c} \left(\frac{1}{\rho_{\text{out}}} - \frac{1}{\rho_{\text{in}}} \right) \quad (11)$$

where

- G = mass flux, lb/s ft² (kg/m²s)
- ρ_{out} = outlet homogeneous density, lb/ft³ (kg/m³)
- ρ_{in} = inlet homogeneous density, lb/ft³ (kg/m³)

Separated flow model In the steady-state separated flow model, the steam and water are treated as separate streams under the same pressure gradient but different velocities and differing properties. When the actual flow velocities of steam and water are equal, the simplest separated flow models approach the homogeneous case. Using one of several separated flow models¹ with unequal velocities, the pressure drop components (in differential form) are:

$$-\left(\frac{\delta P}{\delta l} \right)_f = -\left(\frac{\delta P}{\delta l} \right)_{LO} \phi_{LO}^2 \quad (\text{friction}) \quad (12)$$

$$-\left(\frac{\delta P}{\delta l} \right)_{LO} = \frac{f}{D_i} \frac{G^2 v_f}{2 g_c} \quad (\text{single-phase friction}) \quad (13)$$

$$-\left(\frac{\delta P}{\delta l} \right)_a = \frac{G^2}{g_c} \frac{\delta}{\delta l} \left(\frac{x^2 v_g}{\alpha} + \frac{(1.0-x)^2 v_f}{(1.0-\alpha)} \right) \quad (\text{acceleration}) \quad (14)$$

$$-\left(\frac{\delta P}{\delta l} \right)_g = \frac{g}{g_c} \sin \theta \left(\frac{\alpha}{v_g} + \frac{(1.0-\alpha)}{v_f} \right) \quad (\text{static head}) \quad (15)$$

$$\Delta P_l = \Phi K \frac{G^2 v_f}{2 g_c} \quad (\text{local losses}) \quad (16)$$

where

- Φ and ϕ_{LO}^2 = appropriate two-phase multipliers
- G = mass flux, lb/s ft² (kg/m² s)
- f = fanning friction factor (see Chapter 3)
- D_i = tube inside diameter, ft (m)
- g = acceleration of gravity, ft/s² (m/s²)
- g_c = 32.17 lbm ft/lbf s² (1 kg m/N s²)

v_f = liquid specific volume, ft³/lb (m³/kg)
 v_g = vapor specific volume, ft³/lb (m³/kg)
 x = steam quality
 α = void fraction
 θ = angle from the horizontal
 K = loss coefficient

While ΔP_i usually represents just the irreversible pressure loss in single-phase flows, the complexity of two-phase flows results in the loss of ΔP_i typically representing the reversible and irreversible losses for fittings.

To evaluate the individual pressure losses from Equations 12 through 16 and Equation 6b, it is necessary to calculate ϕ_{LO}^2 , α and Φ . Unfortunately, these factors are not well defined.

Specific correlations and evaluations can only be used where experimental data under similar conditions provide confidence in the prediction. Proprietary correlations used by B&W are based upon experimental data and practical experience.

For straight vertical tubes, generally available representative relationships include:

1. **Acceleration loss** The void fraction can frequently be evaluated with the homogeneous model ($S = 1$ in Equation 8).
2. **Friction loss and void fraction** Typical two-phase multiplier, ϕ_{LO}^2 , and void fraction, α , relationships are presented by Thom,¹² Martinelli-Nelson,¹³ Zuber-Findlay¹⁴ and Chexal-Lellouche.¹⁵ For illustration purposes the correlations of Thom are presented in Figs. 15 and 16. These curves can be approximated by:

$$\phi_{LO}^2 = \left\{ \left[0.97303(1-x) + x \left(\frac{v_g}{v_f} \right) \right]^{0.5} \times \left[0.97303(1-x) + x \right]^{0.5} + 0.027(1-x) \right\}^{2.0} \quad (17)$$

and

$$\alpha = \frac{\gamma x}{1 + x(\gamma - 1)} \quad (18)$$

where

$\gamma = (v_g/v_f)^n$
 $n = (0.8294 - 1.1672/P)$
 P = pressure, psi
 v_g = saturated steam specific volume, ft³/lb
 v_f = saturated liquid specific volume, ft³/lb
 x = steam quality

Instabilities

Instability in two-phase flow refers to the set of operating conditions under which sudden changes in flow direction, reduction in flow rate and oscillating flow rates can occur in a single flow passage. Often in manifolded multi-channel systems, the overall mass flow rate can remain constant while oscillating flows in individual channels still may occur. Such unstable conditions in steam generating systems can result in:

Fig. 15 Thom two-phase friction multiplier.¹²

1. unit control problems, including unacceptable variations in steam drum water level,
2. CHF/DNB/dryout,
3. tube metal temperature oscillation and thermal fatigue failure, and
4. accelerated corrosion attack.

Two of the most important types of instabilities in steam generator design are excursive instability, including Ledinegg and flow reversal, and density wave/pressure drop oscillations. The first is a static instability evaluated using steady-state equations while the last is dynamic in nature requiring the inclusion of time dependent factors.

Fig. 16 Thom void fraction correlation (>3% SBW).¹²

Excursive and flow reversal instability evaluation The excursive instability is characterized by conditions where small perturbations in operating parameters result in a large flow rate change to a separate steady-state level. This can occur in both single channel and multi-channel manifolded systems. Excursive instabilities can be predicted by using the Ledinegg criteria.¹⁶ Instability may occur if the slope of the pressure drop versus flow characteristic curve (internal) for the tube becomes less than the slope of the supply (or applied) curve at any intersection point:

$$\left(\frac{\delta \Delta P}{\delta G} \right)_{\text{internal}} \leq \left(\frac{\delta \Delta P}{\delta G} \right)_{\text{applied}} \quad (19)$$

The stable and unstable situations are illustrated in Fig. 17. As shown in the figure for unstable conditions, if the mass flow rate drops below point B then the flow rate continues to fall dramatically because the applied pumping head is less than that needed to move the fluid. For slightly higher mass flow rates (higher than point B), a dramatic positive flow excursion occurs because the pumping head exceeds the flow system requirement.

In most systems, the first term in Equation 19 is generally positive and the second is negative. Therefore, Equation 19 predicts stability. However, in two-phase systems, thermal-hydraulic conditions may combine to produce a local area where $(\delta \Delta P / \delta G)_{\text{internal}}$ is negative and the potential for satisfying Equation 19 and observing an instability exists. A heated tube flow characteristic showing a potential region of instability is illustrated in Fig. 18 where multiple flow rates can occur for a single applied pressure curve. Operating at point B is unstable with small disturbances resulting in a shift to point A or point C. More intense disturbances could result in flow shifts between A and C.

For the relatively small subcooling found at the entrance to tube panels in recirculating drum boilers and due to the relatively low exit steam qualities, negative slope regions in the pressure drop versus flow curves are typically not observed for positive flow cases. However, for once-through fossil fuel boilers and nuclear steam generators with high subcooling at the inlet and evaporation to dryness, negative slope regions in the upflow portion of the pressure drop characteristic may occur. Steps can be taken to avoid operation in any region where the circuit internal $\delta \Delta P / \delta G \leq 0$. General effects of operating and design parameters on the pressure drop versus mass flow curves include:

Parameter Increased	Effect on ΔP	Comment
heat input	decrease	more stable
inlet ΔP	increase	more stable
pressure	increase	more stable

In situations where static instability may occur, the inlet pressure drop can be increased by adding an orifice or flow restriction to modify the overall flow characteristic as shown in Fig. 18.

(a) Stable

(b) Unstable

Fig. 17 Stable and unstable flow-pressure drop characteristics.

Fig. 18 Pressure drop characteristics showing unstable region.

Density wave/pressure drop instability Density wave instabilities involve kinematic wave propagation phenomena. Regenerative feedback between flow rate, vapor generation rate and pressure drop produce self sustaining alternating waves of higher and lower density mixture that travel through the tube. This dynamic instability can occur in single tubes that contain two-phase flows. In addition, when multiple tubes are connected by inlet and outlet headers, a more complex coupled channel instability, which is driven by density wave oscillations, may occur. Vertical heat flux distribution is a particularly sensitive parameter in dynamic instability evaluation.

Density wave oscillations can be predicted by the application of feedback control theory. A number of computer codes have been developed to provide these predictions. In addition, instability criteria, which use a series of dimensionless parameters to reduce the complexity of the evaluation, have been developed.

Effects of operating and design parameters on the density wave instability include:

Parameter Increased	Change in stability
mass flux	improved
heat flux	reduced
pressure	improved
inlet ΔP	improved
inlet subcooling	improved (large subcooling) reduced (small subcooling)

Steam-water separation

Subcritical pressure recirculating boilers and steam generators are equipped with large cylindrical vessels called *steam drums*. Their primary objective is to permit separation of the saturated steam from the steam-water mixture leaving the boiling heat transfer surfaces. The steam-free water is recirculated with the feedwater to the heat absorbing surfaces for further steam generation. The saturated steam is discharged through a number of outlet nozzles for direct use or further heating. The steam drum also serves to:

1. mix the feedwater with the saturated water remaining after steam separation,
2. mix the corrosion control and water treatment chemicals (if used),
3. purify the steam to remove contaminants and residual moisture,
4. remove part of the water (blowdown) to control the boiler water chemistry (solids content), and
5. provide limited water storage to accommodate rapid changes in boiler load.

However, the primary function of the steam drum is to permit the effective separation of steam and water. This may be accomplished by providing a large steam-water surface for natural gravity-driven separation or by having sufficient space for mechanical separation equipment.

High efficiency separation is critical in most boiler applications in order to:

1. prevent water droplet *carryover* into the superheater where thermal damage may occur,
2. minimize steam *carryunder* in the water leaving the drum where residual steam can reduce the effective hydraulic pumping head, and
3. prevent the carryover of solids dissolved in the steam-entrained water droplets into the superheater and turbine where damaging deposits may form.

The last item is of particular importance. Boiler water may contain contaminants, principally in solution. These arise from impurities in the makeup water, treatment chemicals and condensate system leaks, as well as from the reaction of the water and contaminants with the boiler and preboiler equipment materials. Even low levels of these solids in the steam (less than 0.6 ppm) can damage the superheater and turbine. Because the solubility of these solids is typically several orders of magnitude less in steam than in water (see Chapter 42), small amounts of water droplet carryover (greater than 0.25% by weight) may result in dramatically increased solids carryover and unacceptable deposition in the superheater and turbine. The deposits have caused turbine damage as well as superheater tube temperature increases, distortion and burnout.

A cross-section of a horizontal steam drum found on a modern high capacity fossil fuel boiler is shown in Fig. 19. This illustrates the general arrangement of the baffle plates, primary cyclone separators, secondary separator elements (scrubbers), water discharger (downcomer) and feedwater inlets. The blowdown (water removal) connections are not shown. The steam-water separation typically takes place in two stages. The primary separation removes nearly all the steam from the water so that very little steam is recirculated from the bottom of the drum through the outlet connection (downcomer) towards the heated tubes. The steam leaving the primary separators in high pressure boilers still typically contains too much liquid in the form of contaminant-containing droplets for satisfactory superheater and turbine performance. Therefore, the steam is passed through a secondary set of separators, or scrubber elements (usually closely spaced, corrugated parallel plates) for final water droplet removal. The steam is then exhausted through several connections. As this figure indicates, successful steam-water separation involves the integrated operation of primary separators, secondary scrubbers and general drum arrangement.

Factors affecting steam separation

Effective steam separation from the steam-water mixture relies on certain design and operating factors. The design factors include:

1. pressure,
2. drum length and diameter,
3. rate of steam generation,
4. average inlet steam quality,
5. type and arrangement of mechanical separators,
6. feedwater supply and steam discharge equipment arrangement, and
7. arrangement of downcomer and riser connections to the steam drum.

Fig. 19 Steam drum with three rows of primary cyclone separators.

The operating factors include:

1. pressure,
2. boiler load (steam flow),
3. type of steam load,
4. chemical analysis of boiler water, and
5. water level.

Primary separation equipment generally takes one of three forms:

1. natural gravity-driven separation,
2. baffle-assisted separation, and
3. high capacity mechanical separation.

Natural gravity-driven separation

While simple in concept, natural steam-water separation is quite complex. It is strongly dependent upon inlet velocities and inlet locations, average inlet steam quality, water and steam outlet locations, and disengagement of liquid and steam above the nominal water surface. Some of these effects are illustrated in Figs. 20 and 21.

For a low rate of steam generation, up to about 3 ft/s (0.9 m/s) velocity of steam leaving the water surface, there is sufficient time for the steam bubbles to separate from the mixture by gravity without being drawn into the discharge connections and without

carrying entrained water droplets into the steam outlet (Fig. 20a). However, for the same arrangement at a higher rate of steam generation (Fig. 20b), there is insufficient time to attain either of these desirable results. Moreover, the dense upward traffic of steam bubbles in the mixture may also cause a false water level indication, as shown.

The effect of the riser or inlet connection locations in relation to the water level is illustrated in diagrams a and b of Fig. 21. Neither arrangement is likely to yield desirable results in a drum where gravity alone is used for separation.

From an economic standpoint, the diameter of a single drum may become prohibitive. To overcome this limitation, several smaller steam drums may be used, as shown in Fig. 22a, although this is no longer common. However, in most boiler applications, natural gravity-driven separation alone is generally uneconomical, leading to the need for separation assistance.

Baffle-assisted primary separation

Simple screens and baffle arrangements may be used to greatly improve the steam-water separation process. Three relatively common baffle arrangements are illustrated in Fig. 22. In each case, the baffles provide: 1) changes in direction, 2) more even distri-

Fig. 20 Effect of rate of steam generation on steam separation in a boiler drum without separation devices.

Fig. 21 Effect of location of discharge from risers on steam separation in a boiler drum without separation devices.

bution of the steam-water mixture, 3) added flow resistance, and 4) the maximum steam flow travel length to enhance the gravity-driven separation process. Various combinations of perforated plates have also been used. The performance of these devices must be determined by experimental evaluations and they are typically limited to smaller, low capacity boilers.

Mechanical primary separators

Centrifugal force or radial acceleration is used almost universally for modern steam-water separators. Three types of separators are shown in Fig. 23: the conical cyclone, the curved arm and the horizontal cyclone. The B&W vertical cyclone steam separator is shown in more detail in Fig. 24. Vertical cyclones are arranged internally in rows along the length of the drum and the steam-water mixture is admitted tangentially as shown in Fig. 19. The water forms a layer against the cylinder walls and the steam moves to the core of the cylinder then upward. The water flows downward in the cylinder and is discharged through an annulus at the bottom, below the drum water level. With the water returning from drum storage to the

downcomers virtually free of steam bubbles, the maximum net pumping head is available for producing flow in the circuits. The steam moving upward from the cylinder passes through a small primary corrugated scrubber at the top of the cyclone (see Fig. 24) for additional separation. Under many operating conditions, no further separation is required.

When wide load fluctuations and water analysis variations are expected, large corrugated secondary scrubbers may be installed at the top of the drum (see Fig. 19) to provide very high steam separation. These scrubbers are also termed secondary separators. They provide a large surface which intercepts water droplets as the steam flows sinuously between closely fitted plates. Steam velocity through the corrugated plate assembly is very low, so that water re-entrainment is avoided. The collected water is drained from the bottom of the assembly to the water below.

One to four rows of cyclone separators are installed in boiler drums, with ample room for access. For smaller boilers at lower pressures [100 psig (0.7 MPa gauge)], the separation rate of clean steam by single and double rows of cyclone separators is approximately

Fig. 22 Simple types of primary steam separators in boiler drums: a) deflector baffle, b) alternate deflector baffle, and c) compartment baffle.

Fig. 23 Typical primary steam-water separators.

4000 and 6000 lb, respectively, per hour per foot of drum length (1.7 and 2.5 kg/s m). At pressures near 1050 psig (7.24 MPa gauge), these values increase to 9000 and 15,000 lb/h ft (3.7 and 6.2 kg/s m), respectively. For large utility boilers operating at 2800 psig (19.3 MPa gauge), separation can be as high as 67,000 lb/h ft (28 kg/s m) of steam with four rows of cyclone separators.

This combination of cyclone separators and scrubbers provides a steam purity of less than 1.0 ppm solids content under a wide variety of operating conditions. This purity is generally adequate in commercial practice. However, further refinement in steam purification is required where it is necessary to remove boiler water salts, such as silica, which are entrained in the steam by a vaporization or solution mechanism.

Washing the steam with condensate or feedwater of acceptable purity may be used for this purpose.

Specialized vertical steam-water separators can be used in once-through fossil fueled boiler systems which are designed for part-load recirculation of water during startup and low-load operation. These are basically vertical cylindrical pressure vessels (see Fig. 25) where the steam-water mixture enters through multiple tangential inlets in the vertical vessel wall. The resulting centrifugal acceleration creates a cyclone action similar to that in the primary cyclone separators (Fig. 24) which separates the water from the steam. Water is returned to the boiler circuitry for further heating and steam generation while the steam is sent to the superheating circuits.

Mechanical separator performance

The overall performance of mechanical separators is defined by: 1) the maximum steam flow rate at a specified average inlet quality per cyclone which meets droplet carryover limits, and 2) the predicted pressure loss. In addition, the maximum expected steam carryunder (% steam by weight) should also be known. These parameters are influenced by total flow rate, pressure, separator length, aperture sizes, drum water level, inlet steam quality, interior separator finish and overall drum arrangement. Performance characteristics are highly hardware-specific. The general trends are listed in Table 2.

Steam separator evaluation To date, theoretical analyses alone do not satisfactorily predict separation performance. Therefore, extensive experimental investigations are performed to characterize individual steam-water primary separator designs.

Fig. 24 Vertical cyclone separator.

Fig. 25 Vertical steam-water separator in a spiral wound universal pressure (SWUP™) boiler startup system.

Pressure drop of two-phase flow through a separator is extremely complex. An approximation involves using the homogeneous model two-phase multiplier, Φ , and a dimensionless loss coefficient, K_{ss} , as follows:

$$\Delta P_{\text{separator}} = K_{ss} \Phi \frac{G^2 v_f}{2g_c} \quad (20)$$

where

$$\Phi = 1.0 + \left(\frac{v_g - v_f}{v_f} \right) x$$

The variable K_{ss} is a unique function of pressure for each steam separator design. The other variables are defined after Equation 16.

The maximum steam flow per primary separator defines the minimum number of standard units required, while the ΔP is used in the circulation calculations. Given the unique design of each separator, B&W has acquired extensive experimental performance data under full-scale, full-flow and full-pressure conditions for its equipment.

Table 2
Mechanical Separator Performance Trends

Moisture carryover with steam

1. increases gradually with steam flow rate until a breakaway point is reached where a sudden rise in carryover occurs,
2. increases with water level until flooding occurs, and
3. increases with steam quality.

Carryunder of steam with water

1. declines with increasing water level, and
2. declines with decreasing inlet steam quality.

Pressure drop ($P_{in} - P_{drum}$)

1. increases with mass flow and steam quality.

Steam drum capacity

Given the flow capabilities of standardized steam-water separation equipment, the boiler drum is sized to accommodate the number of separators necessary for the largest expected boiler load (maximum steam flow rate) and to accommodate the changes in water level that occur during the expected load changes. The drum diameter, in incremental steps, and length are adjusted to meet the space requirements at a minimum cost.

An evaluation limit in steam drum design is the maximum steam carryunder into the downcomer. Carryunder, or transport of steam into the downcomers, is not desirable because it reduces the available thermal pumping force by reducing the density at the top of the downcomer. Carryunder performance is a function of physical arrangement, operating pressure, feedwater enthalpy, free-water surface area, drum water level and separator efficiency. Empirical correction factors for specific designs are developed and used in the circulation calculations to account for the steam entering the downcomers. The steam is eventually completely condensed after it travels a short distance into the downcomer. However, the average density in the top portion of the downcomer is still lower than thermal equilibrium would indicate.

A rapid increase in steam demand is usually accompanied by a temporary drop in pressure until the firing rate can be sufficiently increased. During this interval, the volume of steam throughout the boiler is increased and the resulting swell raises the water level in the drum. The rise depends on the rate and magnitude of the load change and the rate at which the heat and feed inputs can be changed to meet the load demand. Steam drums are designed to provide the necessary volume, in combination with the controls and firing equipment, to prevent excessive water rise into the steam separators. This, in turn, prevents water carryover with the steam.

Circulation

The purpose of the steam-water flow circuitry is to provide the desired steam output at the specified temperature and pressure. The circuitry flow also ensures effective cooling of the tube walls under expected operating conditions, provided the unit is properly operated and maintained. A number of methods have been developed. Four of the most common systems are illustrated in Fig. 26. These systems are typically classified as either *recirculating* or *once-through*.

In recirculating systems, water is only partially evaporated into steam in the boiler tubes. The residual water plus the makeup water supply are then recirculated to the boiler tube inlet for further heating and steam generation. A steam drum provides the space required for effective steam-water separation. Once-through systems provide for continuous evaporation of slightly subcooled water to 100% steam without steam-water separation. Steam drums are not required. These designs use forced circulation for the necessary water and steam-water flow. In some cases, a combination of these approaches is used. At low loads, recirculation maintains adequate tube wall cool-

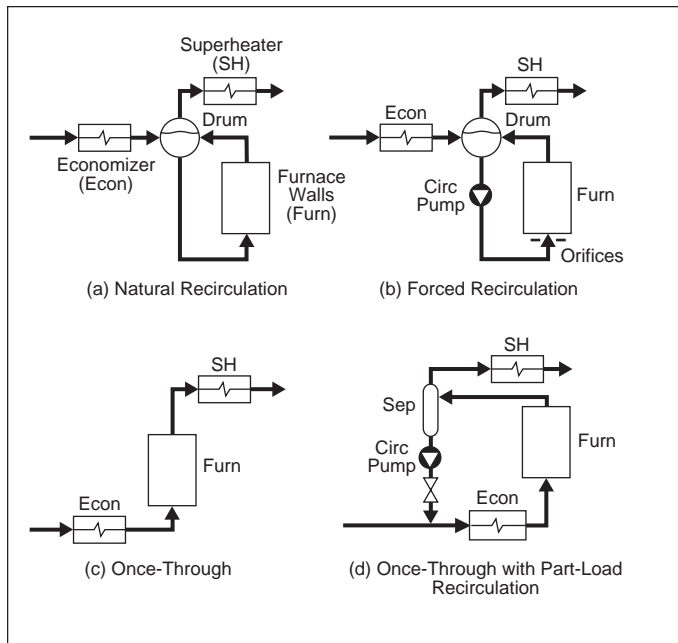

Fig. 26 Common fossil fuel boiler circulation systems.

ing while at high loads, high pressure once-through operation enhances cycle efficiency.

Natural circulation

In *natural circulation*, gravity acting on the density difference between the subcooled water in the downcomer and the steam-water mixture in the tube circuits produces the driving force or pumping head to drive the flow. As shown in Fig. 27, a simplified boiler circuit consists of an unheated leg or downcomer and heated boiler tubes. The water in the downcomer is subcooled through the mixing of the low temperature feedwater from the economizer with the saturation-temperature water discharged from the steam-water separators. Steam-water, two-phase flow is created in the boiler tubes as a result of the heat input. Because the steam-water mixture has a lower average density than the single-phase downcomer flow, a pressure differential or pumping pressure is created by the action of gravity and the water flows around the circuit. The flow increases or decreases until the pressure losses in all boiler circuits are balanced by the available pumping pressure. For steady-state, incompressible flow conditions, this balance takes the form:

$$\left(Z\bar{\rho}_d - \int_0^Z \rho(z) dz \right) \left(\frac{g}{g_c} \right) = (\Delta P_{\text{friction}} + \Delta P_{\text{acceleration}} + \Delta P_{\text{local}}) \quad (21)$$

where

- Z = total vertical elevation, ft (m)
- z = incremental vertical elevations, ft (m)
- $\rho(z)$ = heated tube local fluid density, lb/ft³ (kg/m³)
- $\bar{\rho}_d$ = average downcomer fluid density, lb/ft³ (kg/m³)
- g = acceleration of gravity, ft/s² (m/s²)

Fig. 27 Simple furnace circulation diagram.

$$g_c = 32.17 \text{ lbm ft/lbf s}^2 \text{ (1 kg m/N s}^2\text{)}$$

$$\Delta P = \text{circuitry pressure loss due to friction, fluid acceleration and local losses, lb/ft}^2 \text{ (Pa)}$$

As the heat input increases, circulation rate increases until a maximum flow rate is reached (Fig. 28). If higher heat inputs occur, they will result in larger pressure losses in the heated tubes without corresponding increases in pressure differential. As a result, the flow rate declines.

Natural circulation boilers are designed to operate in the region where increased heat input results in an increase in flow for all specified operating conditions. In this mode, a natural circulation system tends to be self compensating for numerous variations in heat absorption. These can include sudden changes in load,

Fig. 28 Typical relationship between circulation at a given pressure and steam production (arbitrary scale).

changes in heating surface cleanliness and changes in burner operation.

Natural circulation is most effective where there is a considerable difference in density between steam and water phases. As shown in Fig. 29, the potential for natural circulation flow remains very high even at pressures of 3100 psi (21.4 MPa).

Forced circulation

In recirculating or once-through *forced circulation* systems, mechanical pumps provide the driving head to overcome the pressure losses in the flow circuitry. Unlike natural circulation, forced circulation does not enjoy an inherent flow-compensating effect when heat input changes, i.e., flow does not increase significantly with increasing heat input. This is because a large portion of the total flow resistance in the boiler tubes arises from the flow distribution devices (usually orifices) used to balance flow at the circuit inlets. The large resistance of the flow distributors prevents significant increases in flow when heat absorption is increased.

Forced circulation is, however, used where the boilers are designed to operate near or above the critical pressure [3200 psi (22.1 MPa)]. There are instances in the process and waste heat fields and in some specialized boiler designs where the use of circulating pumps and forced circulation can be economically attractive. At pressures above 3100 psi (21.4 MPa) a natural circulation system becomes increasingly large and costly and a pump can be more economical. In addition, the forced circulation principle can work effectively in both the supercritical and subcritical pressure ranges.

In forced recirculation there is a net thermal loss because of the separate circulating pump. While practically all the energy required to drive the pumps reappears in the water as added enthalpy, this energy originally came from the fuel at a conversion to useful energy factor of less than 1.0. If an electric motor drive is used, the net energy lost is about twice the energy supplied to the pump motor for typical fossil fuel systems.

Fig. 29 Effect of pressure on pumping head.

Circulation design and evaluation

The furnace wall enclosure circuits are very important areas in a boiler. High constant heat flux conditions make uninterrupted cooling of furnace tubes essential. Inadequate cooling can result in rapid overheating, cycling thermal stress failure, or material failures from differential tube expansion. Sufficient conservatism must be engineered into the system to provide adequate cooling even during transient upset conditions. Simultaneously, the rated steam flow conditions must be maintained at the drum outlet. Any of the circulation methods discussed may be used to cool the furnace waterwall tubes. In evaluating the circulation method selected for a particular situation, the following general procedure can be used:

1. The furnace geometry is set by the fuel and combustion system selected. (See Chapters 11, 14, 19 and 21.)
2. Standardized components (furnace walls, headers, drums, etc.) are selected to enclose the furnace arrangement as needed. (See Chapters 19 and 21.)
3. The local heat absorption is evaluated based upon the furnace geometry, fuel and firing method. Local upset factors are evaluated based upon past field experience. (See Chapter 4.)
4. Circulation calculations are performed using the pressure drop relationships.
5. The calculated circulation results (velocities, steam qualities, etc.) are compared to the design criteria.
6. The flow circuitry is modified and the circulation re-evaluated until all of the design criteria are met.

Some of the design criteria include:

1. *Critical heat flux limits* For recirculating systems, CHF conditions are generally avoided. For once-through systems, the temperature excursions at CHF are accommodated as part of the design.
2. *Stability limits* These limits generally indicate acceptable pressure drop versus mass flow relationships to ensure positive flow in all circuits and to avoid oscillating flow behavior.
3. *Steam separator and steam drum limits* These indicate maximum steam and water flow rates to individual steam-water separators and maximum water flow to the drum downcomer locations to ensure that steam carryunder and water carryover will not be problems.
4. *Minimum velocity limits* Minimum circuit saturated velocities assure that solids deposition, potentially detrimental chemistry interactions, and selected operating problems are minimized.
5. *Sensitivity* The system flow characteristic is checked to ensure that flow increases with heat input for all expected operating conditions.

Circulation is analyzed by dividing the boiler into individual simple circuits – groups of tubes or circuits with common end points and similar geometry and heat absorption characteristics. The balanced flow condition is the simultaneous solution of the flow characteristics of all boiler circuits.

At the heart of a B&W circulation evaluation is a circulation computer program that incorporates tech-

Fig. 30 Moody critical flow model for maximum steam-water flow rate.¹⁷

niques for calculating the single- and two-phase heat transfer and flow parameters discussed above and in Chapters 3 and 4. With this program, a circulation model of the entire boiler is developed. Input into the program is a geometric description of each boiler circuit including descriptions of downcomers, supplies, risers, orifices, bends and swages, as well as individual tubes. Each of the circuits within the boiler is subjected to the local variation in heat transfer through inputs based upon the furnace heat flux distribution. (See Chapter 4.) Given the geometry description and heat absorption profile, the computer program determines the balanced steam-water flow to each circuit by solving the energy, mass and momentum equations for the model. The results of the program provide the detailed information on fluid properties, pressure drop and flow rates for each circuit so that they can be compared to the design criteria. Adjustments frequently made to improve the individual circuit circulation rates can include: changing the number of riser and supply connections, changing the number or type of steam separators in the drum, adding orifices to the inlets to individual tubes, changing the drum internal baffling, changing the operating pressure (if possible) and lowering the feedwater temperature entering the drum. Once the steam-water circuitry is finalized, the detailed mechanical design proceeds.

Critical flow

A two-phase flow parameter of particular importance in nuclear reactor safety analysis and in the operation of valves in many two-phase flow systems is the *critical flow rate*. This is the maximum possible flow rate through an opening when the flow becomes choked and further changes in upstream pressure no longer affect the rate. For single-phase flows, the critical flow rate is set by the sonic velocity. The analysis is based upon the assumption that the flow is one dimensional, homogeneous, at equilibrium and isentropic. These assumptions result in the following relationships:

$$\text{Sonic velocity} = C = \sqrt{\left(\frac{dP}{d\rho}\right)_s} g_c \quad (22)$$

$$\text{Critical flow} = G_{\max} = \rho \sqrt{\left(\frac{dP}{d\rho}\right)_s} g_c \quad (23)$$

where

- C = velocity, ft/s (m/s)
- P = pressure, lb/ft² (Pa)
- ρ = fluid density, lb/ft³ (kg/m³)
- g_c = 32.17 lbm ft/lbf s² (1 kg m/N s²)
- G_{\max} = mass flux, lb/s ft² (kg/m² s)

However, when saturated water or a two-phase steam-water mixture is present, these simplifying assumptions are no longer valid. The flow is heterogeneous and nonisentropic with strong interfacial transport and highly unstable conditions.

Moody's analysis¹⁷ of steam-water critical flow is perhaps the most frequently used. It is based upon an annular flow model with uniform axial velocities of each phase and equilibrium between the two phases. A key element of the analysis involves maximizing the flow rate with respect to the slip ratio and the pressure. The results are presented in Fig. 30. The critical steam-water flow rate is presented as a function of the stagnation condition. Compared to experimental observations, this correlation slightly overpredicts the maximum discharge at low qualities ($x < 0.1$) and predicts reasonably accurately at moderate qualities ($0.2 < x < 0.6$), but tends to underpredict at higher qualities ($x > 0.6$).

Chapter 6

Numerical Modeling for Fluid Flow, Heat Transfer, and Combustion

Numerical modeling – an overview

Continuous and steady advances in computer technology have changed the way engineering design and analyses are performed. These advances allow engineers to deal with larger-scale problems and more complex systems, or to look in more detail at a specific process. Indeed, through the use of advanced computer technology to perform engineering analysis, numerical modeling has emerged as an important field in engineering. While this chapter focuses on fluid flow and heat transfer, Chapter 8 provides a brief discussion of numerical modeling for structural analysis.

In general, the term *numerical method* describes solving a mathematical description of a physical process using a numerical rather than an analytical approach. This may be done for a number of reasons, including the following:

1. An analytical means of solving the equations that describe the system may not exist.
2. Even though an analytical method is available, it may be necessary to repeat the calculation many times, and a numerical method can be used to accelerate the overall process.

A small-scale replica of an apparatus is considered a *physical model* because it describes the full-size apparatus on a smaller scale. This model can incorporate varying levels of detail depending on need and circumstances. A mathematical description of a physical system (referred to as a *mathematical model*) can also incorporate varying levels of detail. Similar to a physical model, the amount of detail is often determined by the accuracy required and the resources available to use the model. This creates a need to strike a balance between accuracy, complexity and efficiency.

There are two basic approaches to mathematical modeling.

1. *Model the behavior of a system.* Network flow models and heat exchanger heat transfer correlations are examples of a system model.
2. *Model the fundamental physics of a system to determine the behavior.* Computational fluid dynamics (CFD) and chemical reaction models fall into this category.

The term *numerical modeling* usually refers to the use of numerical methods on high-powered computers to solve a complex system of mathematical models based on the fundamental physics of the system. In this respect, it describes the second approach identified above.

As an example, consider analysis of hot air moving through a length of duct composed of several different components all in a cold environment.

The first type of analysis would involve a network model. This model would describe the pressure drop and heat loss along the duct based on the length, shape, number of turns, etc. This model is based on extensive flow measurements taken on the individual components (i.e., straight sections, turns, reductions, etc.) that make up the duct. A set of empirical and fundamental correlations is used to analyze the flow rate through the duct. The computation can be set up quickly and with minimal effort. Results and multiple variations can be rapidly obtained. While results are reasonably accurate, they are limited to the components for which a flow correlation already exists. A unique component design that has not been described by a correlation may not be accurately evaluated with this type of model.

The second type of analysis would involve a CFD model of the same duct. The detailed behavior of the flow through the entire duct is modeled. From this information, pressure drop and heat loss along the length of the duct may be determined. However, unlike the first analysis, this type of model provides additional details. For example, the first model does not consider how the flow through a bend differs if it is followed by another bend or a straight section; the first model may result in the same pressure drop regardless of how the components are arranged. The second analysis would account for these differences. In addition, variation in heat loss from one side of the duct to the other can be determined. Most importantly, this model is not restricted to duct components where extensive experimental data is available. New concepts can easily be evaluated.

These two approaches have both benefits and limitations. The appropriate use of each is determined by the information needed and the information available. While both approaches are important engineering tools, the remaining discussion here will focus on the second, specifically on CFD and combustion modeling, and how they relate to furnaces, boilers and accessory equipment.

Benefits

There are numerous benefits to using a sophisticated tool such as a numerical model for engineering analysis. These tools can often provide information that can only be obtained through expensive experiments or may not be available any other way. Numerical modeling may often be used to obtain needed information quickly and at a reduced cost.

While it is important to understand the advantages of using numerical modeling, it is equally important to understand that it is only one means of obtaining the required information. Engineering has long relied on *theory* and *experiments* for design and analysis. *Numerical modeling* adds a third approach. Each approach offers different insights with different benefits.

Increased understanding

The primary purpose of using numerical modeling is to increase understanding of a physical process. As such, it is often used in addition to or in conjunction with other available tools. Consider the duct example described above. It is possible to use a network model on a large number of duct designs to narrow the possibilities to a few candidate designs. A full CFD model could then be used to analyze each of the candidate designs to gain a better understanding of the strengths and weaknesses of each design.

Exploration of unfamiliar conditions

As previously described, it is possible that a component of the duct can not be accurately described within the context of a flow network model. A conservative approximation can be used but may result in an overly conservative solution. A CFD model of the new component can provide the missing information, or a CFD model of the entire system can be performed. The model allows the exploration and analysis of new equipment and systems.

Design validation/examination of interactions

Traditional methods of analysis and design are often focused on individual system components such as the burners, air system, or heat transfer surfaces in a furnace. A full accounting of the complex interaction between the components is often not given. Numerical modeling provides a vehicle to evaluate the interactions and validate the system design.

Troubleshooting

Engineering analysis often investigates the behavior of existing systems. This is particularly true when the behavior does not agree with the expectations. Numerical modeling can play a vital role in determining the nature of the problem and suggesting solutions.

Flexibility

A distinct feature of numerical modeling is that it is a flexible method of analysis. Modeling can be used to look at any number of different geometries or operating conditions. In addition, the level of detail used in the model can vary from use to use. A high level of detail may be required to model flow near a fuel inlet

to a burner, but the same level of detail may not be necessary for flow in a duct. The complexity is often dictated by the problem.

Historical perspectives

In many ways, the history of numerical modeling in the context of CFD has followed the development of computational capabilities. Early efforts in CFD started in the 1960s, when computers first became commercially available, and when many of the concepts and ideas that form the basis of current techniques in CFD were first developed. One example is the way much of the turbulent flow is modeled today. Early efforts were often limited to simple two-dimensional laminar flows. The resolution of the geometry was also very limited.

It was not until the 1970s that CFD saw substantial successes. It was during this time that CFD began to be used for general engineering problems. Progress included turbulence modeling, two-dimensional reacting flows and three-dimensional flows.

As further advances were made in computational technology, more sophisticated and detailed numerical models, as well as increased resolution, became possible. This increased the acceptance of CFD as a useful engineering tool and gave it a much wider application base. Soon, large comprehensive combustion CFD models were developed. These were fully three-dimensional turbulent-reacting flow models. Sub-models of detailed physics for specific applications were included, such as pulverized coal combustion and radiation heat transfer models. Improvements continue to be made today that promise to increase the utility of combustion CFD modeling.

Modeling process

In its simplest terms, a numerical model is provided with input data that is used to fix specific operating parameters and return results. Without further understanding, this simplistic view of modeling can lead to unsatisfactory results. More appropriately, a multi-step process is used:

1. Obtain a complete situational description including physical geometry, process flow, physical property data and the level of detail needed. It is important to obtain detailed information because seemingly small differences can have a significant effect on numerical solutions.
2. Define the modeling assumptions appropriate for the specific flow system and computer model selected while making appropriate tradeoffs; cost and time are balanced against level of detail and information required.
3. Prepare the input data by converting the general technical information obtained in step 1 into the detailed inputs required by the computational model selected. Much of this is accomplished with the use of various computer programs such as computer assisted drafting (CAD) software and mesh generation software. Verification of the input data is an important part of this process.

4. Run the numerical computational model until an acceptable solution is obtained.
5. Analyze the results to verify the initial model assumptions, to check the results against known trends, to benchmark the output with known field data, and to present the results in a usable form.

In application, the computer programs or software used to perform the modeling function are broken down into three general groups that work together to complete the analysis:

1. Pre-processing: generation of the calculational mesh or grid representing all boundary conditions (part of step 3 above and discussed later under *Mesh generation*),
2. Solution: execution of the numerical model to derive an acceptable solution (step 4 above), and
3. Post-processing: generation of typically graphical or tabular key results from the numerical model to permit interpretation and evaluation of the results (part of step 5 above).

Limitations

Despite recent advances in technology, increased understanding of physics, and improvements in describing input conditions, limitations remain in applying numerical modeling to engineering problems. Numerical modeling can only be applied where there is an adequate understanding of the physics involved. In situations where there is not an appropriate mathematical description of the physics, numerical modeling is not possible. Even when a description exists, it may be too complex to be readily used in a model and a simplified approach is required. In this case, results will reflect the simplifying assumptions of the model.

Computer technology continues to limit the level of detail that can be modeled with numerical methods. Our understanding of the physics of systems that are routinely modeled with CFD far exceeds the computational resources (size and speed) that are available to model them. A considerable amount of effort is expended on developing simplified descriptions of the physics to make the problem manageable with current computer technology.

The precision and accuracy of the input data also represents a significant limitation to numerical modeling. Sources where this may be significant include the level at which the geometry is described and represented, the accuracy of imposing an inlet condition, and the assumptions made in specifying other boundary conditions and modeling parameters.

Despite these limitations, numerical modeling can be used in conjunction with other engineering analyses. When applied appropriately, numerical modeling can provide invaluable information.

Uses

Many applications for CFD and combustion modeling exist within the design and evaluation of steam generators (or boilers) and related equipment. Numerical models of the flue gas and steam-water flows

are used to predict boiler behavior, evaluate design modifications, or investigate localized phenomena. Examples of flue gas applications include predicting temperature distributions within a furnace, evaluating fluid mixing due to the retrofit of systems to control nitrogen oxides (NO_x) emissions, and improving air heater flow distributions to increase heat absorption. Water-side applications include determining flow rates for boiler furnace circulation systems and evaluating system stability, among others. Many of the uses are summarized in Table 1.

Theory

The foundation of numerical modeling is the development of a mathematical description of the physical system to be modeled. Whether this is as simple as heat transfer through a wall or as complex as a pul-

Table 1
Sample Numerical Model Applications

Application	Purpose
Windboxes	Evaluate flow field within windbox, determine expected air distribution to combustion equipment, and determine pressure losses throughout system
Burners	Accurately determine boundary conditions for furnace models, evaluate flame and burner flow characteristics
Overfire air ports	Accurately determine boundary conditions for furnace models, determine flow characteristics and pressure losses through port
Pulverized coal-fired boilers	Examine combustion characteristics throughout the entire furnace; evaluate fuel/air mixing, furnace performance, heat transfer, emissions and flow characteristics
Recovery boilers	Examine combustion characteristics throughout the entire furnace; evaluate fuel/air mixing, furnace performance, heat transfer, emissions, carryover and flow characteristics within the furnace
Waste-to-energy boilers	Examine combustion characteristics of the entire furnace; evaluate fuel/air mixing, furnace performance, heat transfer, emissions and flow characteristics
Selective catalytic reduction systems	Determine inlet flow and temperature distributions; evaluate flow correction devices to meet specified velocity and temperature criteria
Wet scrubbers	Determine flow and pressure drop conditions, evaluate scrubber emission removal performance

verized coal flame, the first step is to adequately define the mathematical description.

The description is derived from first principles and physical laws and is primarily based on a set of conservation relationships that result in a series of ordinary and partial differential equations (ODE and PDE). The PDEs describe such things as the conservation of mass, momentum, energy, and others. In addition, fundamental relationships are used to complete the description of the system. The complete description is made up of these PDEs and algebraic relationships.

Combustion modeling results in a particularly complex mathematical description of the overall process. Each physical process involved in a combustion system is described individually; however, they interact with other physical processes. This interaction creates a coupling between all the descriptions of the individual processes.

To demonstrate this coupling, consider a simple diffusion flame. Fluid dynamics describe the process of mixing two streams of reactants. The resulting reaction alters the constituents of the fluid, and heat release from the reaction increases the local temperature. The change in temperature and chemical composition has a strong effect on local density. This change in density, in turn, has a strong effect on the fluid flow.

The system of processes, equations and interrelationships in a coal-fired boiler is far more complex, as shown in Fig. 1. Five fundamental processes must be addressed while providing for all key interactions:

1. *Fluid transport*: fluid motion, component mass and energy transport in a turbulent mixing environment.
2. *Particle transport*: particle (in this case coal) or *discrete phase* motion in a fluid.
3. *Homogeneous chemical reactions*: gaseous species combustion.
4. *Heterogeneous chemical reactions*: particle combustion.
5. *Radiative heat transfer*: radiative heat transfer in a particle-laden participating media.

The second step to modeling the system is to use an appropriate technique to solve the set of equations that has been chosen to describe the physical system. It is not possible to analytically solve the partial differential equations typically encountered in modeling combustion systems. Thus, the differential equations are *discretized* to obtain a set of non-linear algebraic equations that can be solved with known numerical techniques. The last step in the process is to obtain the final solution.

Following is a more detailed description of each of these processes.

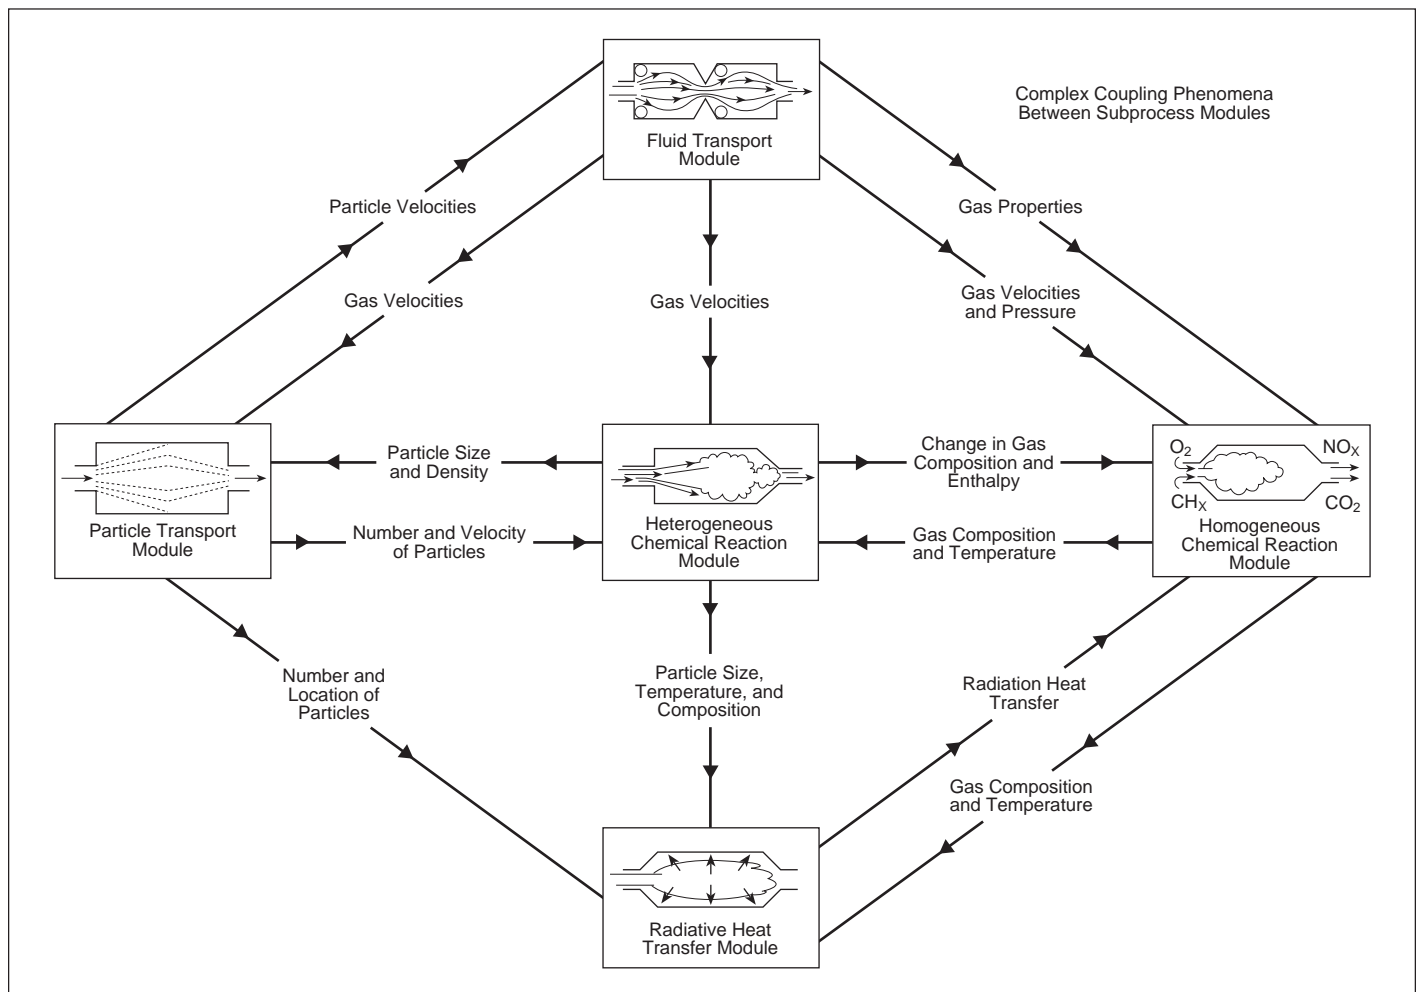

Fig. 1 Model for the evaluation of pulverized coal-fired combustion based upon five fundamental processes.

Fundamental equations

Combustion systems involve a complex interaction of many different physical processes. This includes fluid flow, heat transfer, chemical reactions, and potentially fluid-solid interactions. Some of the fundamental equations that describe these processes are introduced in Chapters 3 and 4. Each of these processes is briefly described below in the context of numerical modeling.

Representation of turbulence

Large-scale combustion systems are typically characterized by turbulent, reacting flow conditions. The effect of turbulent flow (turbulence) on combustion processes is significant and must be considered to account for this effect. As yet, it is not practical to model the full detail of the temporal and spatial fluctuations that are associated with turbulence. As computing resources become more powerful and our ability to handle the enormous amount of information that will be generated increases, it may one day be possible to model the details of turbulent flow on industrial combustion systems. Until that day, a simplified model representation of turbulence must be used.

Often, dealing with turbulence involves time-averaging the fundamental equations to eliminate the turbulent fluctuations and utilizing a separate turbulence model to account for the influence of turbulent fluctuations on the flow. The fundamental equations can then be solved for the mean quantities. Alternatively, large scale turbulent fluctuations can be directly solved while utilizing a turbulence model for the small scale fluctuations. This technique, called large eddy simulation (LES), is an important advancement in turbulence modeling but requires large computational resources compared to time-averaging.

Time-averaging is typically done either with Reynolds averaging, the conventional time-averaging, or with Favre averaging, a density-weighted averaging. The latter is better suited to handle the large density variations experienced in combustion applications. Averaging of the conservation equations is accomplished by first assuming that instantaneous quantities are represented by mean and fluctuating portions as shown in Equation 1. By allowing ϕ to represent the dependant variable, this can be expressed as:

$$\phi = \bar{\phi} + \phi' \quad (1)$$

where ϕ is the instantaneous value, $\bar{\phi}$ is the mean portion and ϕ' is the fluctuating portion. Density-weighted averaging offers advantages over conventional time-averaging for combustion-related flows since it simplifies the treatment of large density changes. The density-weighted mean value, $\tilde{\phi}$, is defined as:

$$\tilde{\phi} = \frac{\overline{\rho\phi}}{\bar{\rho}} \quad (2)$$

where $\overline{\rho\phi}$ is the time-averaged product of the instan-

taneous density (ρ) and instantaneous value (ϕ) and $\bar{\rho}$ is the time-averaged density. The instantaneous value may then be written as the sum of the density-weighted average and the fluctuating value ϕ'' :

$$\phi = \tilde{\phi} + \phi'' \quad (3)$$

Equation 3 can be substituted into the transport equation and then time-averaged to derive equations in terms of the mean quantities. While it is not important to detail the process here, it is important to note that the results produce additional terms in the resulting equations. These extra terms are known as Reynolds stresses in the equations of motion and turbulent fluxes in the other conservation equations. Turbulence models are generally required to model these extra terms, closing the system of equations.

Fluid flow and heat transfer

Gas-phase transport in combustion systems is governed by PDEs that describe the conservation of mass, momentum, component mass and energy. The conservation of mass or continuity equation is discussed in Chapter 3. The conservation of momentum is represented by the Navier-Stokes equations that are also briefly discussed in Chapter 3. The Cartesian form of Navier-Stokes equations, as well as the continuity equation, can be found in the first four equations in Table 2. In these four equations, ρ is the density, u , v , and w are the velocity components, and x , y , and z are the coordinate directions, μ is the dynamic viscosity, P is the pressure, and g is the body force due to gravity.

The remaining conservation equations used to describe the gas-phase transport are the energy and component mass equations, expressed in Table 2 in terms of specific enthalpy and component mass fraction. The energy source terms are on a volumetric basis and represent the contribution from radiative heat transfer, $-\nabla \cdot \mathbf{q}_r$, energy exchange with the discrete phase particles, S_H^{part} , and viscous dissipation, S_H . The component mass source terms include the mean production rate due to gas-phase reactions, R_i , and the net species production rate from heterogeneous reactions, S_i^{part} .

Turbulence model

As previously mentioned, the process of time-averaging the conservation equations introduces extra terms into the equations. Numerous turbulence models have been developed over the years to determine the values of these extra terms. One of the most common and widely accepted approaches, known as the Boussinesq hypothesis, is to assume that the Reynolds stresses are analogous to viscous dissipation stresses. This approach introduces the turbulent viscosity μ and a turbulent transport coefficient σ into each equation.

Most of the turbulence models currently used for fluid flow and combustion are focused on determining μ . In the k-epsilon model (one of the most widely used and accepted), the turbulent viscosity is given as:

$$\mu_t = \frac{\bar{\rho} C_\mu k^2}{\varepsilon} \quad (4)$$

Table 2
Summary of Fundamental Differential Equations

General form of the transport equation:

$$\frac{\partial}{\partial t}(\bar{\rho}\phi) + \frac{\partial}{\partial x}(\bar{\rho}\tilde{u}\phi) + \frac{\partial}{\partial y}(\bar{\rho}\tilde{v}\phi) + \frac{\partial}{\partial z}(\bar{\rho}\tilde{w}\phi) = \frac{\partial}{\partial x}\left(\Gamma_\phi \frac{\partial\phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\Gamma_\phi \frac{\partial\phi}{\partial y}\right) + \frac{\partial}{\partial z}\left(\Gamma_\phi \frac{\partial\phi}{\partial z}\right) + S_\phi$$

Equation	Physical Parameter ϕ	Transport Coefficient Γ_ϕ	Source Term S_ϕ
Continuity	1	0	S_m^{part}
X-Momentum	\tilde{u}	μ_e	$-\frac{\partial P}{\partial x} + \frac{\partial}{\partial x}\left(\mu_e \frac{\partial\tilde{u}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\mu_e \frac{\partial\tilde{v}}{\partial x}\right) + \frac{\partial}{\partial z}\left(\mu_e \frac{\partial\tilde{w}}{\partial x}\right) + \bar{\rho}g_x + S_u^{part}$
Y-Momentum	\tilde{v}	μ_e	$-\frac{\partial P}{\partial y} + \frac{\partial}{\partial x}\left(\mu_e \frac{\partial\tilde{u}}{\partial y}\right) + \frac{\partial}{\partial y}\left(\mu_e \frac{\partial\tilde{v}}{\partial y}\right) + \frac{\partial}{\partial z}\left(\mu_e \frac{\partial\tilde{w}}{\partial y}\right) + \bar{\rho}g_y + S_v^{part}$
Z-Momentum	\tilde{w}	μ_e	$-\frac{\partial P}{\partial z} + \frac{\partial}{\partial x}\left(\mu_e \frac{\partial\tilde{u}}{\partial z}\right) + \frac{\partial}{\partial y}\left(\mu_e \frac{\partial\tilde{v}}{\partial z}\right) + \frac{\partial}{\partial z}\left(\mu_e \frac{\partial\tilde{w}}{\partial z}\right) + \bar{\rho}g_z + S_w^{part}$
Enthalpy	\tilde{H}	$\frac{\mu_e}{\sigma_H}$	$-\nabla \cdot \mathbf{q}_r + S_H + S_H^{part}$
Turbulent Energy	k	$\frac{\mu_e}{\sigma_k}$	$G - \bar{\rho}\varepsilon$
Dissipation Rate	ε	$\frac{\mu_e}{\sigma_\varepsilon}$	$\frac{\varepsilon}{k}(c_1 G - c_2 \bar{\rho}\varepsilon)$
Species	\tilde{Y}_i	$\frac{\mu_e}{\sigma_i}$	$\bar{\rho}R_i + S_i^{part}$

Other terms appearing in general form:

$$G = \mu_e \left\{ 2 \left[\left(\frac{\partial\tilde{u}}{\partial x} \right)^2 + \left(\frac{\partial\tilde{v}}{\partial y} \right)^2 + \left(\frac{\partial\tilde{w}}{\partial z} \right)^2 \right] + \left(\frac{\partial\tilde{u}}{\partial y} + \frac{\partial\tilde{v}}{\partial x} \right)^2 + \left(\frac{\partial\tilde{u}}{\partial z} + \frac{\partial\tilde{w}}{\partial x} \right)^2 + \left(\frac{\partial\tilde{v}}{\partial z} + \frac{\partial\tilde{w}}{\partial y} \right)^2 \right\}$$

$$\mu_e = \mu + \mu_t$$

Nomenclature

S^{part}	=	source term accounting for exchange between discrete phase particles and gas phase
u, v, w	=	velocity components
H	=	enthalpy
k	=	turbulent kinetic energy
ε	=	turbulent kinetic energy dissipation
μ_e	=	effective viscosity
μ_t	=	turbulent viscosity
g	=	gravitational vector (x, y, z)
ρ	=	density
c_1, c_2	=	model constants
R_i	=	reaction rate
Y_i	=	species mass fraction

Subscripts/Superscripts

e	=	effective
t	=	turbulent
x, y, z	=	directional component
i	=	i th chemical specie
~	=	Favre (density weighted) average
-	=	time-average
part	=	discrete phase particle component

where C_μ is a model parameter, k is the turbulent kinetic energy, and ε is the turbulent kinetic energy dissipation. The turbulent kinetic energy and the dissipation are determined by solving an additional partial differential equation for each quantity as given in Table 2.

Discrete phase transport

Many combustion applications, including pulverized coal, oil, black liquor and even wood involve small solid or liquid particles moving through the combustion gases. The combustion gases are described by assuming that they represent a continuum, whereas a description of the solid and liquid fuel involves discrete particles. Describing the motion of this discrete phase presents unique modeling challenges. There are two basic reference frames that can be used to model the transport of the discrete phase particles, Eulerian and Lagrangian.

The Eulerian reference frame describes a control volume centered at a fixed point in space. Conservation equations similar to the ones used for gas transport are used to describe the transport mass and energy of particles passing through this control volume. The interaction of the particle phase and the gas phase is accomplished through source terms in the respective transport equations.

The Lagrangian reference frame considers a control volume centered on a single particle. This approach tracks the particle on its trajectory as it travels through space and interacts with the surrounding gases. The motion of a particle can be described by:

$$m_{part} \frac{d\vec{u}_{part}}{dt} = \vec{F}_D + \vec{F}_g \quad (5)$$

where m_{part} represents the mass of the particle, \vec{u}_{part} is the particle vector velocity, t is time, and \vec{F}_D and \vec{F}_g represent drag and gravitational forces. Aerodynamic drag is a function of the relative differences between particle and gas velocities, Reynolds number and turbulent fluctuations in the gas. Consideration is also given for mass loss from the particle due to combustion.^{1,2,3}

Turbulence has the effect of dispersing or diffusing the particles. This dispersion effect has been identified with the ratio of the particle diameter to turbulence integral scale. For large particle sizes, particle migration will be negligible, while at small sizes particles will follow the motion of the gas phase. This effect can be modeled using the Lagrangian stochastic deterministic (LSD) model.⁴ The LSD model computes an instantaneous gas velocity which is the sum of the mean gas velocity and a fluctuating component. The instantaneous gas velocity is used in computing the right-hand side of Equation 5.

From the particle velocity the particle position, x_{part} , is expressed as:

$$\frac{d\vec{x}_{part}}{dt} = \vec{u}_{part} \quad (6)$$

This equation, along with appropriate initial conditions, describes the particle trajectory within the computational domain.

Combustion

Homogeneous chemical reactions Homogeneous or gas-phase combustion involves the transport and chemical reaction of various gas species. During this process, heat is released and combustion product species are formed. As mentioned, a transport equation for each of the chemical species involved is solved. The main objective of a gas-phase combustion model is to determine the mean production rate, R_i for turbulent combustion.

Various methods can be used to determine the production rate. One common method known as the Eddy Dissipation Combustion Model (EDM) was developed by Magnussen and Hjertager⁵ and is based on the eddy break-up model.⁶ This model assumes that the rate of combustion is controlled by the rate of mixing of the reactants on a molecular scale. The reaction rate is given by:

$$R_i = \frac{W_i \dot{\omega}_i}{\bar{\rho}} = \underbrace{W_i \sum_{j=1}^{N_{rc}} (v''_{ij} - v'_{ij})}_{\text{Term 1}} \underbrace{C_A \frac{\varepsilon}{\bar{\rho} k}}_{\text{Term 2}} \underbrace{\min \left(\frac{Y_k / W_k}{v'_{kj}} : k \in RCT_j \right)}_{\text{Term 3}} \quad (7)$$

where W_i is the component molecular weight, v'_{ij} and v''_{ij} are the reactant and product stoichiometric coefficients for the i^{th} species and the j^{th} reaction, ε is the turbulent dissipation, k is the turbulent kinetic energy, C_A is the model dependent mixing constant and RCT_j denotes the set of species that are reactants for the j^{th} reaction. Term 1 represents the stoichiometric coefficients in the particular reaction, Term 2 represents the molecular mixing rate, and Term 3 limits the reaction to the availability of individual reactants.

Magnussen⁷ later proposed the eddy dissipation concept (EDC) to overcome some limitations of other models. Specifically, the EDC model is applicable to non-premixed and premixed combustion and can be used with simplified or detailed chemistry to describe the reaction process. A detailed description of the EDC model can be found in Magnussen,⁷ Lilleheie *et al.*,⁸ Magnussen⁹ and Lilleheie *et al.*¹⁰

Magnussen's premise is that chemical reactions occur in the fine structures of turbulence where the turbulent energy is being dissipated. Within these structures, molecular mixing occurs and the reactions can be treated at the molecular level. The EDC model is based on the concept of a reactor defined by a reaction zone in these fine turbulence structures. The length and time scales from the turbulence model are used to characterize these fine turbulence structures. The reaction rates within these fine structures can be defined with the specification of an appropriate chemical kinetics mechanism. These reaction rates are then related to the average reaction rates in the bulk fluid and then applied to the time-averaged transport equations.

While some of the simpler models mentioned above have been utilized extensively, the EDC provides a means of more accurately treating the complexities of coal combustion and modern combustion systems. This is particularly important as the sophistication of the heterogeneous combustion models improves.

Heterogeneous chemical reactions Simulation of coal combustion must account for a complex set of physical processes including drying, devolatilization, and char oxidation. When a coal particle enters the combustion zone, the rapid heatup causes moisture to evaporate.

Evaporation is followed by devolatilization to produce volatiles and char.

The volatiles consist of light gases (primarily hydrogen, carbon monoxide, carbon dioxide, and methane), tars and other residues. The devolatilization rate can not be adequately represented with a single first-order kinetic expression. Ubhayaker *et al.*¹¹ suggested a two first-order kinetic rate expression:

where K_i^d is the kinetic rate of reaction and α_i is the volatiles' mass fraction. The kinetic rates are first-order in the mass of coal remaining and are expressed in an Arrhenius form. The total devolatilization rate becomes:

$$K^d = \sum_i \alpha_i K_i^d \quad (11)$$

A more advanced model known as the Chemical Percolation Devolatilization (CPD)^{12,13,14} has been developed and is described elsewhere. Unlike the empirical formulation of Ubhayaker *et al.*,¹¹ the CPD model is based on characteristics of the chemical structure of the parent coal.

Following devolatilization the remaining particle consists of char residue and inert ash. Char is assumed to react heterogeneously with the oxidizer:

A basic approach to char oxidation was described by Field.¹⁵ The effective char oxidation rate is a function of the kinetic rate of the chemical reaction and the diffusion rate of the oxidizer to the particle.^{15,16}

where K_i^{ch} is the effective char oxidation rate. The total char oxidation rate is expressed as:

$$K^{ch} = \sum_i K_i^{ch} \quad (14)$$

The Carbon Burnout Kinetic (CBK) model has been developed by Hurt *et al.*¹⁷ specifically to model the details of carbon burnout. The model has a quantitative description of thermal annealing, statistical kinetics, statistical densities, and ash inhibition in the late stages of combustion.

Radiative heat transfer

Radiative heat transfer in combustion systems is an important mode of heat transfer and is described by the radiative transfer equation (RTE):

$$\begin{aligned} (\bar{\Omega} \cdot \nabla) I_\lambda(\bar{r}, \bar{\Omega}) &= -(\kappa_\lambda + \sigma_\lambda) I_\lambda(\bar{r}, \bar{\Omega}) \\ &+ \kappa_\lambda I_{b\lambda}(\bar{r}) + \frac{\sigma}{4\pi} \int_\Omega \Phi(\bar{\Omega}' \rightarrow \bar{\Omega}) I_\lambda(\bar{r}, \bar{\Omega}') d\bar{\Omega}' \end{aligned} \quad (15)$$

where κ_λ is the spectral absorption coefficient, σ_λ is the scattering coefficient, and $I_{b\lambda}$ is the black body radiant intensity.

This equation describes the change in radiant intensity, $I_\lambda(\bar{r}, \bar{\Omega})$, at location \bar{r} in direction $\bar{\Omega}$. The three terms on the right-hand side represent the decrease in intensity due to absorption and out-scattering, the increase in intensity due to emission, and the increase in intensity due to in-scattering.

Radiative heat transfer information is obtained by solving the RTE (Equation 15) which is coupled with the thermal energy equation by the divergence of the radiant flux vector $-\nabla \cdot \mathfrak{S}$. The divergence can be obtained from:

$$\nabla \cdot \mathfrak{S} = 4 \int_0^\infty \kappa_\lambda E_{b\lambda}(T) d\lambda - \int_0^\infty \kappa_\lambda \left[\int_0^{4\pi} I_\lambda(\bar{\Omega}) d\Omega \right] d\lambda \quad (16)$$

The two terms on the right-hand side account for emission and absorption, respectively.

Discretization of equations

In the preceding sections, a mathematical description of combustion modeling, consisting of a fundamental set of algebraic relations and differential equations of various forms, has been described. This includes fluid transport, particle transport, combustion and radiative heat transfer. Because this system of equations is too complex to solve with analytic methods, a numerical method must be employed. The methods of discretizing the fluid transport and radiative heat transfer are of particular interest and are presented here.

Finite volume approach

It should be recognized that many of the partial differential equations are of a single general form as provided in Table 2 and can be expressed as:

$$\begin{aligned} &\frac{\partial}{\partial t}(\bar{\rho}\phi) + \frac{\partial}{\partial x}(\bar{\rho}\tilde{u}\phi) + \frac{\partial}{\partial y}(\bar{\rho}\tilde{v}\phi) + \frac{\partial}{\partial z}(\bar{\rho}\tilde{w}\phi) \\ &= \frac{\partial}{\partial x} \left(\Gamma_\phi \frac{\partial \phi}{\partial x} \right) + \frac{\partial}{\partial y} \left(\Gamma_\phi \frac{\partial \phi}{\partial y} \right) + \frac{\partial}{\partial z} \left(\Gamma_\phi \frac{\partial \phi}{\partial z} \right) + S_\phi \end{aligned} \quad (17)$$

Since many of the equations share this form, a single method can be used to solve all of the associated equations. Most of these methods involve dividing the physical domain into small sub-domains and obtaining a solution only at discrete locations, or grid points, throughout the domain. The well-known *finite difference method* is one such method. Another very powerful method, that is particularly suited for use in combustion modeling, is the *finite volume approach*.

The basic idea of the finite volume approach is very straightforward and is detailed in Patankar.¹⁸ The entire domain is divided into non-overlapping control volumes with a grid point at the center of each. The differential equation in the form of Equation 17 is integrated over the entire control volume and after some rearrangement becomes:

$$\iiint_V \frac{\partial}{\partial t} (\rho \phi) dV + \oint_S (\rho \tilde{u} \phi, \rho \tilde{v} \phi, \rho \tilde{w} \phi) \cdot \hat{n} dS + \oint_S \left(-\Gamma_\phi \frac{\partial \phi}{\partial x}, -\Gamma_\phi \frac{\partial \phi}{\partial y}, -\Gamma_\phi \frac{\partial \phi}{\partial z} \right) \cdot \hat{n} dS = \iiint_V S_\phi dV \quad (18)$$

Carrying out the integrations, the resulting equation is:

$$\frac{\partial}{\partial t} (\rho \phi) \Delta V + \sum_f (C_f \phi_f - D_f(\phi)) = S_\phi \Delta V \quad (19)$$

where ΔV is the volume of the control volume, C_f is the mass flow rate out of the control volume, D_f is the diffusive flux into the control volume, and the summation is made over all the control volume faces, f . The temporal derivative in the first term of Equation 19 can be expressed using a first-order backward difference scheme:

$$\frac{\partial}{\partial t} (\rho \phi) = \rho^t \left(\frac{\phi^{t+\Delta t} - \phi^t}{\Delta t} \right) \quad (20)$$

The mass flow rate C_f is determined from the solution of the mass and momentum equations while the diffusive flux D_f is based on the effective diffusivity and the gradient at the control volume face. Combining Equations 19 and 20 with the definitions of C_f and D_f and an interpolated value for ϕ_f results in an algebraic expression in terms of the dependant variable ϕ_i at grid point i and the neighboring grid points. This is expressed as:

$$a_i \phi_i = \sum_n a_n \phi_n + b_i \quad (21)$$

where a_i and a_n are coefficients for the control volume and its neighbors respectively and b_i represents the remaining terms. The number of neighboring values that appear in Equation 21 is a function of the mesh, the method used to interpolate the dependant variable to the control volume face, and the method used to determine gradients at the control volume face.

Following this procedure for each grid point in the entire domain produces a coupled set of algebraic equations. This set of equations can be solved with an appropriate method from linear algebra. Many differ-

ent techniques are possible and can be found in a reference on numerical methods.

There are two advantages to the finite volume approach. First, the dependant variable in the resultant discretized equation is a quantity of fundamental interest such as enthalpy, velocity or species mass fraction, and the physical significance of the individual terms is maintained. Second, this approach expresses the conservation principle for the dependant variable over a finite control volume in the same way the conservation equation expresses it for an infinitesimal control volume. By so doing, conservation is maintained over any collection of control volumes and is enforced over the entire domain.

Discrete ordinates method

Several radiative heat transfer models have been developed and many are described by Brewster¹⁹ and Modest.²⁰ A recent review of radiative heat transfer models²¹ states that the discrete ordinates method coupled with an appropriate spectral model provide the necessary detail to accurately model radiative heat transfer in combustion systems. This is one of the most common methods currently used to model radiative heat transfer.

The discrete ordinates method (DOM)^{22,23} solves the radiative transport equation for a number of ordinate directions. The integrals over direction are replaced by a quadrature and a spectral model is used to determine radiative properties of κ and σ . This results in a set of partial differential equations given by:

$$\mu_m \frac{\partial I_m}{\partial x} + \eta_m \frac{\partial I_m}{\partial y} + \xi_m \frac{\partial I_m}{\partial z} = -(\kappa + \sigma) I_m + \kappa I_b + \frac{\sigma}{4\pi} S_m \quad (22)$$

where μ_m , η_m , ξ_m are the direction cosines of the chosen intensity I_m and S_m is the angular integral. This set of equations is solved by a method outlined by Fiveland²² to find the radiative intensities throughout the combustion space. The source term for the energy equation can be found by summing over all directions:

$$\nabla \cdot \mathbf{q}_r = 4\kappa \tilde{\sigma} T^4 - \kappa \sum_{m'} w_{m'} I_{m'} \quad (23)$$

Mesh generation

Once discretized, the transport equations must be solved at individual points throughout the domain. This requires that the individual points be specified and the relationship between other points be identified. Displaying the points along with the connections between them creates a pattern that looks something like a woven mesh. The process of creating the mesh is therefore known as *mesh generation*.

Mesh generation is an important and often challenging step in the overall modeling effort. The first criterion in mesh generation is to accurately represent the geometry being modeled. Secondly, adequate detail must be placed throughout the domain to obtain

an accurate solution. Other criteria include mesh quality and total mesh size. A discussion on these criteria can be found elsewhere.²⁴

Cell types

The basic unit in a mesh is the control volume or cell. The cells are arranged such that they cover the entire domain without overlapping. Common cell types are shown in Fig. 2. The mesh may be made of a single cell type (homogeneous mesh) or possibly a combination of different types (hybrid mesh).

Structured mesh

Structured meshes consist of cells placed in a regular arrangement such that adjacent cells can be identified simply by their order in a list. Fig. 3 shows how the neighboring cells are identifiable simply by incrementing an index that is typically aligned with the coordinate directions. This greatly simplifies the task of retrieving information from neighboring cells. For simple geometries, a structured mesh is both simple to generate and efficient when solving the problem. However, complex geometries highlight particular challenges with this approach. This is illustrated in Fig. 4. Two common techniques of dealing with irregularities in geometry are 1) a cartesian stair-stepped mesh and 2) body-fitted mesh. The stair-stepped mesh can place cells in areas outside of the domain and approximates boundaries by stair-stepping the mesh (Fig. 4a). The cells outside of the domain are maintained as part of the mesh structure but are unused during the computation. The body-fitted mesh follows geometric features and the cell shape changes to accommodate these physical features (Fig. 4b).

Slight variations of the simple structured mesh can be used. Block structured meshes provide more geometric flexibility since the entire mesh is a composite of smaller structured meshes.

Unstructured mesh

An unstructured mesh provides the maximum flexibility for complex geometries. While the ease of obtaining neighboring cell information has been lost, the ability to place cells anywhere in the computational domain increases the ease by which the geometry can be accurately represented. Fig. 4 compares an unstructured mesh with two structured mesh approaches. With an unstructured mesh approach there is greater control over the level of detail in the mesh for different parts of the domain.

Embedding and adaption

More detail can be obtained in portions of the domain through increasing the mesh resolution by embedding more cells. This is accomplished by splitting an existing cell in some fashion to create additional cells. By splitting a cell in each of the cell's parametric coordinate directions, a single hexahedron would become eight. This greatly increases the resolution in this region.

Often it is not possible to know where resolution is needed a priori. The process of adaption can be used to increase the resolution based on the actual solution. For example, high discretization error may often be related

to high solution gradients across cells. In this case the velocity gradient from the solution can be used to discover where more cells are needed. This is an especially powerful tool when computational resources are limited.

Example applications

Wet scrubbers

Situation The two-phase flow in a wet flue gas desulfurization (WFGD) scrubber tower is a complex process involving spray atomization, liquid entrainment, droplet disengagement and phase separation. The physical arrangement of a basic WFGD scrubber module is shown in Chapter 35, Fig. 2. With a tray, there is a bubbly froth due to countercurrent flow of liquid and gas with holdup of liquid on the tray. The various two-phase flow regimes complicate the calculation of pressure drop and gas velocity distribution in a wet scrubber. Prediction of two-phase flow is essential since liquid residence time and total interfacial liquid/gas area are important factors in determining the amount of SO₂ absorption. Therefore, The Babcock & Wilcox Company (B&W) has implemented a multi-dimensional two-phase flow model for wet scrubbers based on CFD analysis.

A multi-dimensional hydraulic model solves separate equations for mass and momentum for both the liquid and gas phases. An interfacial drag law calculates the resistance of liquid to the gas flow and vice versa. These interfacial drag laws depend primarily on droplet diameter. However, alternate drag equations can be implemented in the multi-dimensional model for the various two-phase flow regimes. By using the fundamental relations for interfacial drag, the model can calculate separate three-dimensional velocity fields for the liquid and gas phases. Both liquid and gas momentum equations share a common static pressure field.

Fig. 2 Cell or control volume types used in numerical modeling grids or meshes.

The numerical model is used as an analysis tool to compare and contrast various design configurations for wet scrubbers. The design features considered by the model include:

1. an overall cylindrical geometry,
2. a tray model with baffles and porous plates,
3. nozzles located at various elevations,
4. conventional or interspatial headers,
5. separate air and water outlets,
6. multiple mist eliminator heights and elevations,
7. conical or straight inlets with or without inlet awnings, and
8. cylindrical or conical outlet ducts.

These design features are adjustable, thereby permitting a wide range of scrubber configurations for utility boiler applications. The boundary conditions at the gas inlet and spray nozzles can be adjusted to cover all scrubber gas velocities and liquid mass fluxes.

Analysis The model was initially validated against hydraulic data from a one-eighth scale laboratory wet scrubber. By comparing model predictions to scale model pressure drop data, confidence was built in the two-phase flow modeling capability. Once validated, the model was tested for full-scale application by comparing results to company design standards. Although the model compared favorably to data and standards, absolute prediction of wet scrubber performance is not the primary purpose. Instead, comparative studies are done to predict relative performance of various design options. The numerical model excels at looking at new design configurations that fall outside of existing design standards.

Results As discussed in Chapter 35, *Sulfur Dioxide (SO₂) Control*, the flue gas enters the side of the scrubber tower and turns upward to flow through the tower while the reagent slurry flows countercurrent downward, removing SO₂. A uniform gas velocity profile across the tower diameter maximizes removal efficiency as the reagent slurry and flue gas flow are uniformly mixed. Fig. 5 shows the CFD modeling results as vertical velocity profiles at several plains through the tower, and illustrates the impact of the B&W tray design in producing uniform flue gas flow

Fig. 3 Unit cell identification in a rectangular arrangement.

Fig. 4 How mesh or grid structure approximates geometric features.

through the unit. Fig. 5a shows the case without the tray. The lowest profile shows how non-uniform flow develops as the high velocity flue gas is introduced into the tower, is decelerated, and makes a sharp right-angle turn to flow up the tower. In the absence of a tray, the high velocity (red) and low velocity (blue) regions persist as the flue gas moves through the middle of the tower (middle velocity profile) entering the first level of spray headers. Some of the non-uniformity persists even up to the mist eliminators. With the addition of the tray (Fig. 5b), the large high and low velocity regions are effectively eliminated. The resulting more-uniform velocity profile and the gas/reagent mixing on top of the tray permit higher levels of SO₂ control at reduced slurry recirculation rates.

This model has also been used to explore design changes to meet site-specific new and retrofit requirements.²⁵ These have included alternate flue gas exit geometries, flue gas inlet conditions, tower diameter transitions, header locations, slurry recirculation rates or other factors while still achieving the desired performance. It has also been used to investigate internal design alternatives to boost performance and reduce pressure drop.

Popcorn ash

Situation Popcorn, or large particle, ash forms under certain conditions from the combustion of coal and

is light, porous, irregularly shaped, and often forms in the upper boiler furnace or on the convective heat transfer surface. This ash can plug the top catalyst layer in selective catalyst reduction (SCR) NO_x control systems, increasing pressure drop and decreasing catalyst performance. Modifications to both the economizer outlet hoppers and the ash removal systems can increase ash capture to address this situation.

Accurately predicting how the popcorn ash behaves within the economizer gas outlet requires detailed knowledge of the aerodynamic properties of the ash particles and sophisticated modeling techniques. Key ash properties include the particle density, drag coefficient, coefficients of restitution, and its coefficient of friction with a steel plate. CFD models involve solving the gas flow solution, then calculating the particle trajectories using B&W's proprietary CFD software.

Analysis Most CFD programs that handle particle-to-wall interactions are not adequate to accurately predict the complex behavior seen in the popcorn ash physical experiments. These deficiencies have been remedied by adding capabilities to B&W's proprietary CFD software. First, the coefficient of restitution is separated into its normal and tangential components. Next, a particle-to-wall friction model is used for particles sliding along the wall and experiencing a friction force proportional to the coefficient of friction measured in the physical tests. Also, the ability to set

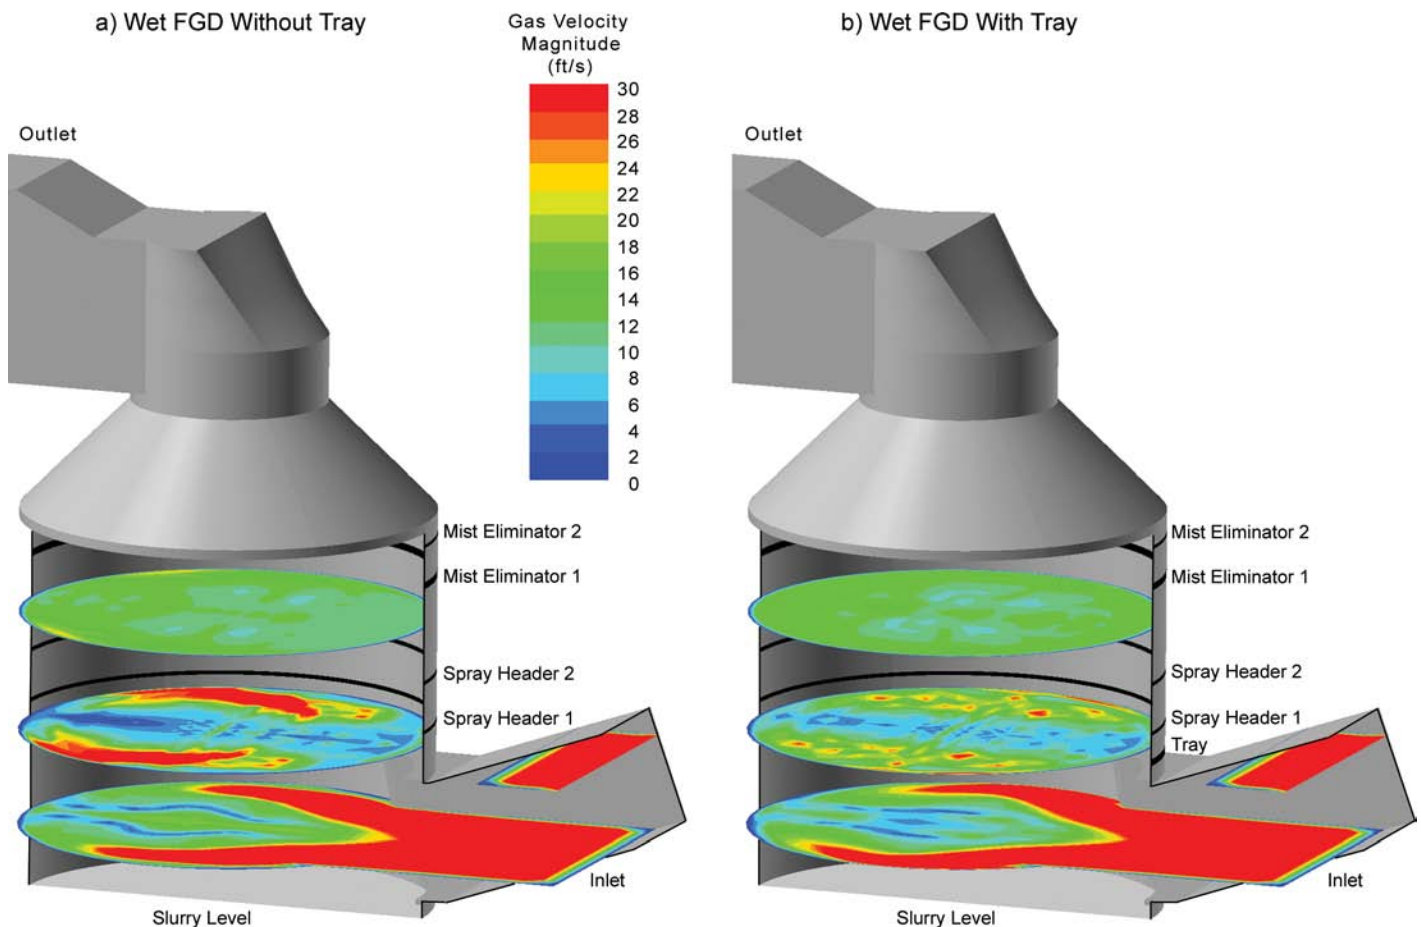

Fig. 5 Effect of B&W's tray design on gas velocities through a wet flue gas desulfurization system – numerical model results on a 650 MW absorber.

Fig. 6 Profile of popcorn ash evaluation numerical model.

up user-defined planes through which flue gas could flow, but off which particles would reflect, has been developed to accurately model particle interaction with wire mesh screens.

Results The numerical models used in popcorn ash analysis normally extend from just above the bottom of the economizer (providing a reasonably uniform inlet flow distribution) to just beyond the opening of the economizer gas outlet flue (see Fig. 6). For this sample geometry, the baseline particle trajectories from the numerical model are shown in Fig. 7. Over the ash

Fig. 7 Base case particle trajectories from popcorn ash evaluation.

Fig. 8 Comparison of sensitivity to particle density between base case and baffled numerical models.

particle size range typical of this application, 20 to 50 % of the particles (Fig. 8) pass through the economizer hopper into the downstream equipment depending on particle size, potentially causing the plugging problems in the SCR or air heater. Several solutions were evaluated for this sample geometry including a design that relies on the aerodynamic separation of the particles from the flue gas and another design that involves physical barriers to the particles using a wire mesh screen. The aerodynamic solution was selected and a baffle was designed and installed. The general baffle location and the particle trajectories from the numerical model are shown in Fig. 9. The fully three-dimensional model predicted a dramatic improvement in the particle collection efficiency with more than 90% of particles collected for the range of particle sizes evaluated and virtually 100% above a certain cut size

Fig. 9 Particle trajectories from popcorn ash evaluation numerical model with baffle.

(see Fig. 8). Using numerical models also permitted an optimization of the baffle position to achieve the greatest capture rate while minimizing the pressure drop. In other cases, where an aerodynamic solution is not obtainable, barriers made from wire mesh screens have been recommended. In these cases, the screen openings would be smaller than the openings in the catalyst.²⁶

Kraft recovery boilers

Situation A kraft process recovery boiler, as its name implies, recovers energy and chemicals from black liquor, a byproduct of the papermaking process (see Chapter 28). Air and liquor delivery systems control several complex and interacting combustion processes (black liquor spray, deposition and burning on furnace walls, char bed burning, smelt flow) that affect boiler performance (capacity, reliability, emissions, chemical recovery, and energy efficiency). Good air jet penetration and effective mixing of secondary and tertiary air are desirable for complete combustion and reduced emissions of carbon monoxide (CO) and hydrogen sulfide. Distribution of air to three or more air injection levels produces fuel-rich conditions in the lower furnace that are desirable for smelt reduction and reduced emissions of NO_x. Flow and temperature uniformity in the furnace minimize carryover of inorganic salts, provide an even heat load, and minimize deposition on convection surfaces at the furnace exit. Uniform distribution of liquor spray ensures adequate drying of liquor spray, minimum carryover, and stable char bed combustion.

Analysis Detailed combustion models for black liquor have been developed^{27,28} and are used in conjunction with CFD modeling. Black liquor combustion is simulated for individual droplets as they heat up and burn in suspension. Stages of combustion along a single trajectory include drying, devolatilization, char burning, smelt oxidation, and molten salt formation. The trajectories of thousands of particles determine the distribution of liquor spray in the furnace as shown in Fig. 10 for a range of droplet sizes. Combustion processes on the walls and char bed are also simulated with particle deposition, char burning, smelt flow and char accumulation. These capabilities are useful for evaluating the effect of air and liquor delivery systems on combustion processes in the furnace and for predicting the quantity and composition of particulate that leaves the furnace.

Results Fig. 11 shows gas velocity vectors at selected planes that cross-section the furnace. The char bed shape is approximated so its impact on flow in the lower furnace can be evaluated with the model. Jets of air penetrate across the furnace to produce uniform upward flow and effective mixing with combustion gases. Three-dimensional computer-generated images can be examined interactively to help visualize air jet penetration and the interaction of jets from neighboring air ports. Gas temperature distribution predictions, shown in Fig. 12, are used to analyze heat transfer in the furnace and convection pass. Other information such as char bed surface temperature and burning rates, gas species concentrations (i.e., O₂, CO, NO_x), and wall heat flux distribution are also gener-

ated. Results are used by boiler designers and operators to evaluate air system designs, liquor spraying systems, liquor firing capacity, char bed combustion instabilities, convection pass fouling, furnace wall corrosion, and CO and NO_x emissions. The results shown were created by B&W's proprietary CFD software.

Wall-fired pulverized-coal boiler furnaces

Situation Within a staged, wall-fired furnace, the mixing between the upward-flowing partially-reacted fuel and the jets from the overfire air (OFA) ports is a complex, three-dimensional process. This mixing process can have a significant impact on the distribution and magnitude of CO emissions. While proprietary technology standards can initially be used to set effective OFA port arrangements for a staged combustion system, numerical modeling is often used to confirm this design and suggest alternatives to improve performance. Modeling is especially useful when there are physical obstructions that prevent OFA port placement in the optimal locations. In these circumstances, compromises must be made and determining the best available port layout may not be obvious.

Analysis In this example, a numerical model has been used to predict the steady-state flow, heat transfer, and combustion processes within a wall-fired pulverized-coal boiler being upgraded with low NO_x burners and OFA ports. As part of the design process, many

Fig. 10 Liquor spray distribution in the lower furnace of a recovery boiler.

configurations (number and location) of OFA ports were modeled, and the results were compared to determine the best port configuration. Boiler geometry, including a portion of the convection tube banks, was approximated using a collection of control volumes, also called a *computational grid* or *mesh*, for one of the configurations considered (see Fig. 13). Local refinement of the mesh was used as needed to better resolve the solution, such as within the OFA region. The coal analysis and boiler operating conditions including burner and OFA port settings were used to set inlet and boundary conditions for the model.

Results The model produces tabular (integrated species concentrations, gas temperatures, gas flow rates, emissions) and graphical (color contour plots of gas speed, gas temperature, or species; coal particle

trajectories; gas streamlines) output that are used to evaluate each configuration. As an example, Fig. 14 compares contours of CO concentration throughout the boiler for two different OFA arrangements for a 775 MW wall-fired pulverized coal boiler. Arrangement 1 has the OFA ports directly above the burner openings and directly across from the ports on the opposing wall, while arrangement 2 uses horizontally offset ports which provide better mixing and cross-sectional coverage. As shown in the figure, OFA arrangement 2 results in lower CO concentrations in the upper furnace than the OFA arrangement 1 (15% lower at the arch, and 23% lower at the furnace exit). The results for this example were created by the B&W-developed computer software.

The numerical model described above also provides

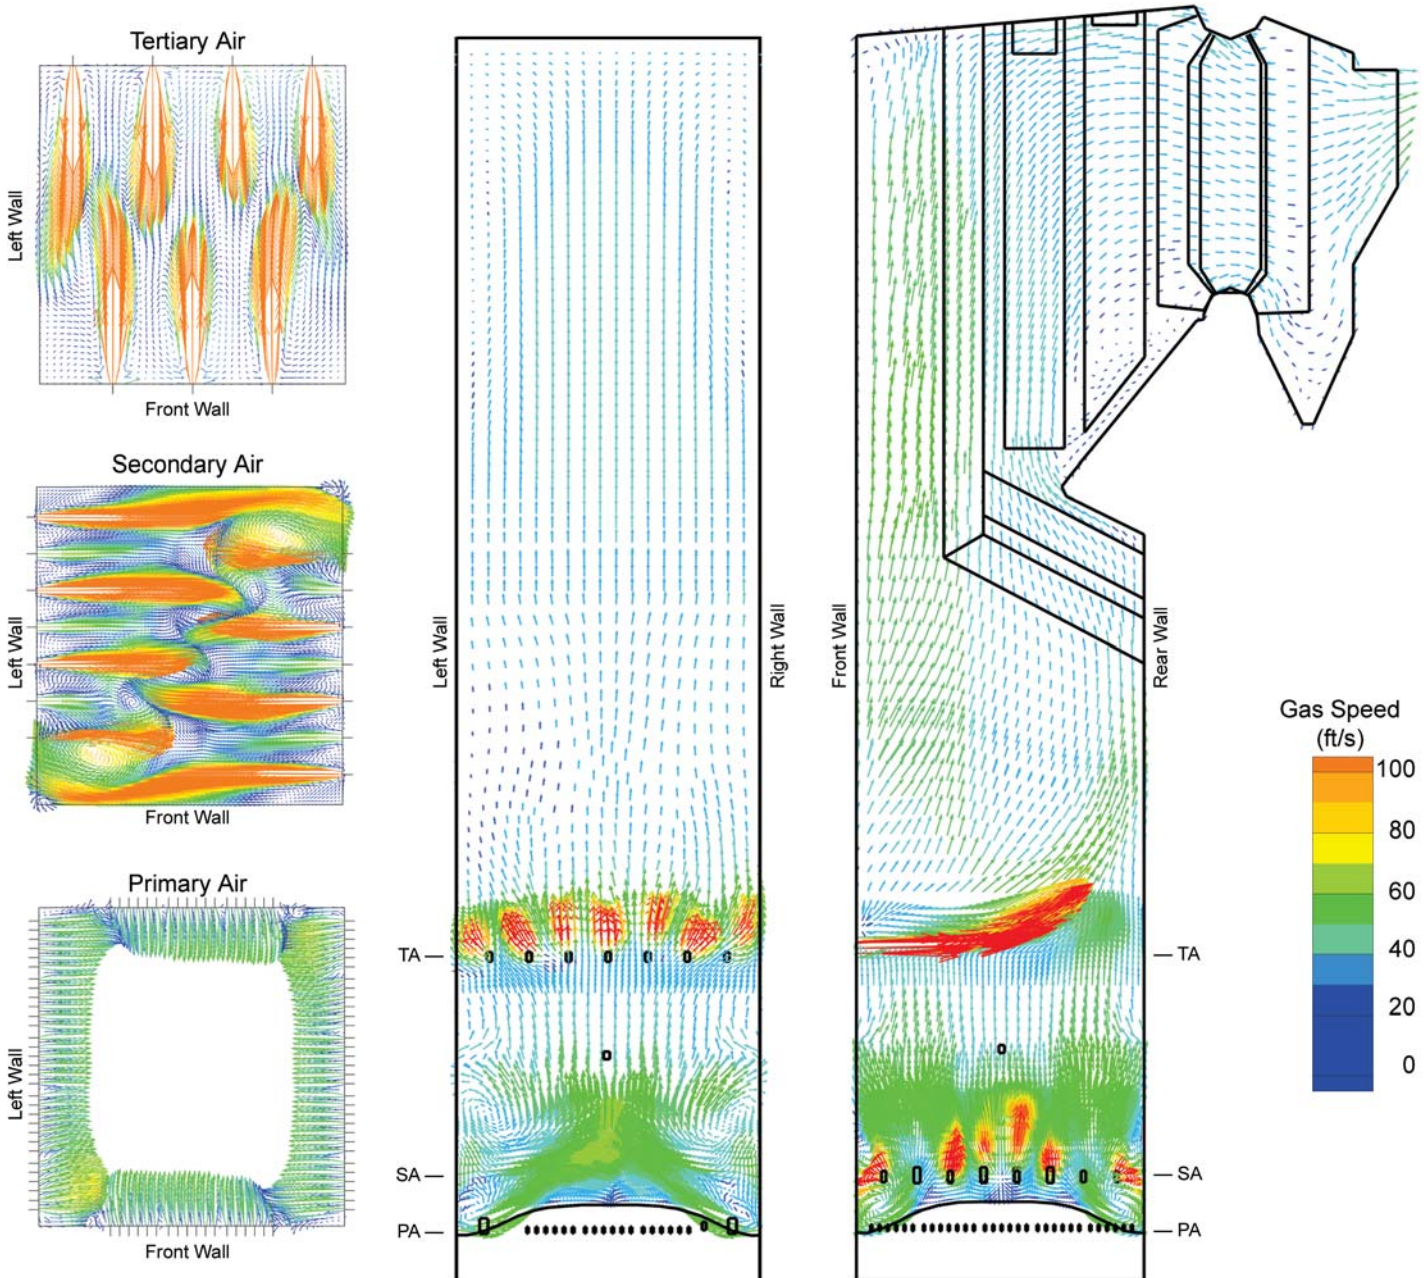

Fig. 11 Velocity vectors at selected planes that cross-section a recovery furnace – horizontal planes at primary, secondary and tertiary levels (left); vertical planes at center of furnace (center and right).

a wealth of other information for the boiler designer. Fig. 15 provides a flue gas temperature profile through the center of the furnace and a horizontal section profile across the furnace exit gas pass. As noted in Chapter 19, the average or integrated furnace exit gas temperature (FEGT) is a critical design parameter in boiler sizing for performance while mitigating slagging and fouling. Flow areas with excessively high local temperatures identified by such numerical models may be more prone to slagging in the furnace or fouling in the convection pass. Additional parameters of interest provided by the numerical models include, but are not limited to, local velocity profiles for performance enhancement and erosion evaluation, furnace heat flux profiles for steam-water circulation evaluation,²⁹ variation in local chemical constituents such as oxygen for studying combustion optimization, and many others. Numerical boiler furnace models continue to evolve and more closely simulate field conditions. While current models as of

this publication are not sufficient alone for final boiler design, they offer an additional tool to: 1) aid in design optimization, 2) address non-standard conditions, 3) evaluate the relative impact of fuel changes, 4) highlight areas for design improvement, 5) help investigate the root causes of unusual field observations, and 6) screen potential approaches to address design issues. Numerical modeling will become an increasingly important tool in boiler engineering.

Windbox

Situation The problems encountered in a windbox analysis deal with air flow imbalance and/or excess system pressure loss. Difficulties in tuning burner combustion performance can be frequently attributed to the flow distribution within the windbox. Therefore, creating a uniform flow distribution to each burner is highly desirable to obtain optimum emissions performance. The flow imbalance problem can be between the front and rear walls of a furnace, compartments in a

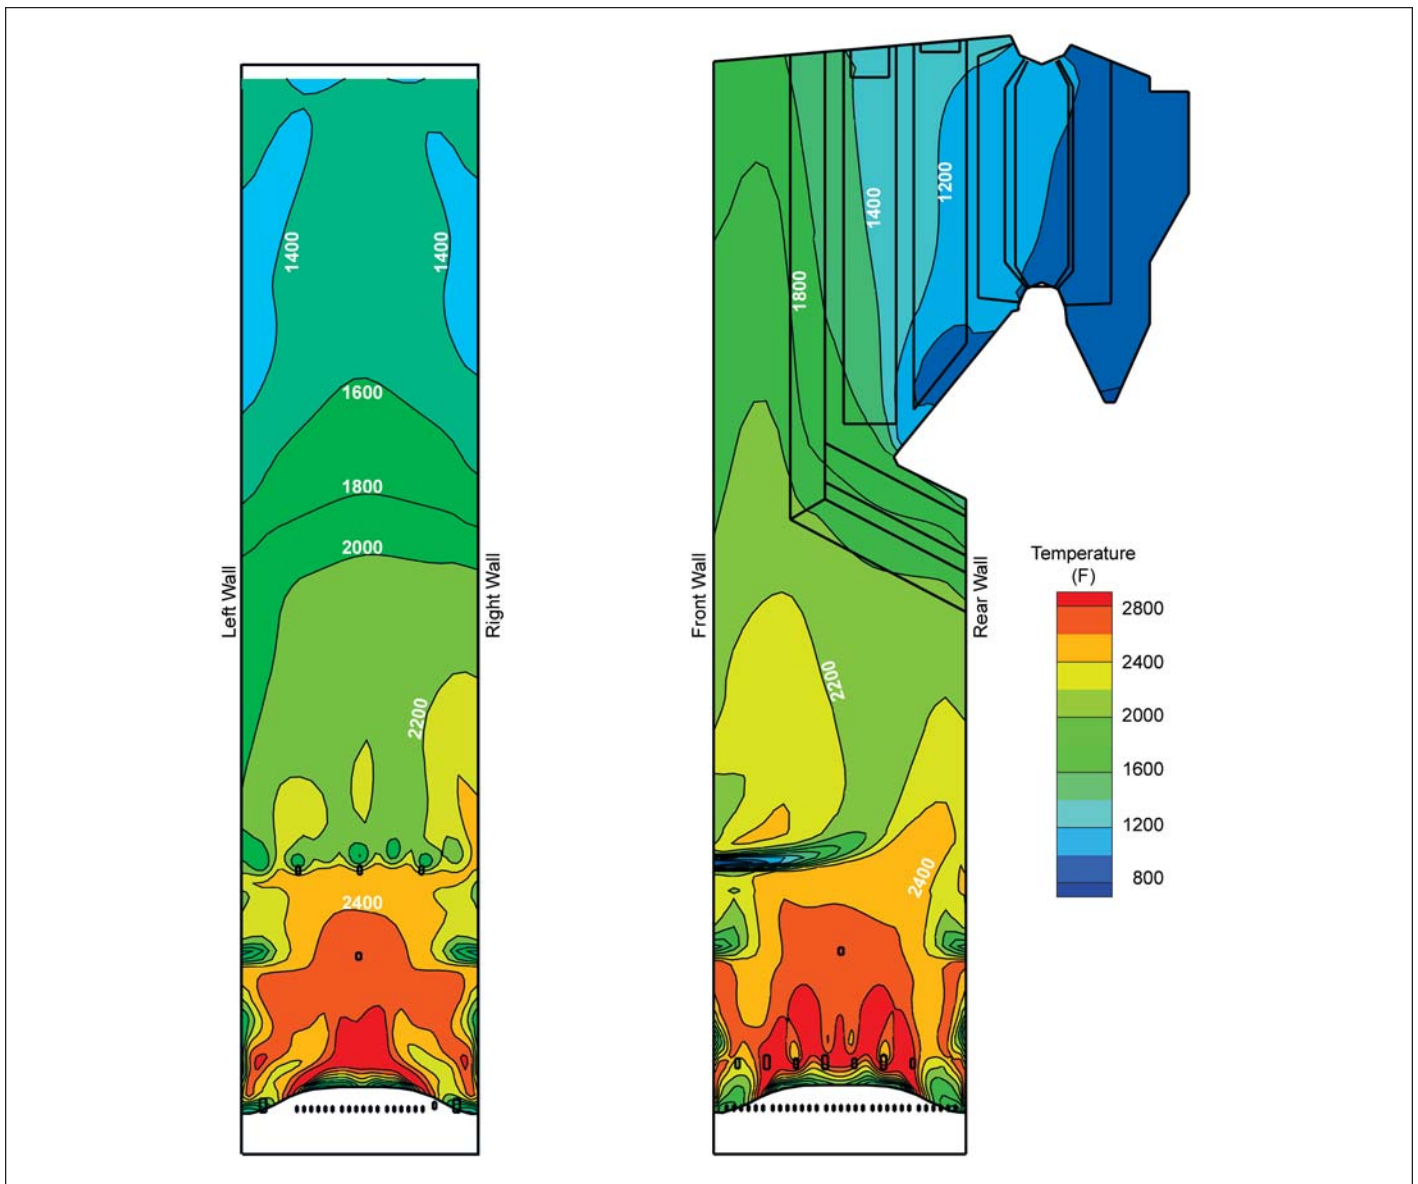

Fig. 12 Gas temperature contours at vertical planes at the center of a recovery boiler furnace.

Fig. 13 Computational mesh on wall-fired boiler surface – full mesh (left) and enlarged view of upper burners and OFA ports (right).

windbox, or individual burners and/or ports. Any imbalance or maldistribution causes non-uniform air introduction into the furnace. This imbalance can lead to poor furnace combustion and potentially higher gas emissions. The system can be modeled to reduce air flow imbalance and reduce system pressure loss, which allows more flexibility in combustion tuning of a single burner.

Analysis A computer model that describes the details of the windbox (walls, bends, etc.) must first be built (see Fig. 16). This requires both flow and geometric design information. Care must be taken to ensure accurate representation of the entire air flow path including any significantly-sized internal obstructions. The inlet of the model is usually the outlet of the air heater. This is done for two reasons. An accurate and simple air flow distribution is usually known at this

location, and it is far enough upstream to capture all the resulting flow disturbances. The burners and ports must also be modeled accurately to ensure precise flow results. Boundary conditions are the final and very important step, to be placed accurately in the model to exactly represent the windbox/duct flow conditions.

Results Once the model has been built, it is checked to make sure grid characteristics are acceptable. This step ensures that there is enough grid resolution to accurately represent the flow conditions in any area (i.e., turns, ducts, plenums) and around any objects (i.e., turning vanes, perforated plates, air foils). The model is then run using CFD software. These calculations yield an accurate representation of the air flowing in the space inside the ducts and windbox.

Fig. 17 shows the plan view of the secondary air

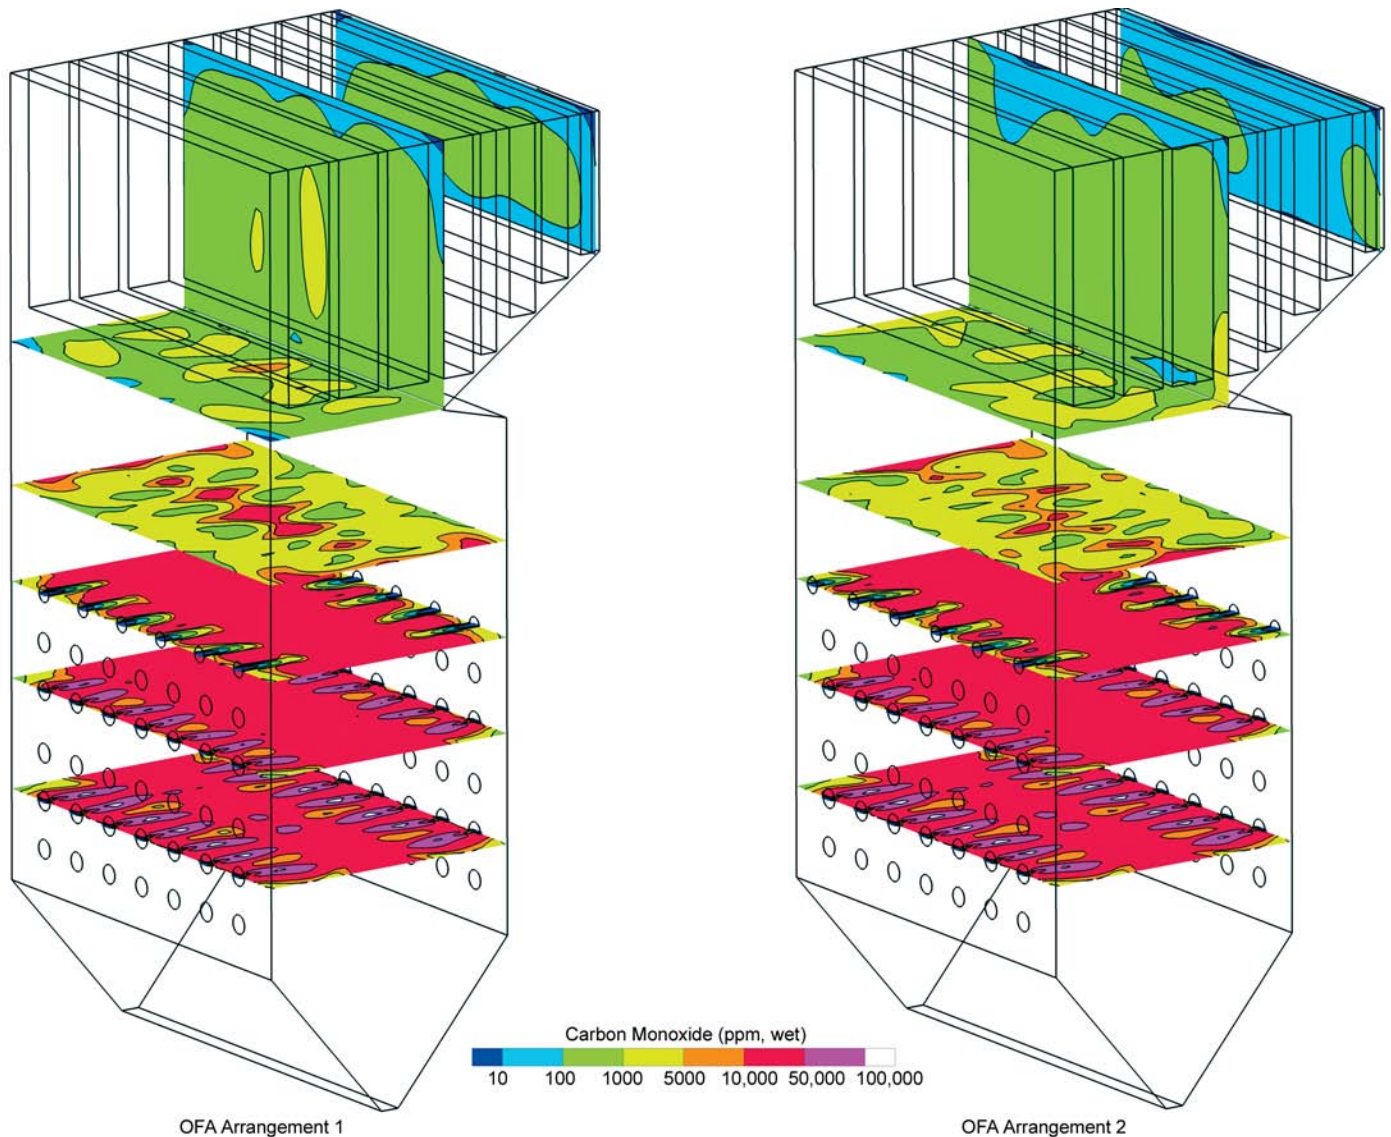

Fig. 14 Carbon monoxide concentration contours at various elevations – comparison between two OFA arrangements.

ducts and the windbox with the velocity-vector flow field at the middle of the duct system. Each arrow provides the direction and the magnitude (arrow length) of the local air flow. Fig. 18 is Section A-A through the windbox plan view of Fig. 17, looking into the furnace. Fig. 18a shows the original design which included a simple windbox with a large horizontal perforated plate intended to provide uniform flow to the bottom three burner rows. The numerical model results indicated a very high velocity zone (large red arrows) in the upper windbox which forced much of the air to bypass the upper burner row and over-supply the bottom two rows. The 30% flow variation between highest and lowest flow burners was too high and could lead to poor emissions performance and incomplete combustion. Several numerical modeling iterations using CFD computer software suggested the optimized solution shown in Fig. 18b. Eliminating the original large horizontal perforated plate plus adding two turning vanes, a vertical solid plate in the top of the windbox, and ten short vertical perforated plates

dramatically improved the burner-to-burner flow distribution to within normal design tolerances.

The numerical model permitted testing of ten alternatives prior to selecting the low-cost solution which would also achieve the desired performance results.

SCR systems with economizer bypass

Situation A selective catalyst reduction (SCR) system with an economizer bypass is designed to reduce NO_x emissions by a chemical reaction between NO_x and added ammonia in the presence of a catalyst. (See Chapter 34.) To optimize the chemical reaction at low and intermediate loads, an economizer bypass is needed to increase the temperature of the economizer exit flue gas. The ammonia injection grid (AIG) distributes ammonia uniformly into the exit gas for the correct molar ratio of ammonia to NO_x . Finally, the catalyst is used to aid in the chemical reaction.

CFD modeling of the SCR system includes full-scale representation, multiple temperature gas paths, heat absorption modeling capability, multi-point testing

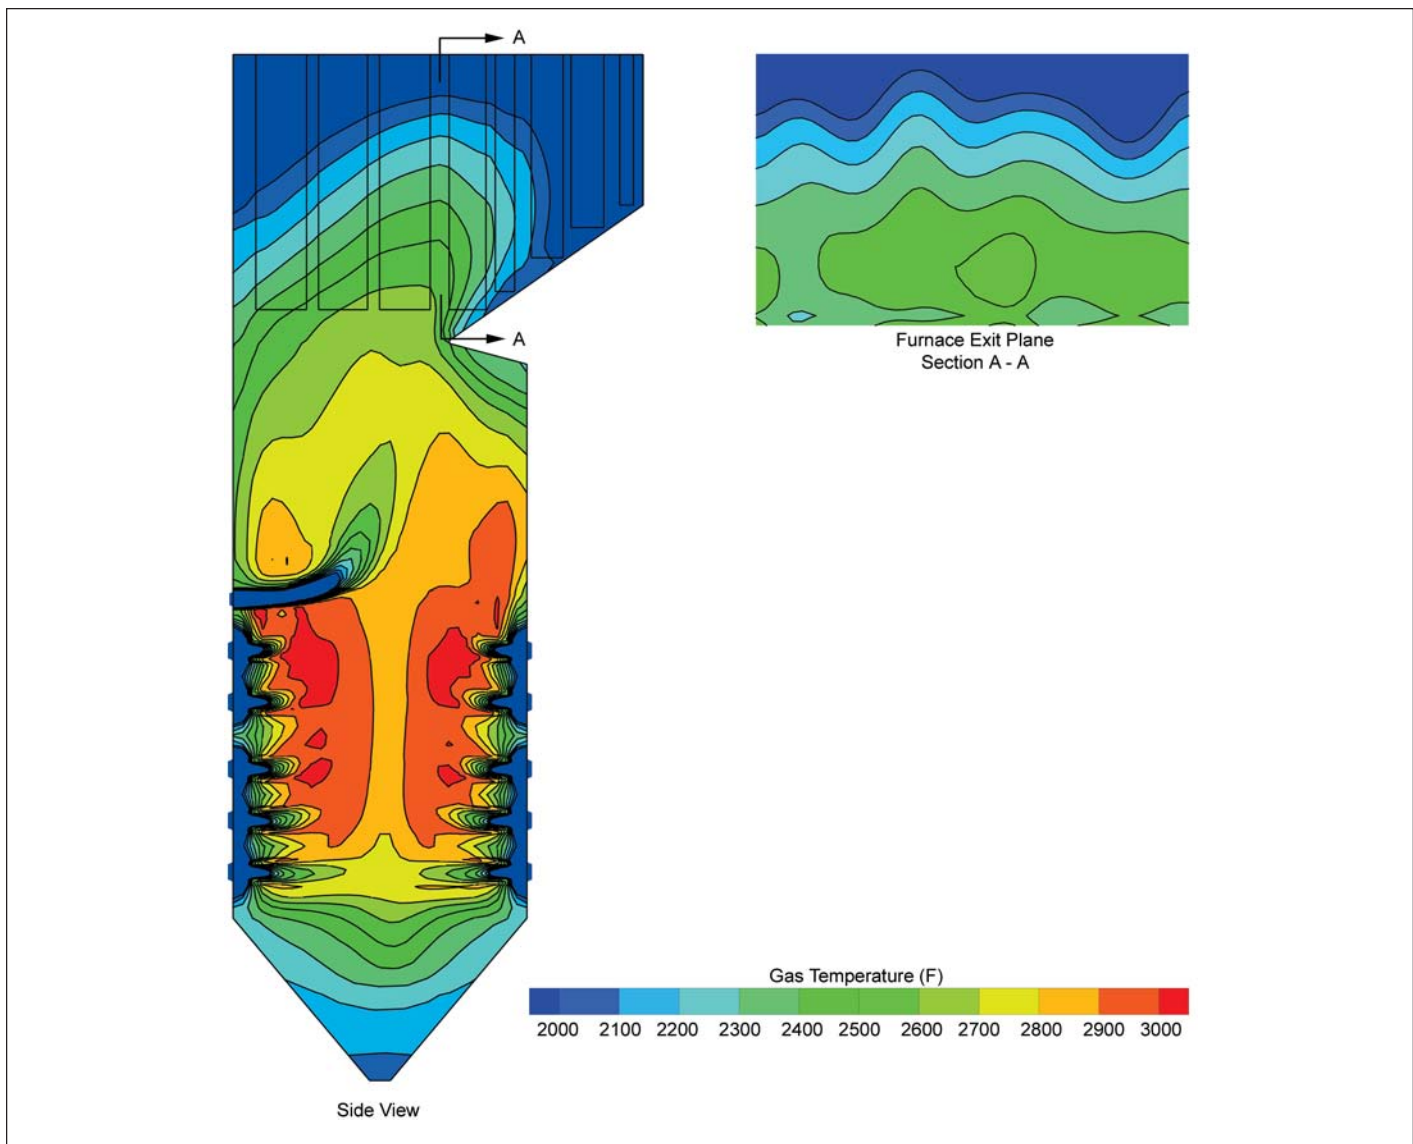

Fig. 15 Numerical modeling results of furnace temperature profiles for a typical 775 MW bituminous coal-fired boiler.

over an entire grid plane or discrete point testing, chemical species tracking, and rapid flow device testing for proper mixing, flow distribution, and minimal pressure drop.

Analysis The numerical model is constructed and tuned for actual conditions of an unmodified system according to existing economizer exit flue gas conditions. Drawings of future construction and design of the flue work, AIG, and information supplied by the catalyst vendor are used to establish a base operating condition. The chemical species are tracked for accurate mixing of ammonia and NO_x reagents. The data collected at specific planes in the grid are evaluated against established criteria for efficient NO_x removal such as velocity distribution, ammonia-to- NO_x ratio, and average temperature entering the catalyst. Internal corrective devices such as turning vanes, flow distribution diverters, static mixers and porous plates, are used to precondition the flue gas to meet the criteria for NO_x reduction. Grid refinement may be necessary to accurately predict the physical characteristics of in-

ternal objects, flue bends and flow distribution devices.

Results One such design involves a unit operating at three loads with an economizer bypass taken off the reheat side of the back wall convection pass to achieve adequate remix temperatures for the chemical reaction. For bypass operation, three gas paths are considered in the design process: superheat, reheat, and economizer bypass. Because of physical constraints and potential changes in the economizer outlet temperature with reheater or superheater bypass arrangements, a bypass around the economizer surface was selected. Fig. 19 shows the velocity flow field for the numerical evaluation from the superheater through the exit of the SCR. Fig. 20 shows the detailed velocity field and physical geometry at the bypass location. A key issue was the complete mixing of the high temperature bypass flow with the main flue gas flow exiting the economizer in order to provide an acceptably uniform flue gas temperature entering the SCR catalyst. To achieve the desired mixing, a series of turning vanes and mixing devices for the economizer

Fig. 16 Numerical model of 1100 MW coal-fired boiler windbox and secondary air system.

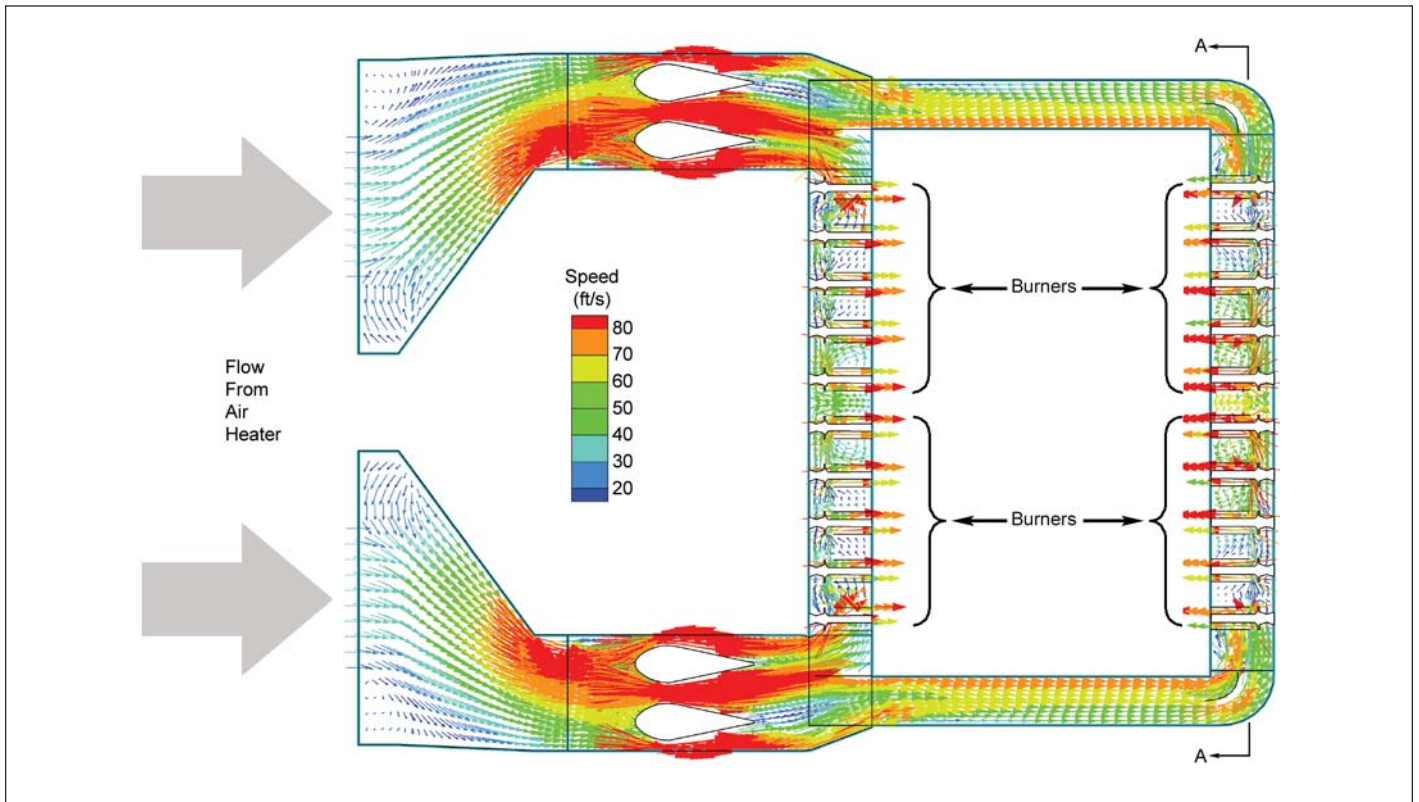

Fig. 17 Plan view of secondary air system flow model results – velocity vectors.

outlet hopper were developed with the aid of the numerical model to provide the high velocity bypass jet that would adequately penetrate the main economizer outlet flue gas flow. Success in the design iteration process was achieved when the velocity profile entering the AIG and the temperature profile entering the SCR achieved the specified uniformity.

Waste-to-energy systems

Situation Effective combustion of municipal solid waste (MSW) and biomass fuels has become more challenging over time as emissions regulations have been tightened and the variation of fuel characteristics has increased. As part of the process to meet these more demanding requirements, numerical modeling has become a routine engineering tool used in the installation of emissions control systems such as selective non-catalytic reduction (SNCR) NO_x control systems (see Chapter 34), refinement of the design and operation of the stoker/grate combustion system with auxiliary burners (Chapter 16) and overall design of the boiler (Chapters 29 and 30). Control of the flue gas in the furnace in terms of chemical species, particles, temperature and flow is important where a *good* furnace design results in more uniform velocity profiles. High velocity regions can cause: 1) increased wall deterioration from the hot corrosive flue gas with premature component replacement, 2) sub-optimal emissions control without adequate residence time at temperature, and 3) incomplete burnout of the fuel.

Analysis A numerical evaluation of the furnace was conducted as part of the design of a 132 ton per day (120 t_m/d) mass burn MSW stoker-fired system. Fig. 21 shows the sectional side view of a European waste-to-energy plant design supplied by B&W. A complete flow field evaluation of the furnace design using numerical modeling was conducted to determine the physical furnace modifications necessary to minimize high velocity areas.

Results Fig. 22 shows the numerically evaluated velocity vector flow field before (a) and after (b) the design changes. The flow field is represented by arrows that show the local velocity direction and magnitude (arrow length). In Fig. 22a, a high velocity jet region impinges on the top of the grate, and high velocity regions exist along the first (up) and second (down) pass furnace walls. The addition of *noses* at the bottom of the first pass and the top of the second pass walls as shown in Fig. 22b significantly reduce the velocities throughout the furnace and reduce the peak velocity regions near the grate and along the furnace walls. The more moderate velocity in the first pass results in less particle impingement and longer overall residence time. The maximum velocity in the second pass is reduced from 13 m/s to 9 m/s (42.6 to 29.5 ft/s), which reduced the thermal load on the back wall of the second pass.

Advanced burner development

Situation Advanced burner and combustion system development are increasingly relying on the use of numerical modeling as an integral tool in the quest for new hardware and concepts to improve the NO_x

reduction performance of coal-fired burners. While traditional experimental methods of burner development have been able to dramatically reduce NO_x emission levels from bituminous pulverized coal burners below $0.4 \text{ lb}/10^6 \text{ Btu}$ ($492 \text{ mg}/\text{Nm}^3$), increasingly more stringent emission reduction regulations are pushing specified combustion emission limits to well below $0.15 \text{ lb}/10^6 \text{ Btu}$ ($184 \text{ mg}/\text{Nm}^3$). To develop such equipment, it is becoming even more necessary to understand not only what is happening at the macro-level (which can be observed and tested) but also with small-scale interactions deep within the flame and initial ignition zone. Numerical modeling studies of detailed burner designs offer a valuable tool by combining fundamental knowledge of combustion with complex fluid and thermal dynamics to better understand how to further reduce NO_x emissions and improve combustion efficiency. When combined with small-scale and large-scale tests with advanced test instrumentation, nu-

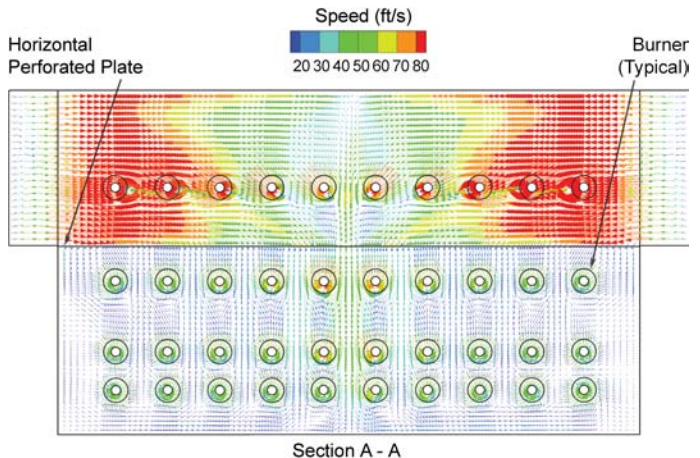

Fig. 18a Before – high velocity zone in upper windbox (red arrows) under-supplies top row of burners and over-supplies other rows.

Fig. 18b After – removal of the large horizontal perforated plate plus the addition of two turning vanes and 10 small vertical perforated plates provides more uniform flow to the burners.

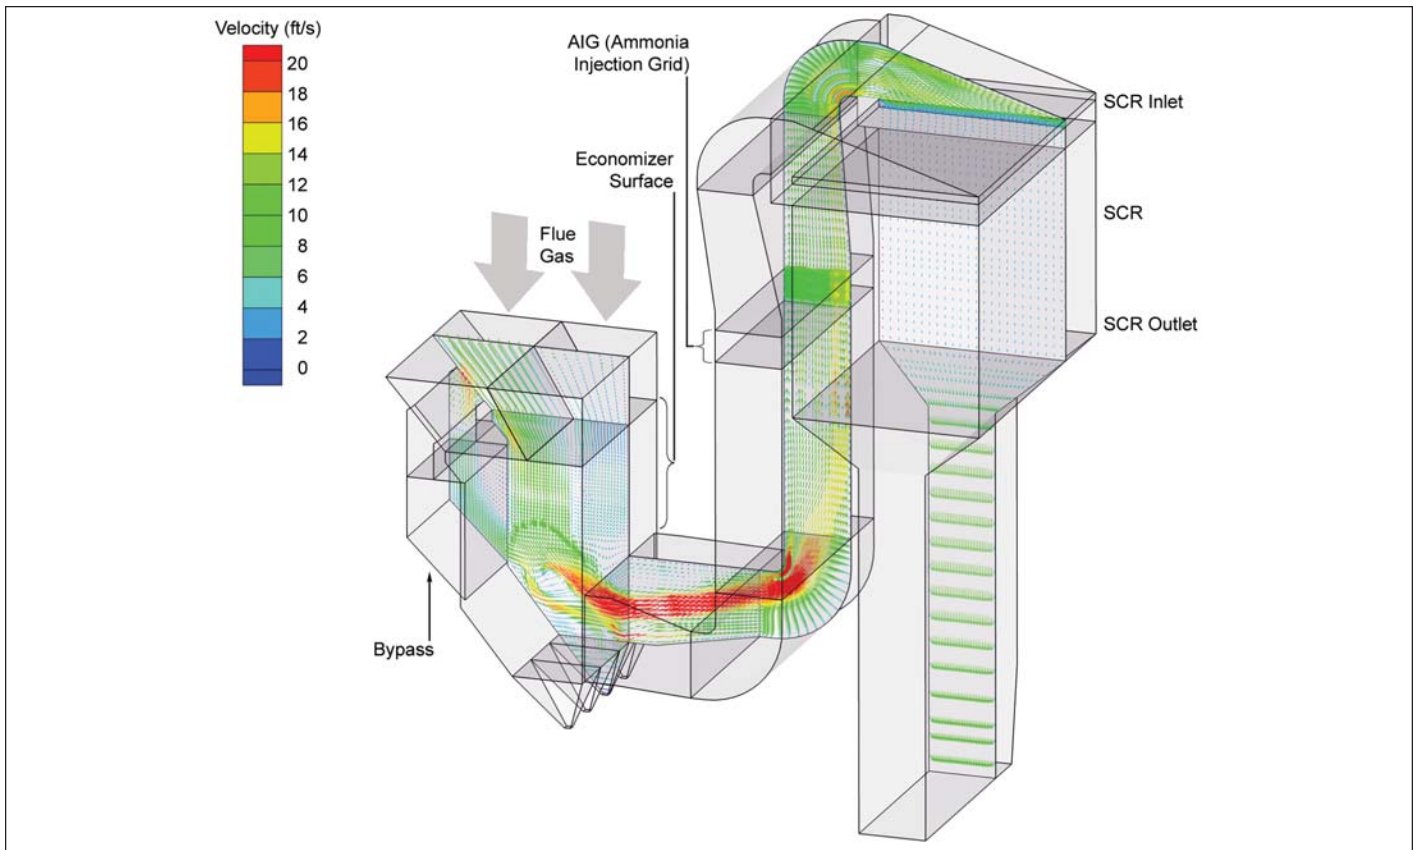

Fig. 19 Velocity field numerical model output – SCR system from the boiler convection pass to SCR outlet. The high velocity, high temperature bypass flow is visible as high jet penetration is needed to achieve good thermal mixing by the SCR inlet. See also Fig. 20.

Fig. 21 Sectional view of a 132 t/d (120 t_m/d) mass burn municipal solid waste (MSW) boiler for European application.

merical modeling is helping identify techniques to burn fuels more cleanly.

Analysis Numerical models, with enhanced resolution (see Fig. 23), have been developed that accurately represent the critical details of physical burners. Experimental studies provide inlet flow boundary conditions that can offer the starting point for the analysis. These are combined with the results from fundamental studies of fuel devolatilization, burning of gaseous species, gaseous diffusion, combustion of solid material and other factors to develop numerical models that begin to simulate the complex combustion process in commercial coal-fired burners. Physical testing, validation and adjustments to the model can produce numerical tools that can be used for advanced burner development.

Results Fig. 24 shows detailed gas velocity fields for an advanced burner design. In this case, analysis of the numerical model predictions helped identify the value of an additional burner air supply zone to induce recirculation of nitrogen oxide (NO) formed in the outer oxygen-rich portions of the flame into the fuel-rich internal recirculation zone where NO is reduced. See Chapter 14 for further discussion of coal-fired burners and combustion systems.

Chapter 7

Metallurgy, Materials and Mechanical Properties

Boilers, pressure vessels and their associated components are primarily made of metals. Most of these are various types of steels. Less common, but still important, are cast irons and nickel base alloys. Finally, ceramics and refractories, coatings, and engineered combinations are used in special applications.

Metallurgy

Crystal structure

The smallest unit of a metal is its atom. In solid structures, the atoms of metals follow an orderly arrangement, called a *lattice*. An example of a *simple point lattice* is shown in Fig. 1a and the unit cell is emphasized. The lengths of the unit cell axes are defined by a , b and c , and the angles between them are defined by α , β and γ in Fig. 1b. The steels used in boilers and pressure vessels are mainly limited to two different lattice types: *body-centered cubic* (BCC) and *face-centered cubic* (FCC). (See Fig. 2.) Where changes in the structure or interruptions occur within a crystal, these are referred to as *defects*. *Crystal* (or *grain*) *boundaries* are a type of crystal defect. A few useful structures are composed of a single crystal in which all the unit cells have the same relationship to one another and have few defects. Some high performance jet engine turbine blades have been made of single crystals. These structures are difficult to make, but are worthwhile; their strength is very high as it is determined by close interactions of the atomic bonds in their

Fig. 1 Simple point lattice and unit cell (courtesy of Addison-Wesley).¹

Fig. 2 Two Bravais lattices.¹

optimum arrangement. The behavior of all other metallic structures, which make up the huge majority of engineering metallic materials, is determined by the nature and extent of the defects in their structures. Structures are made of imperfect assemblies of imperfect crystals, and their strengths are orders of magnitude lower than the theoretical strengths of perfect single crystals.

Defects in crystals

Perfect crystals do not exist in nature. The imperfections found in metal crystals and their interactions control their material properties.

Point defects Point defects include missing atoms (vacancies), atoms of a different element occurring on crystal lattice points (substitutionals), and atoms of a different element occurring in the spaces between crystal lattice points (interstitials). Thermally created vacancies are always present, because they reduce the free energy of the crystal structure by raising its entropy. There is an equilibrium number of vacancies present; this number varies with the temperature of the crystal. The presence of such vacancies permits *diffusion* (the transport of one species of metal atom through the lattice of another) and helps facilitate some forms of time dependent deformation, such as *creep*.

Vacancies can also be created by irradiation damage and plastic deformations, and the thermodynamically controlled processes of diffusion and creep can also be affected by these other processes.

When atoms of two metals are mixed in the molten state and then cooled to solidification, the atoms of one metal may take positions in the lattice of the other, forming a substitutional *alloy*. Because the atoms may be different sizes and because the bond strength between unlike atoms is different from that of like atoms, the properties of the alloy can be quite different from those of either pure metal.

Atoms of carbon, oxygen, nitrogen and boron are much smaller than metal atoms and they can fit in the spaces, or interstices, between the metal atoms in the lattice structure. The diffusion of an interstitial in a metal lattice is also affected by temperature, and is much more rapid at higher temperatures. Interstitial elements are often only partly soluble in metal lattices. Certain atoms such as carbon in iron are nearly insoluble, so their presence in a lattice produces major effects.

Several crystal defects are illustrated in Fig. 3. This is a two-dimensional schematic of a cubic iron lattice containing point defects (vacancies, substitutional foreign atoms, interstitial atoms), linear and planar defects (dislocations, sub-boundaries, grain boundaries), and volume defects (voids, and inclusions or precipitates of a totally different structure).² *Dislocations* are linear defects formed by a deformation process called *slip*, the sliding of two close-packed crystal structure planes over one another.

Grain boundaries Grain boundaries are more complex interfaces between crystals (grains) of significantly different orientations in a metal. They are arrays of dislocations between misoriented crystals. Because the atomic bonds at grain boundaries and at other planar crystal defects are different from those in the body of the more perfect crystal, they react differently to heat and chemical reagents. This difference appears as grain boundaries on polished and etched metal surfaces under a microscope. Grain size can have positive or negative effects on metal properties. At lower temperatures, a steel with very small grains (fine grain size) may be stronger than the same steel with fewer large grains (coarse grain size) because the

grain boundaries act as barriers to deformation due to slip. At higher temperatures, where thermally activated deformation such as creep can occur, a fine grain structure material may be weaker because the irregular structure at the grain boundaries promotes local creep due to a mechanism known as grain boundary sliding.

Volume defects Volume defects can be voids formed by coalescence of vacancies or separation of grain boundaries. More common volume defects are inclusions of oxides, sulfides and other compounds, or other phases that form during solidification from the molten state.

Physical metallurgy of steel

Phases A phase is a homogeneous body of matter existing in a prescribed physical form. Metallurgists use a graph, called a *phase diagram*, to plot the stable phases at temperature versus composition of any metal composed of two or more elements.

When more than one element is involved, even for binary alloys, a variety of phases can result. One type is the binary isomorphous system, typified by only a few combinations: copper-nickel (Cu-Ni), gold-silver (Au-Ag), gold-platinum (Au-Pt) and antimony-bismuth (Sb-Bi). The phase diagram for one of these simple systems illustrates two characteristics of all solid solutions: 1) a range of composition can coexist in liquid/solid solutions, and 2) the change of phase (in these systems, from liquid to solid) takes place over a range of temperatures (unlike water and pure metals which freeze and change structure at a single temperature). Fig. 4 is a portion of the phase diagram for Cu-Ni, which shows what species precipitate out of solution when the liquid is slowly cooled.⁴ (In the remainder of this chapter, chemical symbols are often used to represent the elements. See *Periodic Table*, Appendix 1.)

Alloy systems in which both species are infinitely soluble in each other are rare. More often the species are only partly soluble and mixtures of phases precipitate on cooling. Also common is the situation in which the species attract each other in a particular ratio and form a chemical compound. These intermetallic compounds may still have a range of compositions, but it is much narrower than that for solid solutions. Two systems that form such intermetallic compounds are chromium-iron (Cr-Fe) and iron-carbon (Fe-C).

Iron-carbon phase diagram Steel is an iron base alloy containing manganese (Mn), carbon and other alloying elements. Virtually all metals used in boilers and pressure vessels are steels. Mn, usually present at about 1% in carbon steels, is a substitutional solid solution element. Because its atomic size and electronic structure are similar to those of Fe, it has little effect on the Fe lattice or phase diagram in these low concentrations. Carbon, on the other hand, has significant effects; by varying the carbon content and heat treatment of Fe, an enormous range of mechanical properties can be obtained. These effects can best be understood using the Fe-C equilibrium phase diagram, shown in Fig. 5. This shows that the maximum solu-

Fig. 3 Some important defects and defect complexes in metals (courtesy of Wiley).³

Fig. 4 The copper-nickel equilibrium diagram (courtesy of Hodder and Staughton).⁴

bility of carbon in α (BCC) iron is only about 0.025%, while its solubility in γ (FCC) iron is slightly above 2.0%. Alloys of Fe-C up to 2% C are malleable and are considered steels. Iron alloys containing more than 2% C are decidedly inferior to steels in malleability, strength, toughness and ductility. They are usually used in cast form and are called *cast irons*.

Carbon atoms are substantially smaller than iron atoms, and in BCC iron, they fit at the midpoints of the cube edges and face centers. This structure is called *ferrite*. In FCC iron, the carbon atoms fit at the midpoints of the cube edges at the cube center. This structure is called *austenite*. In both structures, the interstitial spaces are smaller than the carbon atom, leading to local distortion of the lattice and resulting in limited carbon solubility in iron. The interstices are larger in austenite than in ferrite, partly accounting for the higher solubility of carbon in austenite. If austenite containing more than 0.025% C cools slowly and transforms to ferrite, the carbon in excess of 0.025% precipitates from the solid solution. However, it is not precipitated as pure carbon (graphite) but as the intermetallic compound Fe_3C , *cementite*. As with most metallic carbides, this is a hard substance. Therefore, the hardness of steel generally increases with carbon content even without heat treatment.

Critical transformation temperatures The melting point of iron is reduced by the addition of carbon up to about 4.3% C. At the higher temperatures, solid and liquid coexist. The BCC δ iron range is restricted and finally eliminated as a single phase when the carbon content reaches about 0.1%. Some δ iron remains up to about 0.5% C but is in combination with other phases. Below the δ iron region, austenite exists and absorbs carbon up to the composition limits (Fig. 5),

the limiting solid-solution solubility. The temperature at which only austenite exists decreases as the carbon increases (line G-S) to the eutectoid point: 0.80% C at 1333F (723C). Then, the temperature increases along line S-E with the carbon content because the

Fig. 5 Carbon-iron equilibrium diagram showing phase solubility limits.

austenite is unable to absorb additional carbon, except at higher temperatures.

Any transformation in which a single solid phase decomposes into two new phases on cooling, and in which the reverse reaction takes place on heating, is called a *eutectoid* reaction. At the eutectoid composition of 0.80% C, only austenite exists above 1333F (723C) and only ferrite and Fe_3C carbide exist below that temperature. This is the *lower critical transformation temperature*, A_1 . At lower carbon contents, in the *hypoeutectoid* region, as austenite cools and reaches A_3 , the *upper critical transformation temperature*, ferrite precipitates first. As the temperature is further reduced to 1333F (723C) at A_1 , the remaining austenite is transformed to ferrite and carbide. In the *hypereutectoid* region, above 0.80% C, cementite precipitates first when austenite cools to the thermal arrest line (A_{cm}). Again, the remaining austenite transforms to ferrite and carbide when it cools to 1333F (723C). For a given steel composition, A_3 , A_1 and A_{cm} represent the *critical transformation temperatures*, or critical points. A_2 is the Curie point, the temperature at which iron loses its ferromagnetism.

At the A_1 temperature, on cooling, all the remaining austenite must transform to ferrite and carbide. Because there is not time for the carbon to go very far as it is rejected from the forming ferrite matrix, the resulting structure is one of alternating thin plates, or lamellae, of ferrite and carbide. This lamellar structure is typical of all eutectoid decomposition reactions. In steel, this structure is called *pearlite*, which always has the eutectoid composition of 0.8% C.

When pearlite is held at a moderately high temperature, such as 950F (510C), for a long time (years), the metastable cementite eventually decomposes to ferrite and graphite. First, the Fe_3C lamellae agglomerate into spheres. The resulting structure is considered *spheroidized*. Later, the iron atoms are rejected from the spheres, leaving a *graphitized* structure. Graphitized structures are shown in Fig. 6.

Isothermal transformation diagrams The transformation lines on the equilibrium diagram, Fig. 5, are subject to displacement when the austenite is rapidly cooled or when the pearlite and ferrite, or pearlite and cementite, are rapidly heated. This has led to the refinement of A_1 and A_3 into A_{c1} and A_{c3} on heating (c, from the French *chauffage*, heating) and into A_{r1} and A_{r3} for the displacement on cooling (r, from *refroidissement*, cooling). Because these are descriptions of dynamic effects, they distort the meaning of an equilibrium diagram which represents prevailing conditions given an infinite time for reactions to occur. Because fabrication processes involve times ranging from seconds (laser welding) to several days (heat treatment of large vessels), the effect of time is important. Isothermal transformation experiments are used to determine phase transformation times when the steel is cooled very rapidly to a particular temperature. The data are plotted on time-temperature-transformation (TTT) diagrams.

The isothermal transformation diagram in Fig. 7, for a hypoeutectoid steel, shows the time required for transformation from austenite to other constituents at

Fig. 6 Chain graphitization (black areas) in carbon-molybdenum steel, 200 X magnification.

the various temperature levels. The steel is heated to about 1600F (871C) and it becomes completely austenitic. It is then quickly transferred to and held in a furnace or bath at 700F (371C). Fig. 5 shows that ferrite and carbides should eventually exist at this temperature and Fig. 7 indicates how long this reaction takes. By projecting the time intervals during the transformation, as indicated in the lower portion of Fig. 7, to the top portion of the diagram, the austenite is predicted to exist for about three seconds before transformation. Then, at about 100 s, the transformation is 50% complete. At 700 s, the austenite is entirely replaced by an agglomerate of fine carbides and ferrite.

For this particular steel, at temperatures below about 600F (316C) austenite transforms to *martensite*, the hardest constituent of heat treated steels. The temperature at which martensite starts to form is denoted M_s . It decreases with increasing carbon content of the austenite. The nose of the left curve in Fig. 7, at about 900F (482C), is of prime significance because the transformation at this temperature is very rapid. Also, if this steel is to be quenched to form martensite (for maximum hardness), it must pass through about 900F (482C) very rapidly to prevent some of the austenite from transforming to pearlite (F + C), which is much softer.

Martensite is therefore a supercooled metastable structure that has the same composition as the austenite from which it forms. It is a solution of carbon in iron, having a *body-centered tetragonal* (BCT) crystal structure. (See Reference 1.) Because martensite forms with no change of composition, diffusion is not required for the transformation to occur. It is for this reason that martensite can form at such low temperatures. Its hardness is due to the high, supersaturated carbon content, to the great lattice distortion caused by trapping excess carbon, and to the volume change of the transformation. The specific volume of martensite is greater than that of the austenite.

Fig. 7 Typical isothermal transformation diagram. Time required in a specific steel at 700F (371C) taken as an example.

The formation of martensite does not occur by nucleation and growth. It can not be suppressed by quenching and it is athermal. Austenite begins to form martensite at a temperature M_s . As the temperature is lowered, the relative amount of martensite in the structure increases. Eventually, a temperature (M_f) is reached where the transformation to martensite is complete. At any intermediate temperature, the amount of martensite characteristic of that temperature forms instantly and holding at that temperature results in no further transformation. The M_s and M_f temperatures, therefore, are shown on the isothermal transformation diagram (Fig. 8) as horizontal lines. Under the microscope, martensite has the appearance of acicular needles. Each needle is a martensite crystal.

Bainite is produced when the eutectoid (0.8% C) transformation takes place at a lower temperature (but above the M_s temperature for the alloy). The temperature regions of the TTT curve in which pearlite, bainite and martensite form are shown in Fig. 8. In the pearlite transformation, the cementite and the ferrite form in a fine lamellar pattern of alternating layers of ferrite and cementite.

Effects of alloying elements on the Fe-Fe₃C phase diagram Adding one or more elements to the Fe-C alloy can have significant effects on the relative size of the phase fields in the Fe-Fe₃C phase diagram. The elements Ni, Mn, Cu and cobalt (Co) are called *austenite formers* because their addition to the Fe-C alloy system raises the temperature at which austenite trans-

forms to δ ferrite and lowers A_3 in Fig. 5. Adding a sufficient amount of these elements increases the size of the austenite field and the FCC structure may become stable at room temperature. Because most of these elements do not form carbides, the carbon stays in solution in the austenite. Many useful material properties result, including high stability, strength and ductility, even at high temperatures. The elements Cr, molybdenum (Mo), tungsten (W), vanadium (V), aluminum (Al) and silicon (Si) have the opposite effect and are considered *ferrite formers*. They raise the A_3 temperature and some of them form very stable carbides, promoting the stability of BCC ferrite, even at very high temperatures.

Specific effect of alloying elements

Steel alloys are the chief structural materials of modern engineering because their wide range in properties suits so many applications. These properties are affected directly not only by the characteristics and the amounts of the elements which, either alone or in combination, enter into the composition of the steel, but also by their reaction as constituents under various conditions of temperature and time during fabrication and use. For example, Cr increases resistance to corrosion and scaling, Mo increases creep strength at elevated temperatures, and Ni (in adequate amounts) renders the steel austenitic. The specific effects of the most important elements found in steel are as follows.

Carbon (C) is the most important alloying element in steel. In general, an increase in carbon content produces higher ultimate strength and hardness but lowers the ductility and toughness of steel alloys. The curves in Fig. 9 indicate the general effect of carbon on the mechanical properties of hot rolled carbon steel. Carbon also increases air hardening tendencies and

Fig. 8 Time-temperature-transformation curves for a 0.8% plain carbon steel.⁴

weld hardness, especially in the presence of Cr. In low alloy steel for high temperature applications, the carbon content is usually restricted to a maximum of about 0.15% to ensure optimum ductility for welding, expanding and bending operations, but it should be no lower than 0.07% for optimum creep strength. To minimize intergranular corrosion caused by carbide precipitation, the carbon content of austenitic stainless steel alloys is limited to 0.10%. This maximum may be reduced to 0.03% in extremely low carbon grades used in certain corrosion resistant applications. However, at least 0.04% C is required for acceptable creep strength. In plain, normalized carbon steels, the creep resistance at temperatures below 825F (441C) increases with carbon content up to 0.4% C; at higher temperatures, there is little variation of creep properties with carbon content. An increase in carbon content also lessens the thermal and electrical conductivities of steel and increases its hardness on quenching.

Manganese (Mn) is infinitely soluble in austenite and up to about 10% soluble in ferrite. It combines with residual sulfur while the steel is molten to form manganese sulfides, which have a much higher melting point than iron sulfides. Without the Mn, iron sulfides, which melt at about 1800F (982C), would form. This would lead to *hot-shortness*, a brittle-failure mechanism, during hot forming operations. The Mn therefore produces the malleability that differentiates steel from cast iron.

Mn is a good solid solution strengthener, better than Ni and about as good as Cr. In alloy steels, manganese decreases the critical cooling rate to cause martensitic structure and thus contributes to deep hardening. It can also be used in austenitic stainless steels to replace Ni as the austenite stabilizer at lower cost.⁵

Molybdenum (Mo), when added to steel, increases its strength, elastic limit, resistance to wear, impact qualities and hardenability. Mo contributes to high temperature strength and permits heating steel to a red hot condition without loss of hardness. It also in-

creases the resistance to softening on tempering and restrains grain growth. Mo makes chromium steels less susceptible to temper embrittlement and it is the most effective single additive that increases high temperature creep strength.

An important use of Mo is for corrosion resistance improvement in austenitic stainless steels. It enhances the inherent corrosion resistance of these steels in reducing chemical media and it increases their passivity under mildly oxidizing conditions. Under certain conditions, molybdenum reduces the susceptibility of stainless steels to pitting.

Chromium (Cr) is the essential constituent of stainless steel. While other elements are stronger oxide formers, Cr is the only one that is highly soluble in iron (about 20% in austenite and infinite in ferrite) and forms a stable, tightly adherent oxide. It is virtually irreplaceable in resisting oxidation at elevated temperatures.

Cr raises the yield and ultimate strength, hardness, and toughness of ferritic steel at room temperature. It also contributes to high temperature strength. The optimum chromium content for creep strength in annealed low alloy steels is about 2.25%.

A steady improvement in resistance to atmospheric corrosion and to attack by many reagents is also noted when the chromium content is increased. A steel with 12% or more Cr is considered stainless, i.e., the Cr_2O_3 film is sufficient to prevent surface rust (hydrated iron oxide) formation. The chemical properties of the steel, however, are affected by the carbon content. Higher chromium and lower carbon levels generally promote increased corrosion resistance.

Adding more than 1% of chromium may cause appreciable air hardening in the steel. Up to about 13.5% Cr, air hardening is a direct function of chromium and carbon content. Low carbon alloy steels containing more than 12% Cr can become nonhardening, but the impact strength is reduced and the ductility is poor. Cr lessens thermal and electrical conductivities. The addition of sufficient Cr prevents *graphitization* during long-term high temperature service of ferritic steels.

Nickel (Ni) increases toughness when added to steel, particularly in amounts over 1%. Improved resistance to corrosion by some media is attained with Ni contents over 5%. Ni dissolves in the iron matrix in all proportions and, therefore, raises the ultimate strength without impairing the ductility of the steel. Ni is particularly effective in improving impact properties, especially at low temperature.

The most important use of nickel as an alloying element in steel is its combination with chromium in amounts of 8% Ni or more. Ni is such a strong austenite former that the high chromium Fe-Ni-C alloys are austenitic at room temperature. The various combinations of chromium and nickel in iron produce alloy properties that can not be obtained with equivalent amounts of a single element. Common combinations are 18% Cr - 8% Ni, 25% Cr - 12% Ni, 25% Cr - 20% Ni, and 20% Cr - 30% Ni. These steels are resistant to atmospheric corrosion and to oxidation at high temperatures. In addition, they offer greatly enhanced creep strength.

Ni is only slightly beneficial to creep properties of

Fig. 9 General effect of carbon on the mechanical properties of hot-rolled carbon steel.

low alloy ferritic steels. It reduces the coefficient of thermal expansion and diminishes the electrical and thermal conductivities. It is attacked by sulfur compounds at elevated temperatures.

Cobalt (Co) suppresses hardenability in steels. However, when added to austenite, it is a strong solution strengthener and a carbide former. It also significantly improves creep strength. Binary Fe-Co alloys have the highest magnetic saturation induction of any known materials. Therefore, such alloys are often used in permanent magnets.

Tungsten (W) acts similarly to molybdenum. It is a very strong carbide former and solid solution strengthener. It forms hard, abrasion resisting carbides in tool steels, develops high temperature hardness in quenched and tempered steels, and contributes to creep strength in some high temperature alloys.⁵

Vanadium (V) is a degasifying and deoxidizing agent, but it is seldom used in that capacity because of high cost. It is applied chiefly as an alloying element in steel to increase strength, toughness and hardness. It is essentially a carbide forming element which stabilizes the structure, especially at high temperatures. Vanadium minimizes grain growth tendencies, thereby permitting much higher heat treating temperatures. It also intensifies the properties of other elements in alloy steels. Small additions of vanadium (0.1 to 0.5%), accompanied by proper heat treatment, give steels containing 0.5 to 1.0% molybdenum pronounced improvement in high temperature creep properties.

Titanium (Ti) and **columbium (Cb)** (also known as *niobium*) are the most potent carbide forming elements. Ti is also a good deoxidizer and denitrider. These elements are most effective in the Cr-Ni austenitic alloys, where they react more readily with carbon than does Cr. This allows the Cr to remain in solid solution and in the concentrations necessary to maintain corrosion resistance. Ti and Cb [or Cb plus tantalum (Ta)] are used to reduce air hardening tendencies and to increase oxidation resistance in steel containing up to 14% Cr. These elements have a beneficial effect on the long term, high temperature properties of Cr-Ni stainless steels because of the stability of their carbides, nitrides and carbonitrides. Cb and Ti have also been used in some of the super alloys to improve high temperature properties. Ti forms an intermetallic compound with Ni in these alloys, Ni_3Ti , called gamma prime (γ'), which is a potent strengthening phase.

Copper (Cu), when added to steel in small amounts, improves its resistance to atmospheric corrosion and lowers the attack rate in reducing acids. Cu, like Ni, is not resistant to sulfur compounds at elevated temperatures. Consequently, it is not ordinarily used in low alloy steels intended for high temperature service where sulfur is a major component of the environment, as in combustion gases. Cu is added (up to 1%) in low alloy constructional steels to improve yield strength and resistance to atmospheric corrosion. Its presence in some of the high alloy steels increases corrosion resistance to sulfuric acid.

Boron (B) is usually added to steel to improve hardenability, that is, to increase the depth of hardening during quenching of alloy steels. When com-

bined with Mo, it is a strong bainite stabilizer. Small amounts of boron in the presence of Mo suppress the formation of martensite, leading to the complete transformation to bainite before the M_s temperature is reached. This substantially improves the strength and stability of Cr-Mo pressure vessel steels. The B-10 isotope of boron has a very high neutron-capture cross-section, so it is added to steels used for containment and storage vessels of nuclear fuels and waste products.

Nitrogen (N) has two primary functions as an alloying agent in steels. In carbon and low alloy steels, it is used in case hardening, in which nascent nitrogen is diffused into the steel surface. Nitrogen and carbon are interstitial solid solution strengtheners. In the presence of Al or Ti, additional strengthening results by precipitate formations of the respective nitrides or carbonitrides. In austenitic stainless steels, nitrogen provides the same interstitial strengthening as carbon, but does not deplete the austenite of chromium as does carbon by the formation of carbides. The strength of nitrogen-containing stainless steels is therefore equivalent to that of the carbon-containing stainlesses. This strength is achieved without the susceptibility to corrosive attack that results from local carbide formation at grain boundaries of these steels.

Oxygen (O) is not normally considered to be an alloying element. It is present in steel as a residual of the steel making process.^{6,7} However, a few oxides are so hard and stable, notably those of Al, Ti and thorium (Th), that they are potent strengtheners when dispersed as fine particles throughout an alloy. This can be accomplished by internal oxidation in an oxygen-containing atmosphere or by powder metallurgical techniques.

Aluminum (Al) is an important minor constituent of low alloy steels. It is an efficient deoxidizer and grain refiner, and is widely used in producing killed steel. When added to steel in appreciable quantities, Al forms tightly adhering refractory oxide scales and therefore, increases resistance to scaling. It is difficult, however, to add appreciable amounts of this element without producing undesirable effects. In the amounts customarily added (0.015 to 0.080%), Al does not increase resistance to ordinary forms of corrosion. Because of their affinity for oxygen, high-aluminum steels generally contain numerous alumina inclusions which can promote pitting corrosion. The refined grain size does improve room temperature toughness and ductility of carbon steels.

An excessive quantity of aluminum has a detrimental effect on creep properties, particularly in plain carbon steel. This is attributable to its grain refining effect and to its acceleration of graphitization of the carbide phase.

Silicon (Si) greatly contributes to steel quality because of its deoxidizing and degasifying properties. When added in amounts up to 2.5%, the ultimate strength of steel is increased without loss in ductility. Si in excess of 2.5% causes brittleness and amounts higher than 5% make the steel nonmalleable.

Resistance to oxidation of steel is increased by adding silicon. Si increases the electrical conductivity of steel and decreases hysteresis losses. Si steels are, therefore, widely used in electrical apparatus.

Killing agents, such as Si and Al, are added to steel for deoxidation; the latter is used for grain size control. Calcium and rare earth metals, when added to the melt, have the same effects. Additionally, these elements form complex oxides or oxysulfides and can significantly improve formability by controlling the sulfide shape.

Phosphorus (P) is a surprisingly effective hardener when dissolved in quantities of up to 0.20%.⁵ However, a high phosphorus content can notably decrease the resistance of carbon steel to brittle fracture and reduce ductility when the metal is cold worked. This embrittling effect is referred to as *cold-shortness*. The detrimental effect of phosphorus increases with carbon content.

Phosphorus is effective in improving the machinability of free-cutting steels. This is related to its embrittling effect, which permits easier chip formation on machining. In alloy steels intended for boiler applications, the permissible phosphorus content is less than that for machining steels and its presence is objectionable for welding. Phosphorus is used as an alloying element (up to 0.15%) in proprietary low alloy, high strength steels, where increased yield strength and atmospheric corrosion resistance are primary requirements. In the presence of certain acids, however, a high phosphorus content may increase the corrosion rate.

Sulfur (S) is generally undesirable in steel and many processes have been developed to minimize its presence. However, sulfur is sometimes added to steel to improve its machinability, as are phosphorus and other free-machining additives: calcium, lead, bismuth, selenium and tellurium. Several of these elements are virtually insoluble in steel and have low melting points, or they form low melting temperature compounds. These compounds can lead to cracking due to liquid metal embrittlement or hot-shortness at even moderately elevated temperatures. Hot-shortness occurs when liquid iron sulfide forms at grain boundaries during hot-working and heat treatment of steels.⁶ Because the fastener industry favors free machining steels due to their beneficial production effects, boiler and pressure vessel manufacturers must exercise care in applying threaded fasteners containing these elements at high temperatures.

Heat treating practices

Steel can be altered by modifying its microstructure through heat treatment. Various heat treatments may be used to meet hardness or ductility requirements, improve machinability, refine grain structure, remove internal stresses, or obtain high strength levels or impact properties. The more common heat treatments, annealing, normalizing, spheroidizing, hardening (quenching) and tempering, are briefly described.

Annealing is a general term applied to several distinctly different methods of heat treatment. These are full, solution, stabilization, intercritical, isothermal, and process annealing.

Full annealing is done by heating a ferritic steel above the upper critical transformation temperature (A_3 in Fig. 5), holding it there long enough to fully transform the steel to austenite, and then cooling it at a controlled rate in the furnace to below 600F

(316C). A full anneal refines grain structure and provides a relatively soft, ductile material that is free of internal stresses.

Solution annealing is done by heating an austenitic stainless steel to a temperature that puts most of the carbides into solution. The steel is held at this temperature long enough to achieve grain growth. It is then quenched in water or another liquid for fast cooling, which prevents most of the carbides from reprecipitating. This process achieves optimum creep strength and corrosion resistance. For many boiler applications, austenitic stainless steels require the high creep strength of a coarse grain structure but do not require aqueous corrosion resistance, because they are only exposed to dry steam and flue gases. *Solution treatment*, used to achieve grain growth, is required for these applications, but the quenching step is not required.

Stabilization annealing is performed on austenitic stainless steels used in severe aqueous corrosion environments. The steel is first solution annealed, then reheated to about 1600F (871C) and held there. Initially, chromium carbides precipitate at the grain boundaries in the steel. Because these are mostly of the complex $M_{23}C_6$ type, which are very high in Cr, the austenite adjacent to the grain boundaries is depleted of chromium. This would normally leave the steel susceptible to corrosive attack, but holding it at 1600F (871C) permits the Cr remaining in the austenite solution to redistribute within the grains, restoring corrosion resistance, even adjacent to the grain boundaries.

Intercritical annealing and *isothermal annealing* are similar. They involve heating a hypoeutectoid ferritic steel above the lower critical transformation temperature (A_1 in Fig. 5) but below the upper critical temperature, A_3 . This dissolves all the iron carbides but does not transform all the ferrite to austenite. Cooling slowly from this temperature through A_1 produces a structure of ferrite and pearlite that is free of internal stresses. In intercritical annealing, the steel continues to cool slowly in the furnace, similarly to full annealing. In isothermal annealing, cooling is stopped just below A_1 , assuring complete transformation to ferrite and pearlite, and eliminating the potential for bainite formation.

Process annealing, sometimes called subcritical annealing or stress relieving, is performed at temperatures just below the lower critical temperature A_1 , usually between 950 and 1300F (510 and 704C). Process annealing neither refines grains nor redissolves cementite, but it improves the ductility and decreases residual stresses in work hardened steel.

Normalizing is a variation of full annealing. Once it has been heated above the upper critical temperature, normalized steel is cooled in air rather than in a controlled furnace atmosphere. Normalizing is sometimes used as a homogenization procedure; it assures that any prior fabrication or heat treatment history of the material is eliminated. Normalizing relieves the internal stresses caused by previous working and, while it produces sufficient softness and ductility for many purposes, it leaves the steel harder and with higher tensile strength than full annealing. To remove cooling stresses, normalizing is often followed by tempering.

Spheroidizing is a type of subcritical annealing used to soften the steel and to improve its machinability. Heating fine pearlite just below the lower critical temperature of the steel, followed by very slow cooling, causes spheroidization.

Hardening (quenching) occurs when steels of the higher carbon grades are heated to produce austenite and then cooled rapidly (quenched) in a liquid such as water or oil. Upon hardening, the austenite transforms into martensite. Martensite is formed at temperatures below about 400F (204C), depending on the carbon content and the type and amount of alloying elements in the steel. It is the hardest form of heat treated steels and has high strength and abrasion resistance.

Tempering is applied after normalizing or quenching some air hardening steels. These preliminary treatments impart a degree of hardness to the steel but also make it brittle. The object of tempering, a secondary treatment, is to remove some of that brittleness by allowing certain transformations to proceed in the hardened steel. It involves heating to a predetermined point below the lower critical temperature, A_1 , and is followed by any desired rate of cooling. Some hardness is lost by tempering, but toughness is increased, and stresses induced by quenching are reduced or eliminated. Higher tempering temperatures promote softer and tougher steels. Some steels may become embrittled on slow cooling from certain tempering temperatures. These steels are said to be temper brittle. To overcome this difficulty, they are quenched from the tempering temperature.

Post fabrication heat treatments are often applied to restore more stable, stress free conditions. These include post weld and post forming heat treatments and solution treatment.

Fabrication processes

Any mechanical work applied to the metal below its recrystallization temperature is *cold* work. Mechanical work performed above the recrystallization temperature is *hot* work and the simultaneous annealing that occurs at that temperature retards work-hardening. The recrystallization temperature is dependent on the amount of deformation. If a material is formed at a temperature significantly above room temperature, but below its recrystallization temperature, the process is sometimes referred to as *warm working*.

The temperature at which steel is mechanically worked has a profound effect on its properties. Cold work increases the hardness, tensile strength and yield strength of steel, but its indices of ductility – elongation and reduction of area – are decreased. The extent of the work-hardening, with progressive elongation of the grains in the direction of working, depends on the amount of cold work and on the material. If the work-hardening caused by the necessary shaping operation becomes excessive, the ductility may be exhausted and further work can cause fracture.

Hot working variations include forging, rolling, pressing, extruding, piercing, upsetting and bending. Most of these are largely compressive operations, in which the metal is squeezed into a desired shape. They

introduce some degree of orientation to the internal structure. Even if the metal experiences phase transformations or other recrystallization processes, some degree of orientation is maintained in the pattern retained by the oxides, sulfides, and other inclusions that do not dissolve during hot working or heat treatment. Depending on the application, the resultant orientation may have no effect, be useful, or be harmful. Rolled plates, for instance, often have inferior properties in the through-thickness direction due to retention of mid-plane segregated inclusions and to the predominant grain orientation in the longitudinal and transverse directions. This can result in a failure mode known as lamellar tearing if not addressed.

Hot rolling of carbon steel and low alloy steel into drum or pressure vessel sections is often done at temperatures above A_3 . Temperatures and times of heating before forming need to be controlled to ensure that the resulting product retains the desired fine grain size and consequent good toughness, and to ensure that excessive plate surface oxidation does not occur.

Cold working operations used in manufacturing boiler components are rolling, forging, bending and swaging. Detailed information about these processes and their effects on materials can be found elsewhere. (See References 6 and 7.)

Cold rolling of plate to make shells for drums is limited only by the capacity and diameter of available rolling equipment and the inherent ductility of the steel. This process is most often applied to carbon steel, and any post forming heat treatment performed is usually combined with post weld heat treatment of the completed drum. In some low pressure applications, tube-to-header or tube-to-drum connections may be made by roll expanding the tube into an internally grooved socket in the shell. The strength of the connection depends on the mechanical interference between the roll expanded tube, which generally deforms plastically, and the hole in the shell, which mostly deforms elastically.

Cold forging of boiler components is usually limited to final size forming of shells. Threaded fasteners used in boilers may have been cold headed or may have had their threads cold rolled. Effects of such forming operations are normally mitigated by heat treatments required by the specification, but occasionally this heat treatment does not eliminate microstructural differences between the cold formed portion and the remainder of the part. This is particularly true of austenitic stainless steel or nickel alloy bolts, which do not transform during heat treatment. These bolts may be susceptible to cracking at the interface between the cold formed head and the shank in certain aqueous environments.

Cold bending is performed on many configurations of tubes and pipes for boilers. Boiler designers consider the effects of this process on the geometry and properties of the finished product.

Austenitic stainless steels and nickel alloys used in high pressure boilers are often exposed to temperatures at which the strain energy of the cold bending is sufficient to cause polygonization and recrystallization to a fine grain size during service. The service

temperature is insufficient to produce grain growth and the fine grain size material has lower high temperature (creep) strength. To prevent this from happening, cold bends in these alloys are given a high temperature (solution) heat treatment to stabilize the coarse grain structure.

Most carbon and low alloy ferritic steel tube and pipe alloys may be used in the cold bent condition, unless the amount of cold strain imparted is very high. If strain in excess of about 30% is developed in bending, the resulting structure and low residual ductility can render the bends susceptible to strain aging and breakage during subsequent handling and service.

Cold working of carbon steels has also been shown to render them susceptible to creep crack growth of minor surface flaws and imperfections when these steels are operating at temperatures where the cracking mechanism is operative.

Certain Cr-Mo high strength ferritic steels can also experience significant degradation of creep strength if they are cold worked to levels near and above about 20% strain. In all of these cases, post fabrication heat treatments must be applied to recover acceptable properties. This most often requires re-annealing, normalization, or normalizing and tempering as is appropriate for the given alloy. In some cases, simple subcritical tempering or stress relief heat treatment may be sufficient.

Welding

Joining of boiler pressure parts and of nonpressure parts to pressure parts is almost always accomplished by welding. This is particularly true of high temperature, high pressure boilers, whose service conditions are too severe for most mechanical joints (bolted flanges with gaskets) and brazed joints.

Welding is the joining of two or more pieces of metal by applying heat or pressure, or both, with or without the addition of filler metal, to produce a localized union through fusion across the interface.⁸ There are many welding processes, but the most widely used for joining pressure parts is fusion welding with the addition of filler metal, using little or no pressure. Fig. 10 indicates the variety of processes.

Weld morphology Because of the heat distribution characteristics of the welding process, the weld joint is usually a chemically and mechanically heterogeneous composite consisting of up to six metallurgically distinct regions: a composite zone, the unmixed zone, the weld interface, the partially melted zone, the heat-affected zone (HAZ) and the unaffected base metal. These zones are shown in Fig. 11. The *composite zone* is the completely melted mixture of filler metal and melted base metal. The narrow region surrounding the composite zone is the *unmixed zone*, which is a boundary layer of melted base metal that solidifies before mixing in the composite zone. This layer is at the edges of the weld pool, with a composition essentially identical to the base metal. The composite zone and the unmixed zone together make up what is commonly referred to as the fusion zone. The third region is the *weld interface*, or the boundary between the unmelted base metal on one side and the solidified weld metal on the other. The *partially melted zone* occurs in the base metal immediately adjacent to the weld interface, where some localized melting of lower melting temperature constituents, inclusions or impurities may have occurred. Liquation, for instance, of manganese sulfide inclusions can result in hot cracking or microfissuring. The *heat-affected zone* is that portion of the base material in the weld joint that has been subjected to peak temperatures high enough to produce solid state microstructural changes, but not high

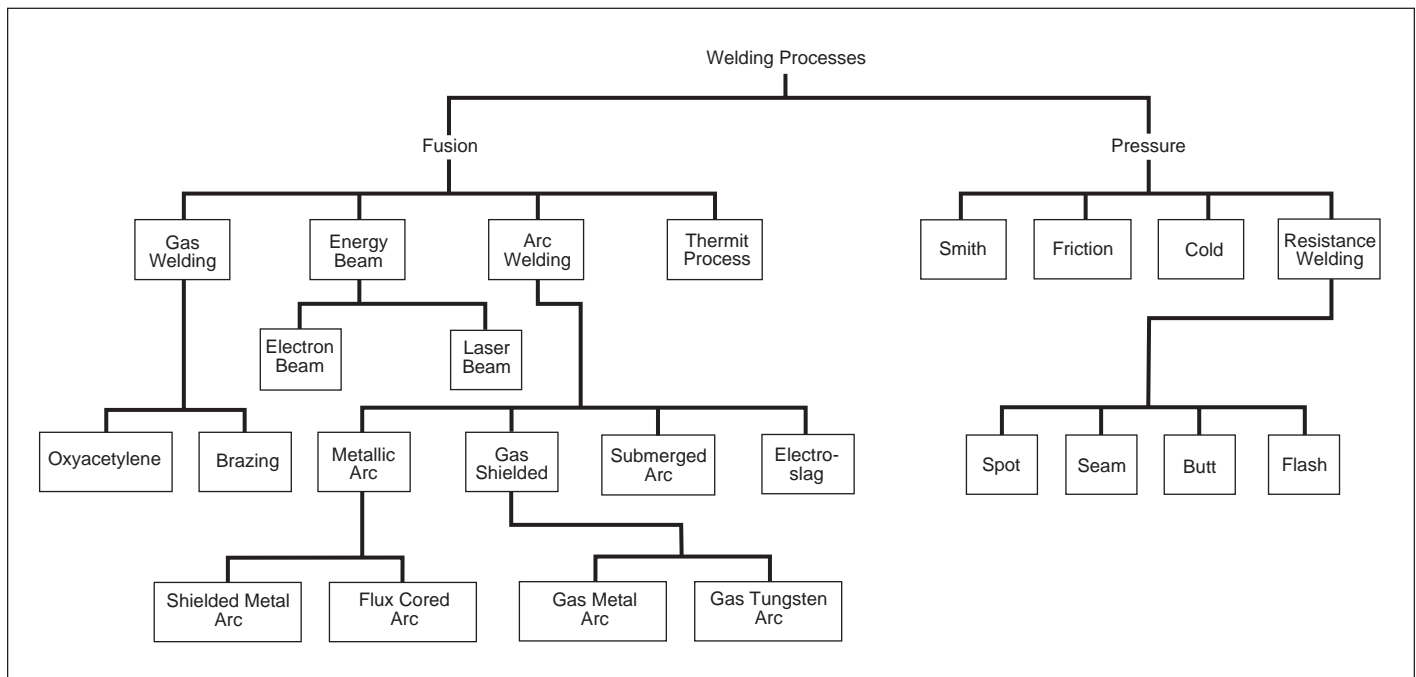

Fig. 10 Classification of welding processes.⁴

Fig. 11 Metallurgical zones developed in a typical weld (courtesy of ASM).⁹

enough to cause melting. Finally, the last part of the work piece that has not undergone a metallurgical change is the *unaffected base metal*.

Weld quality issues

The general subject of welding and weldability is a very broad subject, addressed by a large number of excellent references.^{10,10a} The following addresses only a few issues that are particularly unique and important to boilers and pressure vessels.

Ferrite content Austenitic stainless steel weld metals are susceptible to hot cracking or microfissuring as they cool from the solidus to about 1800F (982C). The microfissuring can be minimized by providing a small percentage of ferrite in the as-deposited welds.

Graphitization The shrinkage of the weld on freezing results in plastic deformation and high residual stresses in the weld joint. In carbon and carbon-molybdenum steels containing no stronger carbide-forming elements, the areas of localized strain adjacent to the heat-affected weld zones provide sites where the volume increase of the cementite to graphite decomposition can be more readily accommodated. At about 900F (482C), graphite nodules can precipitate on these planes of deformation. When samples of such materials are viewed in cross-section, the nodules appear to be arranged in rows or chains, and this condition has been termed *chain graphitization* (Fig. 6). The interfacial bond between the graphite and the ferrite matrix in such weldments is very low, much lower than that between ferrite and pearlite or ferrite and cementite. In the early 1950s, several failures of carbon-molybdenum main steam piping weldments occurred due to this phenomenon. The ruptures occurred with little warning because they were not preceded by swelling of the joints and, as a result, significant damage resulted. In consequence, the use of carbon-molybdenum main steam piping has been essentially eliminated and the maximum use temperature of carbon steel piping has been significantly restricted.

Post weld heat treatment When cooling is complete, the welded joint contains residual stresses comparable to the yield strength of the base metal at its final temperature. The thermal relief of residual stresses by post weld heat treatment (PWHT) is accomplished by heating the welded structure to a temperature high enough to reduce the yield strength of the steel to a fraction of its magnitude at ambient tem-

perature. Because the steel can no longer sustain the residual stress level, it undergoes plastic deformation until the stresses are reduced to the at-temperature yield strength. Fig. 12 shows the effect of stress relief on several steels. The temperature reached during the treatment has a far greater effect in relieving stresses than the length of time the weldment is held at temperature. The closer the temperature is to the critical or recrystallization temperature, the more effective it is in removing residual stresses, provided the proper heating and cooling cycles are used.¹⁰

Lamellar tearing Weld defect causes and inspection procedures are covered more extensively in References 9 and 11. However, one metallurgical effect of residual stresses should be mentioned in the context of boilers and pressure vessels: *lamellar tearing*. Lamellar tearing may result when an attachment is welded to a plate in the T-shaped orientation shown in Fig. 13, particularly if the plate contains shrinkage voids, inclusions, or other internal segregation parallel to the plate surface. In such an instance, the residual shrinkage stresses may be sufficient to open a tear or tears parallel to the plate surface to which the T-portion is welded.

Joining dissimilar metals It may be necessary to join austenitic and ferritic steels. Weld failures have occurred in these welds since the introduction of austenitic stainless steel superheater tubing materials. Nickel base filler metals have long been used to mitigate these problems, but these do not offer a permanent solution. Additional system stresses from component location, system expansion and bending can increase the potential for such failures.

Fig. 12 Effect of temperature and time on stress relief in carbon steel (upper graph) and steels with varying as-welded strengths (courtesy of AWS).¹¹

Fig. 13 Lamellar tearing.

Research is continuing toward the development of filler metals less likely to permit failures but none has become commercially available. The best alternative is to avoid dissimilar metal welds by using higher strength ferritic alloy materials, such as modified 9Cr-1Mo-V tubing and piping, when design conditions permit.

Materials

Almost all of the materials used in constructing boilers and pressure vessels are steels and the vast majority of components are made of *carbon steels*. Carbon steels are used for most types of pressure and nonpressure parts: drums, headers, piping, tubes, structural steel, flues and ducts, and lagging.

Carbon steels may be defined by the amount of carbon retained in the steel or by the steelmaking practice. These steels are commonly divided into four classes by carbon content: *low carbon*, 0.15% C maximum; *medium-low carbon*, between 0.15 and 0.23% C; *medium-high carbon*, between 0.23 and 0.44% C; and *high carbon*, more than 0.44% C. However, from a design viewpoint, high carbon steels are those over 0.35%, because these can not be used as welded pressure parts. Low carbon steels see extensive use as pressure parts, particularly in low pressure applications where strength is not a significant design issue. For most structural applications and the majority of pressure parts, medium carbon steels, with carbon contents between 0.20 and 0.35%, predominate.

Carbon steels are also referred to as killed, semi-killed, rimmed and capped, depending on how the carbon-oxygen reaction of the steel refining process was treated. During the steelmaking process, oxygen, introduced to refine the steel, combines with carbon to form carbon monoxide or carbon dioxide, and also exists as excess oxygen. If the oxygen introduced is not removed or combined prior to or during casting by the addition of Si, Al, or some other deoxidizing agent, the gaseous products are trapped during solidification of the metal in the mold. The amount of gas evolved

during solidification determines the type of steel and the amount of carbon left in the steel. If no gas is evolved and the liquid lies quietly in the mold, it is known as killed steel. With increasing degrees of gas evolution, the products are known as semi-killed and rimmed steels. Virtually all steels used in boilers today are fully killed.

Microalloyed steels are carbon steels to which small amounts (typically less than 1%) of alloying elements have been added to achieve higher strength. Common additions are vanadium and boron. Such steels are seldom used in pressure part applications, but they are gaining acceptance as structural steels.

Residual elements are present in steels in small amounts and are elements other than those deliberately added as alloying or killing agents during the steelmaking process. Their source is the scrap or pig iron used in the furnace charge. Cu, Ni, Cr, V and B are typical examples of residuals often found in carbon steels. S and P, also considered to be residual elements, usually are reported in chemical analyses of steels, and their concentrations are limited by specification because they degrade ductility. The residual elements S, P, Sb and tin (Sn) are also important contributors to temper embrittlement in steels.

Historically, residual elements other than S and P were neither limited nor reported. This practice is changing, however, and several residuals have established limits.

Low and medium alloy steels are the next most important category of steels used in boilers. These are characterized by Cr contents less than 11.5% and lesser amounts of other elements. The most common alloy combinations in this group encountered in boilers are: C-1/2Mo, 1/2Cr-1/2Mo, 1Cr-1/2Mo, 1-1/4Cr-1/2Mo-Si, 2-1/4Cr-1Mo, and 9Cr-1Mo-V. Other less common alloys in this group are 3Cr-1Mo, 5Cr-1/2Mo and 9Cr-1Mo.

Because of the exceptional strength-enhancing capability of Mo in carbon steel, it is not surprising that C-1/2Mo steel has many applications for pressure parts, particularly in the temperature range of about 700 to 975F (371 to 524C). C-Mo steels, however, are particularly prone to graphitization at temperatures above about 875F (468C). Inside the boiler, where graphitization failures do not present a safety hazard, C-Mo tubing has many uses up to 975F (524C), its oxidation limit. Because Al content promotes graphitization, C-Mo steel is usually Si-killed and it has a coarse grain structure as a consequence. Therefore, C-Mo components are somewhat prone to brittle failures at low temperatures. This is not a problem in service, because the design application range of this alloy is at high temperature.

The oxidation resistance of low alloy steels increases with Cr content. The first common alloy in the Cr-Mo family is 1/2Cr-1/2Mo. This steel was developed in response to the graphitization failures of C-Mo piping. It was found that the addition of about 0.25% Cr was sufficient to make the alloy immune to graphitization. Furthermore, 1/2Cr-1/2Mo has essentially the same strength as C-Mo and has therefore displaced it in many applications. Because the application of 1/2Cr-1/2Mo is virtually unique to the boiler industry, it is less readily available in certain sizes and product forms.

The next alloys in this series are the nearly identical 1Cr-1/2Mo and 1-1/4Cr-1/2Mo-Si; the Si-containing version is slightly more oxidation resistant. However, extensive analyses of the databases indicate that the 1Cr-1/2Mo version is stronger over the temperature range of 800 to 1050F (427 to 566C). As a result, this alloy is rapidly displacing 1-1/4Cr-1/2Mo-Si in most applications in this temperature regime.

Absent the addition of other alloying elements, the 2-1/4Cr-1Mo composition is the optimum alloy for high temperature strength. Where the need for strength at temperatures between 975 and 1115F (524 and 602C) is the dominant design requirement, 2-1/4Cr-1Mo is the industry workhorse alloy. The 3Cr through 9Cr alloys are less strong, but they have application where improved oxidation resistance is desired and lower strength can be tolerated. The increasing air-hardenability of these alloys with increasing Cr content makes fabrication processes more complex and their use is somewhat more costly as a result.

Mn-Mo and Mn-Mo-Ni alloys have limited use in fossil-fueled boilers. Their slightly higher strength compared to carbon steels promotes their application in very large components, where the strength to weight ratio is an important consideration. Their generally superior toughness has made them a popular choice for nuclear pressure vessels.

The *heat treatable low alloy steels*, typified by the AISI-SAE 4340 grade (nominally 0.40C-0.80Cr-1.8Ni-0.25Mo), are used for relatively low temperature structural applications in boilers and nuclear pressure vessels. The instability of their microstructures and therefore, of their strength, with long exposure at elevated temperatures, has eliminated them from consideration for boiler pressure parts.

Higher Cr-Mo alloys Because of their tendency toward embrittlement, the martensitic 9Cr-1Mo and 12Cr-1Mo steels have not been widely used for pressure vessel and piping applications in North America prior to the 1980s. However, in the early 1970s, the United States (U.S.) Department of Energy (DOE) sponsored research to develop a 9Cr-1Mo steel with improved strength, toughness and weldability¹² for tubing in steam generators for liquid metal fast breeder nuclear reactors.¹³ The alloy is 9Cr-1Mo-V, commonly called Grade 91. It has exceptional strength, toughness and stability at temperatures up to 1150F (621C). Because it is nearly twice as strong as 2-1/4Cr-1Mo at 1000F (538C), it is displacing that alloy in high pressure header applications. The resultant thinner vessels have significantly reduced thermal stresses and associated creep-fatigue failures compared to 2-1/4Cr-1Mo and 1-1/4Cr-1/2Mo-Si headers.^{14,15} Because Grade 91 is stronger than austenitic stainless steel up to about 1125F (607C), it is also displacing that alloy class in high pressure tubing applications. It has the added advantage of being a ferritic alloy, eliminating the need for many dissimilar metal welds between pressure parts. The Grade 91 gains its strength, toughness, and stability from its alloy additions and features the fully bainitic microstructure resulting from careful normalizing and tempering.

While not popular in North America because of the

care necessary in handling very air-hardenable alloys during fabrication, the 12Cr-Mo and 12Cr-Mo-V alloys have had wide use in the European boiler industry. In addition, the experience being gained with Grade 91 may eventually enhance the acceptance of the 12Cr group.

Austenitic stainless steel Every attempt is made to minimize the use of stainless steels in boilers because of their high cost, but the combination of strength and corrosion resistance they provide makes them the favored choices in certain applications. They are virtually the only choices for service above 1150F (621C). At lower temperatures, down to about 1050F (566C), they often displace the Cr-Mo ferritic steels, where the lower pressure drop afforded by the thinner stainless steel component wall is important.

The common alloys of stainless steels used in boiler pressure parts are 18Cr-8Ni, 18Cr-8Ni-Ti, 18Cr-8Ni-Cb, 16Cr-12Ni-2Mo, 25Cr-12Ni, 25Cr-20Ni, and 20Cr-30Ni. The last alloy in this group is technically a non-ferrous alloy, because it has less than 50% Fe when its other minor alloying constituents are considered. However, because it is so similar to the other austenitic stainless steels, it may be considered one of them. These alloys are commonly designated the 300 series: 304, 321, 347, 316, 309 and 310 stainless steels, respectively. The 20Cr-30Ni alloy is commonly known as Alloy 800. Because the strength of these materials at high temperature is dependent on a moderate carbon content and usually on a coarse grain size, materials with those qualities are often specified for high temperature service. They carry the added designation of the letter H, e.g., 304H or 800H.

Of these alloys, 304H is the most commonly used. It provides an excellent balance of strength and oxidation resistance at the lowest cost of any alloy in this group. However, if severe aqueous corrosive conditions may exist either before or during service, especially in solutions containing halogens, other stainless steel alloys should be substituted. The 304H alloy is susceptible to sensitization at grain boundaries and, thus, may suffer stress corrosion cracking or intergranular attack in that environment. In these cases, a stabilized stainless steel composition such as 347H should be used. Further details on how the American Society of Mechanical Engineers (ASME) Code establishes allowable design stresses for materials can be found in the Appendix to ASME Section II, Part D.

All of the 300 series alloys are susceptible to sigma phase formation after long exposure at temperatures of 1050 to 1700F (566 to 927C). Those with some initial ferrite, such as 309, can form the sigma phase earlier, but all eventually do so. This phase formation decreases toughness and ductility but has no effect on strength or corrosion resistance. It has been a problem in heavy-section piping components made of 316 stainless steels, but it is not a design consideration for smaller (tubing) components.

The 321 type is not as strong as the others in this series. While it is a stabilized grade and has important low temperature applications, the stability of the titanium carbide makes it extremely difficult to heat treat type 321 in one thermal treatment and obtain a

resulting structure that is both coarse grained, for high temperature creep strength, and has stabilized carbides for sensitization resistance. It is possible to apply a lower temperature stabilizing heat treatment, at about 1300F (704C), following the solution treatment to achieve a stabilized condition and good creep strength. The stability of the columbium (niobium) carbides in type 347 is better, and this grade can be heat treated to obtain creep strength and sensitization resistance. This 18Cr-8Ni-Cb alloy is widely used at high temperatures because of its superior creep strength.

The Mo content of the 316 type increases its pitting resistance at lower temperatures. While this alloy has good creep strength, it is not often used because of its higher cost.

These alloys are susceptible to stress corrosion cracking in certain aqueous environments. The 300 series alloys are particularly sensitive to the presence of halide ions. As a result, their use in water-wetted service is usually prohibited. The stress corrosion cracking experience with Alloy 800 has been mixed and, while this grade is permitted in water-wetted service, it is not common practice.

Types 309, 25Cr-12Ni, and 310, 25Cr-20Ni, have virtually identical strengths and corrosion resistance. They are not as strong as 304 or 347 but are more oxidation resistant. The high Ni alloys, like Alloy 800, are somewhat more affected by sulfidation attack. They have been used as nonpressure fluidized-bed boiler components designed to remove particulate from hot gas streams.

Most of these alloys are available in a multiplicity of minor variations: H grades, with 0.04 to 0.10% C and a required high temperature anneal and coarse grain size for creep strength; L grades, with 0.035% maximum C for sensitization resistance; N grades, with 0.010% minimum N added for strength; LN grades, with 0.035% maximum C and 0.010% minimum N for sensitization resistance and strength; and straight (no suffix) grades, with 0.08% maximum C.

Ferritic stainless steels contain at least 10% Cr and have a ferrite-plus-carbide structure. *Martensitic stainless steels* are ferritic in the annealed condition but are martensitic after rapid cooling from above the critical temperature. They usually contain less than 14% Cr.¹⁶ *Precipitation hardened stainless steels* are more highly alloyed and are strengthened by precipitation of a finely dispersed phase from a supersaturated solution on cooling. None of these steels are used for pressure parts or load carrying components in boilers because, at the high temperatures at which their oxidation resistance is useful, they are subject to a variety of embrittling, phase precipitation reactions, including 885F (474C) embrittlement and sigma phase formation. They are used as studs for holding refractories and heat absorbing projections and as thermal shields. These alloys are also difficult to weld without cracking.

Duplex alloys, with mixed austenitic-ferritic structures, have been developed. They are useful in corrosive lower temperature applications such as those found in wet desulfurization equipment used as boiler flue gas scrubbers.

Bimetallic materials Weld cladding of one alloy with

another has been available for many years. A more recent development has been the proliferation of *bimetallic* components, such as tubes and plate containing a load carrying alloy for their major constituent covered with a layer of a corrosion resistant alloy. The first bimetallic tubes to see wide use in boilers were made from Alloy 800H clad with a 50Cr-50Ni alloy (Alloy 671) for coal ash corrosion resistance. The combination in widest use today is carbon steel clad with 304L, used in pulp and paper process recovery (PR) boilers. One of the latest to be developed is carbon steel or 1/2Cr-1/2Mo clad with Alloy 825 (42Ni-21.5Cr-5Mo-2.3Cu) used in PR and refuse-fired boilers.¹⁷ Other combinations that have been used are 1/2Cr-1/2Mo and 2-1/4Cr-1Mo clad with 309.

Cast irons Cast irons and cast steels (containing more than 2% or less than 2% C, respectively) have long had wide acceptance as wear resistant and structural components in boilers. Cast steels are also used for boiler pressure parts. The three types of cast iron used in boilers are white, gray and ductile iron.

White iron White cast iron is so known because of the silvery luster of its fracture surface. In this alloy, the carbon is present in combined form as the iron carbide cementite (Fe₃C). This carbide is chiefly responsible for the hardness, brittleness and poor machinability of white cast iron. Chilled iron differs from white cast iron only in its method of manufacture and it behaves similarly. This type of iron is cast against metal blocks, or chills, that cause rapid cooling at the adjacent areas, promoting the formation of cementite. Consequently, a white or mottled structure, which is characterized by high resistance to wear and abrasion, is obtained. Elverite[®] alloys, a series of white iron, Ni-enriched cast materials developed by The Babcock & Wilcox Company (B&W) for use in pulverizers and other wear resistant parts, have long been noted for their uniformity and high quality.

VAM[®] 20, a more recent development, is a 20% Cr white iron with a carbide-in-martensite matrix, very high hardness and good toughness (compared to other white irons). The hardness and wear resistance of VAM 20 are superior to those of the Elverites and similar alloys. It is always used in the heat treated condition, which accounts for its good toughness and uniformity. VAM 20 is used in grinding elements of coal pulverizers.

Malleable cast iron is white cast iron that has been heat treated to change its combined carbon (cementite) into free, or temper carbon (nodules of graphite). The iron becomes malleable because, in this condition, the carbon no longer forms planes of weakness.

Gray iron Gray cast iron is by far the most widely used cast metal. In this alloy, the carbon is predominantly in the free state in the form of graphite flakes, which form a multitude of notches and discontinuities in the iron matrix. The fracture appearance of this iron is gray because the graphite flakes are exposed. Gray iron's strength depends on the size of the graphite crystals and the amount of cementite formed with the graphite. The strength of the iron increases as the graphite crystal size decreases and the amount of cementite increases. Gray cast iron is easily machinable

because the graphite acts as a lubricant. It also provides discontinuities that break the chips as they are formed. Modern gray iron having a wide range of tensile strength, from 20,000 to 90,000 psi (138 to 621 MPa), can be made by suitable alloying with Ni, Cr, Mo, V and Cu.

Ductile iron Another member of the cast iron family is *ductile cast iron*. It is a high carbon, Mg-treated ferrous product containing graphite in the form of spheroids or impacted particles. Ductile cast iron is similar to gray cast iron in melting point, fluidity and machinability, but it possesses superior mechanical properties. This alloy is especially suited for pressure castings. By special procedures (casting against a chill), it is possible to obtain a carbide-containing abrasion resistant surface with an interior of good ductility.

Cast iron was used extensively in early steam boilers for tubes and headers. This material is no longer used in the pressure parts of modern power boilers but is used in related equipment such as stoker parts and the grinding elements of coal pulverizers.

Cast alloys Cast steels and non-ferrous alloys are used for many support and alignment applications in boilers, and for some pressure parts having complex shapes. The alloys range from carbon steel and 2-1/4Cr-1Mo to 25Cr-12Ni and 50Cr-50Ni.

Ceramics and refractory materials Ceramics and refractory materials are used for their insulating and erosion resisting properties. Brick furnace walls have mostly been replaced by steel membrane panels. (See Chapter 23.) However, in many applications, these walls may still have a rammed, troweled or cast refractory protection applied. Refractory linings are still important features of some furnaces, particularly those exposed to molten slag. In Cyclone furnaces (see Chapter 15) and other wet-bottom boilers, gunned and troweled alumina and silicon carbide refractory products are generally used. Chromium-containing refractories are no longer in general use since being classified as a hazardous material.

Cera-VAM® is a high density alumina ceramic used as an erosion liner in coal-air pipeline elbows, coal pulverizer internals, and pulverizer swing valves to reduce erosion and the associated maintenance costs. (See Chapter 13.) Structural ceramics have also been introduced as hot gas filters. These filters remove particulates from the flue gas of fluidized-bed boilers before the gas enters the high temperature gas turbine of combined cycle plants. (See Chapter 17.)

Coatings Many types of coatings are applied to boiler metal parts. In addition to the cast, gunned and troweled types mentioned above, thinner carbide-containing, metallic matrix coatings are sprayed onto surfaces in boilers exposed to high velocity particulate erosion. Metallic coatings are sprayed on boiler parts exposed to erosion and corrosion wastage by the *flame spraying, twin-wire electric arc, plasma* and *high velocity oxy-fuel* processes. These are shop- and field-applied maintenance processes that protect and repair components that experience wastage. Proper surface preparation and process control must be exercised to ensure that these coatings adhere, have the proper density, and achieve the recommended thickness on all surfaces.

Chromizing In the mid 1970s, B&W pioneered the use of chemical vapor deposition (CVD) coatings for boiler components. *Chromizing*, a process previously applied to aircraft jet engine components, is applied to large surfaces on the interior of tubing and piping. The purpose of this process is to develop a high Cr-containing surface that is resistant to oxidation and subsequent exfoliation. High temperature steam carrying pressure parts suffer from oxidation on their internal surfaces. When the oxide layer becomes thick enough, it spalls off the surface and the particles are carried to the steam turbine, where the resulting erosion damage causes loss of efficiency and creates a risk of mechanical damage. Perfect coverage of tube inside diameter (ID) surfaces is not necessary to reduce this condition. If 95% of the susceptible tube surface is chromized, a twenty-fold reduction in exfoliate particles will result.

In CVD processes, such as chromizing, the surfaces to be coated are usually covered with or embedded in a mixture containing powdered metal of the coating element, e.g., Cr, a halide salt, and a refractory powder, often alumina. When the parts and the mixture are heated to a sufficiently high temperature, the salt decomposes and the metal powder reacts with the halide ion to form a gas, e.g., CrCl_2 or CrBr_2 . At the surface of the part being coated, an exchange reaction takes place. An Fe atom replaces the Cr in the gas and the Cr atom is deposited on the surface. The process is conducted at sufficient time and temperature to permit the Cr to diffuse into the base material. At the chromizing temperature, 2-1/4Cr-1Mo, for example, is fully austenitic. However, as Cr atoms are deposited on the surface, the Cr increases the stability of the ferrite phase. As a result, the diffusion front advances into the matrix concurrently with the phase transformation front. This results in a diffusion zone with a nearly constant Cr content. (See Fig. 14.) Typical depths of this zone range from 0.002 to 0.025 in. (0.051 to 0.64 mm). The diffusion layer on a 2-1/4Cr-1Mo substrate has a Cr content range of 30 to 13%.

Chromizing, though first developed to reduce solid particle erosion of turbines, is now being applied to external surfaces of boiler pressure parts to reduce or prevent corrosion and corrosion-fatigue damage. In these applications, near perfect continuity and integrity of the coating is required. A thicker coating is necessary to resist the more hostile external environments. Improvements in chromized coating composition and processing have been achieved. Co-diffusion of Cr and Si, or Cr and Al, is now possible, improving the corrosion resistance of the coating. Process improvements have allowed for shorter times at diffusing temperature, thus resulting in less undercoating decarburization and better material properties.

Aluminizing Aluminizing, a similar CVD process, has been used for many years to protect components in petrochemical process pressure vessels. However, alumina, as silica, is soluble in high temperature, high pressure steam and it can be carried to the turbine, where pressure and temperature drops cause it to precipitate on the turbine components; this is undesirable. Aluminizing, either with diffusion processes

Fig. 14 Chromized 2-1/4Cr-1Mo at 400 X magnification.

or spray metallizing, has also seen some use as an external, fireside surface protective coating. The diffusion coating over iron-based alloys does create a brittle iron aluminide phase that can lead to premature loss of the coating, but it has had long term success in a number of petrochemical applications, especially sulfuric acid service, and where carburization (metal dusting) must be avoided.

Fused coatings Tungsten carbide/chromium carbide fused metallic coatings are also used for erosion protection of tube membrane panels, for example, in basic oxygen furnace steelmaking furnace hoods. Fused coatings differ from sprayed coatings in possessing higher density and achieving better bond strength due to the brazing-type action of the application process, which includes a high temperature heat treatment following the coating application using a conventional metallizing process.

Galvanizing More mundane coatings, such as galvanizing, painting and organic rust prevention coatings, are also used on boiler components.

Galvanizing, a zinc coating usually applied by dipping in molten metal or by electroplating, is usually used on structural components external to the boiler, when erection is near a seashore or a petrochemical complex.¹⁸ Galvanized components must be kept out of high temperature areas to avoid structural damage due to zinc grain boundary embrittlement, generally believed to occur at temperatures above 450F (232C).

Mechanical properties

Low temperature properties

Steels of different properties are used in boilers, each selected for one or more specific purposes. Each steel must have properties for both manufacturing and satisfactory service life. Each particular type, or grade, of steel must be consistent in its properties, and tests are normally run on each lot to demonstrate that the desired properties have been achieved.

Specifications standardizing all the conditions relating to test specimens, methods and test frequency have been formulated by the American Society for Testing and Materials (ASTM) and other authorities.

Tensile test

In the tensile test, a gradually applied unidirectional pull determines the maximum load that a material can sustain before breaking. The relationship between the stress (load per unit area) and the corresponding strain (change of length as a percent of the original length) in the test piece is illustrated in the stress-strain diagrams of Figs. 15 and 16. The metal begins to stretch as soon as the load is applied and, for some range of increasing load, the strain is proportional to the stress. This is the elastic region of the stress-strain curve, in which the material very closely follows Hooke's Law: strain, ϵ , is proportional to stress, σ . The proportionality constant may be considered as a spring constant and is called Young's modulus, E . Young's modulus is a true material property, characteristic of each alloy. Young's modulus for steel is approximately 30×10^6 psi (206.8×10^6 kPa) at room temperature.

If the stress is released at any point in this region, the test specimen will return to very nearly its initial dimensions. However, if the stress is increased beyond a certain point, the metal will no longer behave elastically; it will have a permanent (plastic) elongation, and the linear relationship between stress and strain ceases. This value is known as the proportional limit of the material and, in this discussion, may be considered practically the same as the elastic limit, which may be defined as the maximum stress that can be developed just before permanent elongation occurs.

Fig. 15 Engineering stress-strain curve for 1030 carbon steel (courtesy of Wiley).¹⁹

Fig. 16 Engineering stress-strain diagram for polycrystalline copper. Left, complete diagram. Right, elastic region and initial plastic region showing 0.2% offset yield strength.¹⁹

When a material has a well defined point at which it continues to elongate without further increase in load, this point is called the yield point. Many steels do not have a yield point and even in those that do, neither it nor the proportional or elastic limits can be determined with accuracy. By convention, therefore, engineers have adopted an arbitrary but readily measurable concept: the *yield strength* of a metal. This is defined as the stress at which the strain reaches 0.2% of the gauge length of the test specimen. This is illustrated in Fig. 16. (Other values, 0.1% or 0.5% are occasionally used, but 0.2% is most common.)

If the loading is continued after yielding begins, a test specimen of a ductile material with homogeneous composition and uniform cross-section will be elongated uniformly over its length, with a corresponding reduction in area. Eventually, a constriction or necking may occur. In some materials, localized necking may not occur, but the cross-section may reduce more or less uniformly along the full gauge length to the instant of rupture. In all ductile materials, however, an appreciable increase in elongation occurs in the reduced area of the specimen. The more ductile the steel, the greater is the elongation before rupture. The maximum applied load required to pull the specimen apart, divided by the area of the original cross-section, is known as the *ultimate tensile strength*. Brittle materials do not exhibit yielding or plastic deformation, and their yield point and ultimate tensile strength are nearly coincident.

The ductility of the metal is determined by measuring the increase in length (total elongation) and the final area at the plane of rupture after the specimen has broken, and is expressed as percent elongation or percent reduction of area.

Hardness test

Hardness may be defined as resistance to indentation under static or dynamic loads and also as resistance to scratching, abrasion, cutting or drilling. To the metallurgist, hardness is important as an indicator of the effect of heat treatment, fabrication processes, or service exposure. Hardness values are roughly indicative of the ultimate tensile strength of steels. Hardness tests are also used as easy acceptance tests and to explore local variations in properties.

Hardness is usually determined by using specially designed and standardized machines: Rockwell, Brinell, Vickers (diamond pyramid), or Tukon. These all measure resistance to indentation under static loads. The pressure is applied using a fixed load and for a specified time, and the indentation is measured either with a microscope or automatically. It is expressed as a hardness number, by reference to tables. Hardness can also be determined by a scleroscope test, in which the loss in kinetic energy of a falling metal weight, absorbed by indentation upon impact of the metal being tested, is indicated by the height of the rebound.

Toughness tests

Toughness is a property that represents the ability of a material to absorb local stresses by plastic deformation and thereby redistribute the stresses over a larger volume of material, before the material fails locally. It is therefore dependent on the rate of application of the load and the degree of concentration of the local stresses. In most steels, it is also temperature dependent, increasing with increasing temperature (although not linearly). Toughness tests are of two types, relative and absolute.

Notched bar impact tests are an example of the relative type. The most common is the Charpy test, in which a simple horizontal beam, supported at both ends, is struck in the center, opposite a V-shaped notch, by a single blow of a swinging pendulum. A Charpy specimen is illustrated in Fig. 17a. The energy absorbed by the breaking specimen can be read directly on a calibrated scale and is expressed in ft lb units. The specimen is also examined to determine how much it has spread laterally and how much of its fracture surface deformed in shear versus cleavage. The toughness is expressed in units of absorbed energy (ft lb or J), mils (thousandths of an inch or mm) lateral expansion and percent shear. The values are characteristic of not only the material and temperature, but also of the specimen size. Therefore, comparison between materials and tests have meaning only when specimen geometries and other test conditions are identical. Specimens are inexpensive and the test is easy to do. Often, vessel designers are interested in the variation of toughness with temperature. Fig. 18 illustrates the variation in toughness with temperature of 22 heats of a fine grained carbon steel, SA-299, as determined by Charpy testing. This material displays a gradual transition from higher to lower toughness.

Another toughness test, and one that provides a more sharply defined transition, is the drop-weight test. The specimen for this test is shown in Fig. 17b. A known weight is dropped from a fixed height and impacts the specimen. This is a pass or fail test and is performed on a series of specimens at varying temperatures, selected to bracket the break versus no-break temperature within 10F (6C). If the impact causes a crack to propagate to either edge of the specimen from the crack-starter notch in the brittle weld bead deposited on the face of the specimen, the specimen is considered to have broken at that temperature. The lowest temperature at which a specimen fails determines the nil-ductility transition temperature

Fig. 17 (a) Charpy specimen, (b) nil ductility transition temperature (drop weight) test specimen, (c) compact tension specimen (courtesy of Prentice-Hall).²⁰

(NDTT). Fig. 19 shows a histogram of NDTTs from 20 heats of fine grained SA-299.

Fracture toughness tests measure true characteristics of a given metal. They are more complex and specimens are more costly. However, they produce values that can be used in analytical stress calculations to determine critical flaw sizes above which flaws or cracks may propagate with little or no increase in load. A typical fracture toughness specimen is shown in Fig. 17c. Variations of fracture toughness tests involve testing under cyclic rather than monotonically increasing load (fatigue crack growth testing) and testing in various environments to determine crack growth rates as a function of concurrent corrosion processes. The same specimen is used to determine fatigue crack

Fig. 18 Charpy V-notch impact energy versus test temperature for fine grained SA-299 plate material.

growth behavior. Fig. 20 illustrates the difference in crack growth rate in air and in a salt solution for 4340 steel tempered to two strength levels.

Formability tests

Several different types of deformation tests are used to determine the potential behavior of a material in fabrication. These include bending, flattening, flaring and cupping tests. They furnish visual evidence of the capability of the material to withstand various forming operations. They are only a rough guide and are no substitute for full scale testing on production machinery.

High temperature properties

Tensile or yield strength data determined at ambient temperatures can not be used as a guide to the mechanical properties of metals at higher temperatures. Even though such tests are made at the higher temperatures, the data are inadequate for designing equipment for long term service at these temperatures. This is true because, at elevated temperatures, continued application of load produces a very slow continuous deformation, which can be significant and measurable over a period of time and may eventually lead to fracture, depending on the stress and temperatures involved. This slow deformation (creep) occurs for temperatures exceeding about 700F (371C) for ferritic steels and about 1000F (538C) for austenitic steels.

Tensile strength

Although the design of high temperature equipment generally requires use of creep and creep-rupture test data, the short time tensile test does indicate the strength properties of metals up to the creep range of the material. This test also provides information on ductility characteristics helpful in fabrication.

The ultimate strength of plain carbon steel and a number of alloy steels, as determined by short time tensile tests over a temperature range of 100F (38C) to 1300 to 1500F (704 to 816C), is shown in Fig. 21. In general, the results of these tests indicate that strength decreases with increase in temperature, although there is a region for the austenitic alloys between 400 and 900F (204 and 482C) where strength is fairly constant. An exception to the general rule is

Fig. 19 Drop weight nil-ductility transition temperature (NDTT) frequency distribution for 20 heats of fine grained SA-299 plate material.

Fig. 20 Corrosion fatigue crack growth rates for 4340 steel.²⁰

the increase in strength over that at room temperature of carbon and many low alloy steels (with corresponding decrease in ductility) over the temperature range of 100 to 600F (38 to 316C). As the temperature is increased beyond 600 to 750F (316 to 399C), the strength of the carbon and most of the low alloy steels falls off from that at room temperature with a corresponding increase in ductility.

Creep and creep-rupture test

It has long been known that certain nonmetallic materials, such as glass, undergo slow and continuous deformation with time when subjected to stress. The concept of creep in metallic materials, however, did not attract serious attention until the early 1920s. Results of several investigations at that time demonstrated that rupture of a metallic material could occur when it is subjected to a stress at elevated temperatures for a sufficiently long time, even though the load applied is considerably lower than that necessary to cause rupture in the short time tensile test at the same temperature.

The earliest investigations of creep in the U.S. were sponsored by B&W in 1926. Many steels now used successfully in power generating units and in the petroleum refining and chemical industries were tested and proved in the course of these investigations, using the best equipment available at the time.

The creep-rupture test is used to determine both the rate of deformation and the time to rupture at a given temperature. The test piece, maintained at constant temperature, is subjected to a fixed static tensile load. The deformation of the test sample is measured during the test and the time to rupture is determined. The duration of the test may range from 1000 to 10,000

h, or even longer. A diagrammatic plot of the observed length of the specimen against elapsed time is often of the form illustrated in Fig. 22.

The curve representing classical creep is divided into three stages. It begins after the initial extension (0-A), which is simply the measure of deformation of the specimen caused by the loading. The magnitude of this initial extension depends on test conditions, varying with load and temperature and normally increasing with increases in temperature and load. The first stage of creep (A-B), referred to as primary creep, is characterized by a decreasing rate of deformation during the period. The second stage (B-C), referred to as secondary creep, is usually characterized by extremely small variations in rate of deformation; this period is essentially one of constant rate of creep. The third stage (C-D), referred to as tertiary creep, is characterized by an accelerating rate of deformation leading to fracture. Some alloys, however, display a very limited (or no) secondary creep and spend most of their test life in tertiary creep.

To simplify the practical application of creep data it is customary to establish two values of stress (for a material at a temperature) that will produce two corresponding rates of creep (elongation): 1.0% per 10,000 h and 100,000 h, respectively.

For any specified temperature, several creep-rupture tests must be run under different loads. The creep rate during the period of secondary creep is determined from these curves and is plotted against the stress. When these data are plotted on logarithmic scales, the points for each specimen often lie on a line

Fig. 21 Tensile strength of various steels at temperatures to 1500F (816C).

Fig. 22 Classic (diagrammatic) creep test at constant load and temperature.

with a slight curvature. The minimum creep rate for any stress level can be obtained from this graph, and the curve can also be extrapolated to obtain creep rates for stresses beyond those for which data are obtained. Fig. 23 presents such creep rate curves for 2-1/4Cr-1Mo steel at 1000, 1100 and 1200F (538, 593 and 649C). The shape of the creep curve depends on the chemical composition and microstructure of the metal as well as the applied load and test temperature.

Creep-rupture strength is the stress (initial load divided by initial area) at which rupture occurs in some specified time, in an air atmosphere, in the temperature range in which creep takes place. The time for rupture at any temperature is a function of the applied load. A logarithmic-scale plot of stress versus time for fracture of specimens generally takes the form of the curves shown for 2-1/4Cr-1Mo steel in Fig. 24.

In general, rapid rates of elongation indicate a transgranular (ductile) fracture and slow rates of elongation indicate an intergranular (brittle) fracture. As a rule, surface oxidation is present when the fracture is transgranular, while visible intercrystalline oxidation may or may not be present when the fracture is intergranular. Because of the discontinuities produced by the presence of intercrystalline oxides, the time to rupture at a given temperature-load relationship may be appreciably reduced. In Fig. 24, the slope of the data at 1200F (649C) is steeper than those for lower temperatures. This is to be expected, because 1200F (649C) is above the usual temperature limit for maximum resistance to oxidation of 2-1/4Cr-1Mo. Therefore, excessive scaling occurs in the long time rupture tests conducted at 1200F (649C).

A complete creep-rupture test program for a given steel actually consists of a series of tests at constant temperature with each specimen loaded at a different level. Because tests are not normally conducted for more than 10,000 h, the values for rupture times longer than this are determined by extrapolation. The ASME Boiler and Pressure Vessel Code Committee uses several methods of extrapolation, depending on

the behavior of the particular alloy for which design values are being established and on the extent and quality of the database that is available. Several informative discussions on these methods may be found in ASME publications. (See Appendix 2.)

Material applications in boilers

ASME specifications and allowable stresses

The ASME Boiler and Pressure Vessel Code Subcommittee on Materials is responsible for identifying and approving material specifications for those metals deemed suitable for boiler and pressure vessel construction and for developing the allowable design values for metals as a function of temperature. Most industrial and all utility boilers are designed to Section I of the Code, *Power Boilers*, which lists those material specifications approved for boiler construction. The specifications themselves are listed in Section II, Part A, *Ferrous Materials*, and Section II, Part B, *Non-Ferrous Materials*. The design values are listed in Section II, Part D, *Properties*. (Section II, Part C, *Specifications for Welding Rods, Electrodes, and Filler Metals*, contains approved welding materials.)

For many years, there were relatively few changes in either specifications or design values. Over the last five or ten years, however, many new alloys have been introduced and much new data have become available. The restructuring of the North American steel industry and the globalization of sources of supply and markets are partly responsible for this rapid rate of change. As a result, detailed tables of design values in a text such as this become obsolete much more rapidly than was once the case. A few examples of current allowable stresses are presented below for illustrative purposes. However, the reader is encouraged to consult Section II for an exposure to material specifications and the latest design values.

The maximum allowable working stresses for materials in power boilers, set by the American Society of Mechanical Engineers (ASME), are based on both time-independent and time-dependent properties.

The ASME Boiler and Pressure Vessel Code, Section I, *Power Boilers*, has established the maximum

Fig. 23 Creep rate curves for 2-1/4Cr-1Mo steel.

Fig. 24 Typical creep rupture curves for 2-1/4Cr-1Mo steel.

allowable design stress values for pressure parts to be no higher than the lowest of:

1. $1 / 3.5 \times$ the minimum specified ultimate tensile strength,
2. $1.1 / 3.5 \times$ the tensile strength at temperature,
3. 67% of the specified minimum yield strength at room temperature,
4. 67% of the yield strength at temperature, for ferritic steels; or 90% of the yield strength at temperature of austenitic steels and nickel base alloys,
5. a conservative average of the stress to give a creep rate of 0.01% in 1000 hours (1% in 100,000 hours), or
6. 67% of the average or 80% of the minimum stress to produce rupture in 100,000 hours.

Furthermore, the allowable stress at a higher temperature can not exceed that at a lower temperature, so no advantage is taken of strain aging behavior. The allowable stress is therefore the lower bound envelope of all these criteria. The tensile and yield strengths at temperature have a particular meaning in Code usage.

For austenitic materials that possess allowable design properties above 1500F (816C), the ASME Code has recently adopted an additional criterion applied to creep rupture data of the specific alloy. The criterion involves a statistical evaluation of the data and ensures that a consistent safety factor exists at the very high temperatures.

Pressure part applications

The metal product forms used in boiler pressure parts are tubes and pipe (often used interchangeably), plate, forgings and castings. Tubular products compose the greatest part of the weight. The matrix in Table 1 shows the common pressure part material specifications used in fossil fuel fired boilers today, their minimum specified properties, recommended maximum use temperatures, and their applications. This list is not meant to be all inclusive, as there are many other specifications permitted by Section I and several of them see occasional use. Neither is it meant to be exclusive, as several of these specifications are used occasionally for components not checked in Table 1. Finally, the recommended maximum use temperatures represent one or more of a variety of limits. The temperature listed may be the highest for which stresses are listed in Section I, the oxidation limit for

long-term service, a temperature at which graphitization may be expected, or current commercial practice, whichever is least.

Boiler, furnace waterwall, convection pass enclosures and economizers

Boiler, furnace waterwall, and convection pass enclosure surfaces are generally made of carbon steel, C-Mo, and 1/2Cr-1/2Mo seamless or electric-resistance-welded (ERW) tubes. Lower carbon grades and 1/2Cr-1/2Mo alloy are used in high heat input regions to avoid the risk of graphitization in this region where tube metal temperatures may be subject to more fluctuation and uncertainty. Higher carbon grades and C-Mo are used in furnace floors, upper furnace walls, convection pass enclosures, and economizers.

The boiler industry is seeing increasing use of higher Cr-Mo grades in these applications, especially as temperatures and pressures increase with the latest designs. 1Cr-1/2Mo, 1-1/4 Cr-1/2Mo-Si, and even 2-1/4 Cr-1Mo will see increased use. Even higher alloys present formidable manufacturing challenges that will likely restrict these applications to alloys possessing less than 3% Cr.

Superheaters and reheaters

The highest metal temperatures of pressure parts in the steam generating unit occur in the superheater and reheater. Consequently, these tubes are made of material having superior high temperature properties and resistance to oxidation. Carbon steel is a suitable and economical material to about 850 to 950F (454 to 510C) metal temperature, depending on pressure. Above this range, alloy and stainless steels are required because of the low oxidation resistance and the low allowable stresses of carbon steel. Usually two or more alloys are used in the construction of the superheater. The lower alloys, such as carbon and C-Mo steels, are used toward the inlet section, while the low and intermediate alloy Cr-Mo steels are used toward the outlet, where the steam and metal temperatures are higher. (See Chapter 19.)

Stainless steel tubes have been required in the hottest sections of the superheater. However, stainless steels are being replaced in many applications by 9Cr-1Mo-V. This high strength ferritic steel was developed initially by The Oak Ridge National Laboratory for fast breeder nuclear reactor components. However, it has found many applications in fossil fuel-fired boilers because of its high strength and excellent toughness. Because it is ferritic, its use in place of stainless steel eliminates dissimilar metal weld failures.

New alloys, both ferritic and austenitic, are constantly being developed and are appearing in boilers around the world. The most promising ferritic alloys use alloying additions of elements such as V, Nb, W and N which, when combined with controlled normalizing and tempering heat treatment, result in materials possessing creep strength far superior to the traditional Cr-Mo alloy grades in the 2.25 to 12% Cr range. Newer austenitic alloys use modified alloying with elements such as Cu, Nb and N, sometimes combined with special thermal mechanical processing,

Notes:

1. Values in parentheses are not required minimums, but are expected minimums.
2. Requires special inspection if used at 100% efficiency above 850F.
3. Limited to 800F maximum for piping 10.75 in. OD and larger and outside the boiler setting.
4. Limited to 875F maximum for applications outside the boiler setting.
5. Requires special inspection if used at 100% efficiency.
6. Maximum OD temperature is 1025F. Maximum mean metal temperature for Code calculations is 1000F.

to enhance creep strength. A new family of Ni and Ni-Cr-Co alloys is also available, specifically for advanced supercritical and advanced supercritical boiler designs.

Fuel ash corrosion considerations might dictate the use of higher alloys at lower temperatures. This is common in process recovery and refuse-fired boilers with very corrosive flue gas and ash. For example, SB-407-825 (42Ni-21.5Cr-3Mo-2.25Cu-0.9Ti-bal Fe) is used in the highly corrosive regions of refuse boiler superheaters, even at temperatures below 1000F (538C). In extreme cases, bimetallic tubes, with a core

of a Code material for pressure retention and a cladding of a corrosion resistant alloy, are used for both furnace wall and superheater applications. Some common combinations are SA-210A1/304L, SA-210A1/Alloy 825, and SB-407-800H/50Cr-50Ni.

Selection factors

Many factors influence material selection in a superheater. These include cost as well as performance factors (heat transfer surface area required, final steam temperature, total mass flow through the tubes,

and flow balancing among circuits); mechanical factors (internal pressure, design temperature, support systems and relative thermal expansion stresses); environmental factors (resistance to steam oxidation and out of service pitting corrosion on the ID, and oxidation, fuel ash corrosion, and erosion on the outside diameter/OD); and manufacturing process and equipment limitations and considerations, such as weldability.

Cost

Material cost is usually the single largest factor affecting material selection when more than one material candidate exists for a given set of boiler application conditions. Raw material cost is established by taking into account each material's allowable design stress, at design temperature and pressure, and required mass flow requirements for the water or steam. Pressure part sizes are established, average weight determined, and material cost is estimated when knowing the raw material cost offered by the selected raw material supplier. Other factors are also considered such as required corrosion allowance, if any, and unique manufacturing costs and risks. Once this evaluation is accomplished and comparison of materials is completed, it is quite common to find that stronger, higher alloys become economically attractive over lower strength, less costly steels at operating conditions usually acceptable and appropriate for the lower alloy steel.

Headers and piping

Specifications for most of the commonly used pipe materials are listed in Table 1. As these components are usually not in the gas stream and are unheated, the major design factor, other than strength at temperature, is steam oxidation resistance. Carbon steels are not used above 800F (427C) outside the boiler setting, and C-Mo is limited to applications of small sizes [less than 10.75 in. (273 mm) OD] and below 875F (468C) to avoid graphitization.

9Cr-1Mo-V has replaced 2-1/4Cr-1Mo for many superheater outlet header applications (see Fig. 25). This material is not operating in the creep range even at the 1000 to 1050F (538 to 566C) design temperatures of most such components. This factor and its very high strength allow thinner components which are much less susceptible to the creep-fatigue failures observed in older 1-1/4Cr-1/2Mo-Si and 2-1/4Cr-1Mo headers. The use of forged outlet nozzle *tee* sections in place of welded nozzles has also reduced the potential for failure of these large piping connections.

Drums

Carbon steel plate is the primary material used in drums. SA-299, a 75,000 psi (517.1 MPa) tensile strength material, ordered to fine grain melting practice for improved toughness, is used for heavy section

Fig. 25 The 9Cr-1Mo-V superheater outlet header features high strength and thin material less susceptible to creep-fatigue failure.

drums, those more than about 4 in. (101.6 mm) in thickness. SA-516 Gr 70, a fine grained 70,000 psi (482.7 MPa) tensile strength steel, is used for applications below this thickness, down to 1.5 in. (38.1 mm) thick shells. SA-515 Gr 70, a coarse grain melting practice steel, is used for thinner shells. Steel grades of 80,000 psi (552 MPa) and higher are available. However, only in rare cases, where crane lifting capacity or long distance shipping costs are important considerations, are higher strength steels used due to increased manufacturing difficulties with the higher strength steels.

Heat resistant alloys for nonpressure parts

High alloy heat resistant materials must be used for certain boiler parts that are exposed to high temperature and can not be water or steam cooled. These parts are made from alloys of the oxidation resistant, relatively high strength Cr-Ni-Fe type, many of them cast to shape as baffles, supports and hanger fittings. Oil burner impellers, sootblower clamps and hangers are also made of such heat resisting alloy steels.

Deterioration of these parts may occur through conversion of the surface layers to oxides, sulfides and sulfates. Experience indicates that 25Cr-12Ni and 25Cr-20Ni steels give reasonably good service life, depending on the location of the part in the flue gas

stream and on the characteristics of the fuel. Temperatures to which these metal parts are exposed may range from 1000 to 2800F (538 to 1538C). Welding of such austenitic castings to ferritic alloy tubes presents a dissimilar metal weld that is susceptible to failure. Normal practice is to use a nickel-base filler metal that better matches the thermal expansion properties of the ferritic tube than would an austenitic stainless weld composition. If possible, a ferritic alloy weld rod should be used to further reduce stresses against the ferritic pressure part, provided there is adequate weldability and operating conditions at the weld location are acceptable. Special patented nonwelded constructions are also used where such combinations are required.

Life may be shortened if these steels are exposed to flue gases from fuel oil containing vanadium compounds. Sulfur compounds formed from combustion of high sulfur fuels are also detrimental and act to reduce life. These may react in the presence of V and cause greatly accelerated rates of attack, especially when the temperature of the metal part exceeds 1200F (649C). Combinations of Na, S and V compounds are reported to melt at as low as 1050F (566C). Such deposits are extremely corrosive when molten because of their slagging action. In these circumstances, 50Cr-50Ni or 60Cr-40Ni castings are used to resist corrosion.

Application of protective coating to boiler tubes.

Chapter 8

Structural Analysis and Design

Equipment used in the power, chemical, petroleum and cryogenic fields often includes large steel vessels. These vessels may require tons of structural steel for their support. Steam generating and emissions control equipment, for example, may be comprised of pressure parts ranging from small diameter tubing to vessels weighing more than 1000 t (907 t_m). A large fossil fuel boiler may extend 300 ft (91.4 m) above the ground, requiring a steel support structure comparable to a 30 story building. To assure reliability, a thorough design analysis of pressure parts and their supporting structural components is required.

Pressure vessel design and analysis

Steam generating units require pressure vessel components that operate at internal pressures of up to 4000 psi (27.6 MPa) and at steam temperatures up to 1100F (566C). Even higher temperature and pressure conditions are possible in advanced system designs. Maximum reliability can be assured only with a thorough stress analysis of the components. Therefore, considerable attention is given to the design and stress analysis of steam drums, superheater headers, heat exchangers, pressurizers and nuclear reactors. In designing these vessels, the basic approach is to account for all unknown factors such as local yielding and stress redistribution, variability in material properties, inexact knowledge of loadings, and inexact stress evaluations by using allowable working stresses that include appropriate factors of safety.

The analysis and design of complex pressure vessels and components such as the reactor closure head, shown in Fig. 1, and the fossil boiler steam drum, shown in Fig. 2, requires sophisticated principles and methods. Mathematical equations based on the theory of elasticity are applied to regions of discontinuities, nozzle openings and supports. Advanced computerized structural mechanics methods, such as the finite element method, are used to determine complex vessel stresses.

In the United States (U.S.), pressure vessel construction codes adopted by state, federal and municipal authorities establish safety requirements for vessel construction. The most widely used code is the American Society of Mechanical Engineers (ASME)

Boiler and Pressure Vessel Code. Key sections include Sections I, *Rules for Construction of Power Boilers*; III, *Rules for Construction of Nuclear Power Plant Components*; and VIII, *Rules for Construction of Pressure Vessels*. A further introduction to the ASME Code is presented in Appendix 2.

Stress significance

Stress is defined as the internal force between two adjacent elements of a body, divided by the area over which it is applied. The main significance of a stress is its magnitude; however, the nature of the applied

Fig. 1 Head of nuclear reactor vessel.

Fig. 2 Fossil fuel boiler steam drum.

load and the resulting stress distribution are also important. The designer must consider whether the loading is mechanical or thermal, whether it is steady-state or transient, and whether the stress pattern is uniform.

Stress distribution depends on the material properties. For example, yielding or strain readjustment can cause redistribution of stresses.

Steady-state conditions An excessive steady-state stress due to applied pressure results in vessel material distortion, progresses to leakage at fittings and ultimately causes failure in a ductile vessel. To prevent this type of failure a safety factor is applied to the material properties. The two predominant properties considered are yield strength, which establishes the pressure at which permanent distortion occurs, and tensile strength, which determines the vessel bursting pressure. ASME Codes establish pressure vessel design safety factors based on the sophistication of quality assurance, manufacturing control, and design analysis techniques.

Transient conditions When the applied stresses are repetitive, such as those occurring during testing and transient operation, they may limit the fatigue life of the vessel. The designer must consider transient conditions causing fatigue stresses in addition to those caused by steady-state forces.

Although vessels must have nozzles, supports and flanges in order to be useful, these features often embody abrupt changes in cross-section. These changes can introduce irregularities in the overall stress pattern called local or peak stresses. Other construction details can also promote stress concentrations which, in turn, affect the vessel's fatigue life.

Strength theories

Several material strength theories are used to determine when failure will occur under the action of multi-axial stresses on the basis of data obtained from uni-axial tension or compression tests. The three most commonly applied theories which are used to establish elastic design stress limits are the maximum (principal) stress theory, the maximum shear stress theory, and the distortion energy theory.

Maximum stress theory The maximum stress theory considers failure to occur when one of the three principal stresses (σ) reaches the material yield point ($\sigma_{y.p.}$) in tension:

$$\sigma = \sigma_{y.p.} \quad (1)$$

This theory is the simplest to apply and, with an adequate safety factor, it results in safe, reliable pressure vessel designs. This is the theory of strength used in the ASME Code, Section I, Section VIII Division 1, and Section III Division 1 (design by formula Subsections NC-3300, ND-3300 and NE-3300).

Maximum shear stress theory The maximum shear stress theory, also known as the Tresca theory,¹ considers failure to occur when the maximum shear stress reaches the maximum shear stress at the yield strength of the material in tension. Noting that the maximum shear stress (τ) is equal to half the difference of the maximum and minimum principal stresses, and that the maximum shear stress in a tension test specimen is half the axial principal stress, the condition for yielding becomes:

$$\tau = \frac{\sigma_{\max} - \sigma_{\min}}{2} = \frac{\sigma_{y.p.}}{2} \quad (2)$$

$$2\tau = \sigma_{\max} - \sigma_{\min} = \sigma_{y.p.}$$

The value 2τ is called the shear stress intensity. The maximum shear stress theory predicts ductile material yielding more accurately than the maximum stress theory. This is the theory of strength used in the ASME Code, Section VIII Division 2, and Section III Division 1, Subsection NB, and design by analysis, Subsections NC-3200 and NE-3200.

Distortion energy theory The distortion energy theory (also known as the Mises criterion¹) considers yielding to occur when the distortion energy at a point in a stressed element is equal to the distortion energy in a uni-axial test specimen at the point it begins to yield. While the distortion energy theory is the most accurate for ductile materials, it is cumbersome to use and is not routinely applied in pressure vessel design codes.

Design criteria¹

To determine the allowable stresses in a pressure vessel, one must consider the nature of the loading and the vessel response to the loading. Stress interpretation determines the required stress analyses and the allowable stress magnitudes. Current design codes establish the criteria for safe design and operation of pressure vessels.

Stress classifications Stresses in pressure vessels have three major classifications: primary, secondary and peak.

Primary stresses (P) are caused by loadings which are necessary to satisfy the laws of equilibrium with applied pressure and other loads. These stresses are further divided into general primary membrane (P_m), local primary membrane (P_L) and primary bending (P_b) stresses. A primary stress is not self-limiting, i.e., if the material yields or is deformed, the stress is not reduced. A good example of this type of stress is that produced

by internal pressure such as in a steam drum. When it exceeds the vessel material yield strength, permanent distortion appears and failure may occur.

Secondary stresses (Q), due to mechanical loads or differential thermal expansion, are developed by the constraint of adjacent material or adjacent components. They are self-limiting and are usually confined to local areas of the vessel. Local yielding or minor distortion can reduce secondary stresses. Although they do not affect the static bursting strength of a vessel, secondary stresses must be considered in establishing its fatigue life.

Peak stresses (F) are concentrated in highly localized areas at abrupt geometry changes. Although no appreciable vessel deformations are associated with them, peak stresses are particularly important in evaluating the fatigue life of a vessel.

Code design/analysis requirements Allowable stress limits and design analysis requirements vary with pressure vessel design codes.

According to ASME Code, Section I, the minimum vessel wall thickness is determined by evaluating the general primary membrane stress. This stress, limited to the allowable material tension stress S , is calculated at the vessel design temperature. The Section I regulations have been established to ensure that secondary and peak stresses are minimized; a detailed analysis of these stresses is normally not required.

The design criteria of ASME Code, Sections VIII Division 1, and Section III Division 1 (design by formula Subsections NC-3300, ND-3300 and NE-3300), are similar to those of Section I. However, they require cylindrical shell thickness calculations in the circumferential and longitudinal directions. The minimum required pressure vessel wall thickness is set by the maximum stress in either direction. Section III Division 1 and Subsections NC-3300 and ND-3300 permit the combination of primary membrane and primary bending stresses to be up to $1.5 S$ at design temperature. Section VIII Division 1 permits the combination of primary membrane and primary bending stresses to be $1.5 S$ at temperatures where tensile or yield strength sets the allowable stress S , and a value smaller than $1.5 S$ at temperatures where creep governs the allowable stress.

ASME Code, Section VIII Division 2 provides formulas and rules for common configurations of shells and formed heads. It also requires detailed stress analysis of complex geometries with unusual or cyclic loading conditions. The calculated stress intensities are assigned to specific categories. The allowable stress intensity of each category is based on a multiplier of the Code allowable stress intensity value. The Code allowable stress intensity, S_m , is based on the material yield strength, S_y , or tensile strength, S_u . (See Table 1.)

The factor k varies with the type of loading:

k	Loading
1.0	sustained
1.2	sustained and transient
1.25	hydrostatic test
1.5	pneumatic test

Table 1
Code-Allowable Stress Intensity

Stress Intensity Category	Allowable Value	Basis for Allowable Value at $k = 1.0$ (Lesser Value)
General primary membrane (P_m)	kS_m	$2/3 S_y$ or $1/3 S_u$
Local primary membrane (P_L)	$3/2 kS_m$	S_y or $1/2 S_u$
Primary membrane plus primary bending ($P_m + P_b$)	$3/2 kS_m$	S_y or $1/2 S_u$
Range of primary plus secondary ($P_m + P_b + Q$)	$3 S_m$	$2 S_y$ or S_u

The design criteria for ASME Code, Section III Division 1, Subsection NB and design by analysis Subsections NC-3200 and NE-3200 are similar to those for Section VIII Division 2 except there is less use of design formulas, curves, and tables, and greater use of design by analysis in Section III. The categories of stresses and stress intensity limits are the same in both sections.

Stress analysis methods

Stress analysis of pressure vessels can be performed by analytical or experimental methods. An analytical method, involving a rigorous mathematical solution based on the theory of elasticity and plasticity, is the most direct and inexpensive approach when the problem is adaptable to such a solution. When the problem is too complex for this method, approximate analytical structural mechanics methods, such as finite element analysis, are applied. If the problem is beyond analytical solutions, experimental methods must be used.

Mathematical formulas² Pressure vessels are commonly spheres, cylinders, ellipsoids, tori or composites of these. When the wall thickness is small compared to other dimensions, vessels are referred to as membrane shells. Stresses acting over the thickness of the vessel wall and tangential to its surface can be represented by mathematical formulas for the common shell forms.

Pressure stresses are classified as primary membrane stresses since they remain as long as the pressure is applied to the vessel. The basic equation for the longitudinal stress σ_1 and hoop stress σ_2 in a vessel of thickness h , longitudinal radius r_1 , and circumferential radius r_2 , which is subject to a pressure P , shown in Fig. 3 is:

$$\frac{\sigma_1}{r_1} + \frac{\sigma_2}{r_2} = \frac{P}{h} \quad (3)$$

From this equation, and by equating the total pressure load with the longitudinal forces acting on a transverse section of the vessel, the stresses in the commonly used shells of revolution can be found.

Fig. 3 Membrane stress in vessels (courtesy Van Nostrand Reinhold).²

1. Cylindrical vessel – in this case, $r_1 = \infty$, $r_2 = r$, and

$$\sigma_1 = \frac{Pr}{2h} \quad (4)$$

$$\sigma_2 = \frac{Pr}{h} \quad (5)$$

2. Spherical vessel – in this case, $r_1 = r_2 = r$, and

$$\sigma_1 = \frac{Pr}{2h} \quad (6)$$

$$\sigma_2 = \frac{Pr}{2h} \quad (7)$$

3. Conical vessel – in this case, $r_1 = \infty$, $r_2 = r/\cos \alpha$ where α is half the cone apex angle, and

$$\sigma_1 = \frac{Pr}{2h \cos \alpha} \quad (8)$$

$$\sigma_2 = \frac{Pr}{h \cos \alpha} \quad (9)$$

4. Ellipsoidal vessel – in this case (Fig. 4), the instantaneous radius of curvature varies with each position on the ellipsoid, whose major axis is a and minor axis is b , and the stresses are given by:

$$\sigma_1 = \frac{Pr_2}{2h} \quad (10)$$

Fig. 4 Stress in an ellipsoid.²

$$\sigma_2 = \frac{P}{h} \left(r_2 - \frac{r_2^2}{2r_1} \right) \quad (11)$$

At the equator, the longitudinal stress is the same as the longitudinal stress in a cylinder, namely:

$$\sigma_1 = \frac{Pa}{2h} \quad (12)$$

and the hoop stress is:

$$\sigma_2 = \frac{Pa}{h} \left(1 - \frac{a^2}{2b^2} \right) \quad (13)$$

When the ratio of major to minor axis is 2:1, the hoop stress is the same as that in a cylinder of the same mating diameter, but the stress is compressive rather than tensile. The hoop stress rises rapidly when the ratio of major to minor axis exceeds 2:1 and, because this stress is compressive, buckling instability becomes a major concern. For this reason, ratios greater than 2:1 are seldom used.

5. Torus – in this case (Fig. 5), R_o is the radius of the bend centerline, θ is the angular hoop location from this centerline and:

$$\sigma_1 = \frac{Pr}{2h} \quad (14)$$

$$\sigma_2 = \frac{Pr}{2h} \left(\frac{2R_o + r \sin \theta}{R_o + r \sin \theta} \right) \quad (15)$$

The longitudinal stress remains uniform around the circumference and is the same as that for a straight cylinder. The hoop stress, however, varies for different points in the torus cross-section. At the bend centerline, it is the same as that in a straight cylinder. At the outside of the bend, it is less than this and is at its minimum. At the inside of the bend, or crotch, the value is at its maximum. Hoop stresses are depen-

dent on the sharpness of the bend and are inversely proportional to bend radii. In pipe bending operations, the material thins at the outside and becomes thicker at the crotch of the bend. This is an offsetting factor for the higher hoop stresses that form with smaller bend radii.

Thermal stresses result when a member is restrained as it attempts to expand or contract due to a temperature change, ΔT . They are classified as sec-

ondary stresses because they are self-limiting. If the material is restricted in only one direction, the stress developed is:

$$\sigma = \pm E \alpha \Delta T \quad (16)$$

where E is the modulus of elasticity and α is the coefficient of thermal expansion. If the member is restricted from expanding or contracting in two direc-

ASME Code calculations

In most U.S. states and Canadian provinces laws have been established requiring that boilers and pressure vessels comply with the rules for the design and construction of boilers and pressure vessels in the ASME Code. The complexity of these rules and the amount of analysis required are inversely related to the factors of safety which are applied to the material properties used to establish the allowable stresses. That is, when the stress analysis is simplified, the factor of safety is larger. When the stress analysis is more complex, the factor of safety is smaller. Thus, overall safety is maintained even though the factor of safety is smaller. For conditions when material tensile strength establishes the allowable stress, ASME Code, Section IV, *Rules for Construction of Heating Boilers*, requires only a simple thickness calculation with a safety factor on tensile strength of 5. ASME Code, Section I, *Rules for Construction of Power Boilers* and Section VIII, Division 1, *Rules for Construction of Pressure Vessels*, require a more complex analysis with additional items to be considered. However, the factor of safety on tensile strength is reduced to 3.5. Section III, *Rules for Construction of Nuclear Components* and Section VIII, Division 2, *Rules for Construction of Pressure Vessels* require extensive analyses which are required to be certified by a registered professional engineer. In return, the factor of safety on tensile strength is reduced even further to 3.0.

When the wall thickness is small compared to the diameter, membrane formulas (Equations 4 and 5) may be used with adequate accuracy. However, when the wall thickness is large relative to the vessel diameter, usually to accommodate higher internal design pressure, the membrane formulas are modified for ASME Code applications.

Basically the minimum wall thickness of a cylindrical shell is initially set by solving the circumferential or hoop stress equation assuming there are no additional loadings other than internal pressure. Other loadings may then be considered to determine if the initial minimum required wall thickness has to be increased to keep calculated stresses below allowable stress values.

As an example, consider a Section VIII, Division 1, pressure vessel with no unreinforced openings and no additional loadings other than an internal design pressure of 1200 psi at 500F. The inside diameter is 10 in. and the material is SA-516, Grade 70 carbon steel. There is no corrosion allowance required by this application and the butt weld joints are 100% radiographed. What is the minimum required wall thickness needed? The equation for setting the minimum required wall thickness in Section VIII, Division 1, of the Code (paragraph UG-27(c)(1), 2001 Edition) is:

$$t = \frac{PR}{SE - 0.6P}$$

where

t = minimum required wall thickness, in.

P = internal design pressure, psi

R = inside radius, in.

S = allowable stress at design temperature, psi (Section II, Part D) = 20,000 psi

E = lower of weld joint efficiency or ligament efficiency (fully radiographed with manual penetrations) = 1.0

For the pressure vessel described above:

$P = 1200$ psi

$R = 5$ in.

$S = 20,000$ psi

$E = 1.0$

$$t = \frac{(1200)(5)}{(20,000)(1.0) - (0.6)(1200)} = 0.311 \text{ in.}$$

Using commercial sizes, this plate thickness probably would be ordered at 0.375 in.

If Equation 5 for simple hoop stress (see Figure below) is used alone to calculate the plate thickness using the specified minimum tensile strength of SA-516, Grade 70 of 70,000 psi, the thickness h would be evaluated to be:

$$h = \frac{1200(5)}{70,000} = 0.0857$$

Therefore, the factor of safety (FS) based on tensile strength is:

$$FS = \frac{0.311}{0.0857} = 3.6$$

Fig. 5 Hoop stress variation in a bend.²

tions, as is the case in pressure vessels, the resulting stress is:

$$\sigma = \pm \frac{E \alpha \Delta T}{1 - \mu} \quad (17)$$

where μ is Poisson's ratio.

These thermal stress equations consider full restraint, and therefore are the maximum that can be created. When the temperature varies within a member, the natural growth of one fiber is influenced by the differential growth of adjacent fibers. As a result, fibers at high temperatures are compressed and those at lower temperatures are stretched. The general equations for radial (σ_r), tangential (σ_t), and axial (σ_z) thermal stresses in a cylindrical vessel subject to a radial thermal gradient are:

$$\sigma_r = \frac{\alpha E}{(1 - \mu)r^2} \left[\frac{r^2 - a^2}{b^2 - a^2} \int_a^b T r dr - \int_a^r T r dr \right] \quad (18)$$

$$\sigma_t = \frac{\alpha E}{(1 - \mu)r^2} \left[\frac{r^2 + a^2}{b^2 - a^2} \int_a^b T r dr + \int_a^r T r dr - T r^2 \right] \quad (19)$$

$$\sigma_z = \frac{\alpha E}{(1 - \mu)} \left[\frac{2}{b^2 - a^2} \int_a^b T r dr - T \right] \quad (20)$$

where

- E = modulus of elasticity
- μ = Poisson's ratio
- r = radius at any location
- a = inside radius
- b = outside radius
- T = temperature

For a cylindrical vessel in which heat is flowing radially through the walls under steady-state conditions, the maximum thermal stresses are:

$$\sigma_{ta}(\text{inside}) = \frac{\alpha E T_a}{2(1 - \mu) \ln\left(\frac{b}{a}\right)} \left[1 - \frac{2b^2}{b^2 - a^2} \ln\left(\frac{b}{a}\right) \right] \quad (21)$$

$$\sigma_{tb}(\text{outside}) = \frac{\alpha E T_a}{2(1 - \mu) \ln\left(\frac{b}{a}\right)} \left[1 - \frac{2a^2}{b^2 - a^2} \ln\left(\frac{b}{a}\right) \right] \quad (22)$$

For relatively thin tubes and $T_a > T_b$, this can be simplified to:

$$\sigma_{ta} = \frac{-\alpha E \Delta T}{2(1 - \mu)} \quad (23)$$

$$\sigma_{tb} = \frac{\alpha E \Delta T}{2(1 - \mu)} \quad (24)$$

To summarize, the maximum thermal stress for a thin cylinder with a logarithmic wall temperature gradient is one half the thermal stress of an element restrained in two directions and subjected to a temperature change ΔT (Equation 17). For a radial thermal gradient of different shape, the thermal stress can be represented by:

$$\sigma = K \frac{E \alpha \Delta T}{1 - \mu} \quad (25)$$

where K ranges between 0.5 and 1.0.

Alternating stresses resulting from cyclic pressure vessel operation may lead to fatigue cracks at high stress concentrations. Fatigue life is evaluated by comparing the alternating stress amplitude with design fatigue curves (allowable stress versus number of cycles or σ - N curves) experimentally established for the material at temperature. A typical σ - N design curve for carbon steel is shown in Fig. 6 and can be expressed by the equation:

$$\sigma_a = \frac{E}{4\sqrt{N}} \ln\left(\frac{100}{100 - d_a}\right) + .01(TS) d_a \quad (26)$$

where

- σ_a = allowable alternating stress amplitude
- E = modulus of elasticity at temperature
- N = number of cycles
- d_a = percent reduction in area
- TS = tensile strength at temperature

The two controlling parameters are tensile strength and reduction in area. Tensile strength is controlling in the high cycle fatigue region, while reduction in area is controlling in low cycle fatigue. The usual di-

Fig. 6 Design fatigue curve.

vision between low and high cycle fatigue is 10^5 cycles. Pressure vessels often fall into the low cycle fatigue category, thereby demonstrating the importance of the material's ability to deform in the plastic range without fracturing. Lower strength materials, with their greater ductility, have better low cycle fatigue resistance than do higher strength materials.

Practical operating service conditions subject many vessels to the random occurrence of a number of stress cycles at different magnitudes. One method of appraising the damage from repetitive stresses to a vessel is the criterion that the cumulative damage from fatigue will occur when the summation of the increments of damage at the various stress levels exceeds unity. That is:

$$\sum \frac{n}{N} = 1 \quad (27)$$

where n = number of cycles at stress σ , and N = number of cycles to failure at the same stress σ . The ratio n/N is called the cycle damage ratio since it represents the fraction of the total life which is expended by the cycles that occur at a particular stress value. The value N is determined from σ - N curves for the material. If the sum of these cycle ratios is less than unity, the vessel is considered safe. This is particularly important in designing an economic and safe structure which experiences only a relatively few cycles at a high stress level and the major number at a relatively low stress level.

Discontinuity analysis method At geometrical discontinuities in axisymmetric structures, such as the intersection of a hemispherical shell element and a cylindrical shell element (Fig. 7a), the magnitude and characteristic of the stress are considerably different than those in elements remote from the discontinuity. A linear elastic analysis method is used to evaluate these local stresses.

Discontinuity stresses that occur in pressure vessels, particularly axisymmetric vessels, are determined by a discontinuity analysis method. A discontinuity stress results from displacement and rotation incompatibilities at the intersection of two elements. The forces and moments at the intersection (Fig. 7c) are redundant and self-limiting. They develop solely to ensure compatibility at the intersection. As a consequence, a discontinuity stress can not cause failure in ductile materials in one load application even if the maximum stress exceeds the material yield strength. Such stresses must be considered in cyclic load applications or in special cases where materials can not safely redistribute stresses. The ASME Code refers to discontinuity stresses as secondary stresses. The application to the shell of revolution shown in Fig. 7 outlines the major steps involved in the method used to determine discontinuity stresses.

Under internal pressure, a sphere radially expands approximately one half that of a cylindrical shell (Fig. 7b). The difference in free body displacement results in redundant loadings at the intersection if Elements (1) and (2) are joined (Fig. 7c). The final displacement and rotation of the cylindrical shell are equal to the

Fig. 7 Discontinuity analysis.

free body displacement plus the displacements due to the redundant shear force V_o and redundant bending moment M_o (Fig. 7d).

The direction of the redundant loading is unknown and must be assumed. A consistent sign convention must be followed. In addition, the direction of loading on the two elements must be set up consistently because Element (1) reacts Element (2) loading and vice versa. If M_o or V_o as calculated is negative, the correct direction is opposite to that assumed.

In equation form then, for Element (1):

$$\delta_{\text{FINAL}1} = \delta_{\text{FREE}1} - \beta_{\delta V1} V_o + \beta_{\delta M1} M_o \quad (28)$$

$$\gamma_{\text{FINAL}1} = \gamma_{\text{FREE}1} + \beta_{\gamma V1} V_o - \beta_{\gamma M1} M_o \quad (29)$$

Similarly for Element (2):

$$\delta_{\text{FINAL}2} = \delta_{\text{FREE}2} + \beta_{\delta V2} V_o + \beta_{\delta M2} M_o \quad (30)$$

$$\gamma_{\text{FINAL}2} = \gamma_{\text{FREE}2} + \beta_{\gamma V2} V_o + \beta_{\gamma M2} M_o \quad (31)$$

where

$$\delta_{\text{FREE}1} = \frac{PR^2}{Et} \left(1 - \frac{\mu}{2} \right) \quad (32)$$

$$\delta_{\text{FREE}2} = \frac{PR^2}{2Et} (1 - \mu) \quad (33)$$

$$\gamma_{\text{FREE}1} = \gamma_{\text{FREE}2} = 0 \text{ in this case}$$

The constants β are the deflections or rotations due to loading per unit of perimeter, and are referred to as influence coefficients. These constants can be determined for a variety of geometries, including rings and thin shells of revolution, using standard handbook solutions. For example:

$\beta_{\delta V1}$ = radial displacement of Element (1) due to unit shear load

$\beta_{\delta M1}$ = radial displacement of Element (1) due to unit moment load
 $\beta_{\gamma V1}$ = rotation of Element (1) due to unit shear load
 $\beta_{\gamma M1}$ = rotation of Element (1) due to unit moment load

Because $\delta_{\text{FINAL}1} = \delta_{\text{FINAL}2}$ and $\gamma_{\text{FINAL}1} = \gamma_{\text{FINAL}2}$ from compatibility requirements, Equations 28 through 31 can be reduced to two equations for two unknowns, V_o and M_o , which are solved simultaneously. Note that the number of equations reduces to the number of redundant loadings and that the force F can be determined by static equilibrium requirements.

Once V_o and M_o have been calculated, handbook solutions can be applied to determine the resulting membrane and bending stresses. The discontinuity stress must then be added to the free body stress to obtain the total stress at the intersection.

Although the example demonstrates internal pressure loading, the same method applies to determining thermally induced discontinuity stress. For more complicated geometries involving four or more unknown redundant loadings, commercially available computer programs should be considered for solution.

Finite element analysis When the geometry of a component or vessel is too complex for classical formulas or closed form solutions, finite element analysis (FEA) can often provide the required results. FEA is a powerful numerical technique that can evaluate structural deformations and stresses, heat flows and temperatures, and dynamic responses of a structure. Because FEA is usually more economical than experimental stress analysis, scale modeling, or other numerical methods, it has become the dominant sophisticated stress analysis method.

During product development, FEA is used to predict performance of a new product or concept before building an expensive prototype. For example, a design idea to protect the inside of a burner could be analyzed to find out if it will have adequate cooling and fatigue life. FEA is also used to investigate field problems.

To apply FEA, the structure is modeled as an assembly of discrete building blocks called elements. The elements can be linear (one dimensional truss or beam), plane (representing two dimensional behavior), or solid (three dimensional bricks). Elements are connected at their boundaries by nodes as illustrated in Fig. 8.

Except for analyses using truss or beam elements, the accuracy of FEA is dependent on the mesh density. This refers to the number of nodes per modeled volume. As mesh density increases, the result accuracy also increases. Alternatively, in *p-method* analysis, the mesh density remains constant while increased accuracy is attained through mathematical changes to the solution process.

A computer solution is essential because of the numerous calculations involved. A medium sized FEA may require the simultaneous solution of thousands of equations, but taking merely seconds of computer time. FEA is one of the most demanding computer applications.

FEA theory is illustrated by considering a simple structural analysis with applied loads and specified node displacements. The mathematical theory is essentially as follows.

Fig. 8 Finite element model composed of brick elements.

For each element, a stiffness matrix satisfying the following relationship is found:

$$[k]\{d\} = \{r\} \quad (34)$$

where

$[k]$ = an element stiffness matrix. It is square and defines the element stiffness in each direction (degree of freedom)

$\{d\}$ = a column of nodal displacements for one element

$\{r\}$ = a column of nodal loads for one element

The determination of $[k]$ can be very complex and its theory is not outlined here. Modeling the whole structure requires that:

$$[K]\{D\} = \{R\} \quad (35)$$

where

$[K]$ = structure stiffness matrix; each member of $[K]$ is an assembly of the individual stiffness contributions surrounding a given node

$\{D\}$ = column of nodal displacements for the structure

$\{R\}$ = column of nodal loads on the structure

In general, neither $\{D\}$ nor $\{R\}$ is completely known. Therefore, Equation 35 must be partitioned (rearranged) to separate known and unknown quantities. Equation 35 then becomes:

$$\begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \begin{Bmatrix} D_s \\ D_o \end{Bmatrix} = \begin{Bmatrix} R_o \\ R_s \end{Bmatrix} \quad (36)$$

where

D_s = unknown displacements

D_o = known displacements

R_s = unknown loads

R_o = known loads

Equation 36 represents the two following equations:

$$[K_{11}]\{D_s\} + [K_{12}]\{D_o\} = \{R_o\} \quad (37)$$

$$[K_{21}]\{D_s\} + [K_{22}]\{D_o\} = \{R_s\} \quad (38)$$

Equation 37 can be solved for D_s and Equation 38 can then be solved for R_s .

Using the calculated displacements $\{D\}$, $\{d\}$ can be

found for each element and the stress can be calculated by:

$$\{\sigma\} = [E][B]\{d\} \quad (39)$$

where

$\{\sigma\}$ are element stresses

$[E]$ and $[B]$ relate stresses to strains and strains to displacements respectively

FEA theory may also be used to determine temperatures throughout complex geometric components. (See also Chapter 4.) Considering conduction alone, the governing relationship for thermal analysis is:

$$[C]\{\dot{T}\} + [K]\{T\} = \{Q\} \quad (40)$$

where

$[C]$ = system heat capacity matrix

$\{\dot{T}\}$ = column of rate of change of nodal temperatures

$[K]$ = system thermal conductivity matrix

$\{T\}$ = column of nodal temperatures

$\{Q\}$ = column of nodal rates of heat transfer

In many respects, the solution for thermal analysis is similar to that of the structural analysis. One important difference, however, is that the thermal solution is iterative and nonlinear. Three aspects of a thermal analysis require an iterative solution.

First, thermal material properties are temperature dependent. Because they are primary unknowns, temperature assumptions must be made to establish the initial material properties. Each node is first given an assumed temperature. The first thermal distribution is then obtained, and the calculated temperatures are used in a second iteration. Convergence is attained when the calculated temperature distributions from two successive iterations are nearly the same.

Second, when convective heat transfer is accounted for, heat transfer at a fluid boundary is dependent on the material surface temperature. Again, because temperatures are the primary unknowns, the solution must be iterative.

Third, in a transient analysis, the input parameters, including boundary conditions, may change with time, and the analysis must be broken into discrete steps. Within each time step, the input parameters are held constant. For this reason, transient thermal analysis is sometimes termed quasi-static.

FEA applied to dynamic problems is based upon the differential equation of motion:

$$[M]\{\ddot{D}\} + [C]\{\dot{D}\} + [K]\{D\} = \{R\} \quad (41)$$

where

$[M]$ = structure lumped mass matrix

$[C]$ = structure damping matrix

$[K]$ = structure stiffness matrix

$\{R\}$ = column of nodal forcing functions

$\{D\}$, $\{\dot{D}\}$ and $\{\ddot{D}\}$ are columns of nodal displacements, velocities, and accelerations, respectively.

Variations on Equation 41 can be used to solve for the natural frequencies, mode shapes, and responses due to a forcing function (periodic or nonperiodic), or to do a dynamic seismic analysis.

Limitations of FEA involve computer and human resources. The user must have substantial experience and, among other abilities, he must be skilled in selecting element types and in geometry modeling.

In FEA, result accuracy increases with the number of nodes and elements. However, computation time also increases and handling the mass of data can be cumbersome.

In most finite element analyses, large scale yielding (plastic strain) and deformations (including buckling instability), and creep are not accounted for; the material is considered to be linear elastic. In a linear structural analysis, the response (stress, strain, etc.) is proportional to the load. For example, if the applied load is doubled, the stress response would also double. For nonlinear analysis, FEA can also be beneficial. Recent advancements in computer hardware and software have enabled increased use of nonlinear analysis techniques.

Although most FEA software has well developed three dimensional capabilities, some pressure vessel analyses are imprecise due to a lack of acceptance criteria.

Computer software consists of commercially available and proprietary FEA programs. This software can be categorized into three groups: 1) preprocessors, 2) finite element solvers, and 3) postprocessors.

A preprocessor builds a model geometry and applies boundary conditions, then verifies and optimizes the model. The output of a finite element solver consists of displacements, stresses, temperatures, or dynamic response data.

Postprocessors manipulate the output from the finite element solver for comparison to acceptance criteria or to make contour map plots.

Application of FEA Because classical formulas and shell analysis solutions are limited to simple shapes, FEA fills a technical void and is applied in response to ASME Code requirements. A large portion of The Babcock & Wilcox Company's (B&W) FEA supports pressure vessel design. Stresses can be calculated near nozzles and other abrupt geometry changes. In addition, temperature changes and the resulting thermal stresses can be predicted using FEA.

The raw output from a finite element solver can not be directly applied to the ASME Code criteria. The stresses or strains must first be classified as membrane, bending, or peak (Fig. 9). B&W pioneered the classification of finite element stresses and these procedures are now used throughout the industry.

Piping flexibility, for example, is an ideal FEA application. In addition, structural steel designers rely on FEA to analyze complex frame systems that support steam generation and emissions control equipment.

Finite element analysis is often used for preliminary review of new product designs. For example, Fig. 10 shows the deflected shape of two economizer fin configurations modeled using FEA.

Fig. 9 Classification of finite element stress results on a vessel cross-section for comparison to code criteria.³

Fracture mechanics methods

Fracture mechanics provides analysis methods to account for the presence of flaws such as voids or cracks. This is in contrast to the stress analysis methods discussed above in which the structure was considered to be free of those kinds of defects. Flaws may be found by nondestructive examination (NDE) or they may be hypothesized prior to fabrication. Fracture mechanics is particularly useful to design or evaluate components fabricated using materials that are more sensitive to flaws. Additionally, it is well suited to the prediction of the remaining life of components under cyclic fatigue and high temperature creep conditions.

During component design, the flaw size is hypothesized. Allowable design stresses can be determined knowing the lower bound material toughness from accepted design procedures in conjunction with a factor of safety.

Fracture mechanics can be used to evaluate the integrity of a flawed existing structure. The defect, usually found by NDE, is idealized according to accepted ASME practices. An analysis uses design or calculated stresses based on real or hypothesized loads, and material properties are found from testing a specimen of similar material. Determining allowable flaw sizes strongly relies on accurate material properties and the best estimates of structural stresses. Appropriate safety factors are then added to the calculations.

During inspection of power plant components, minor cracks or flaws may be discovered. However, the flaws may propagate by creep or fatigue and become significant. The remaining life of components can not be accurately predicted from stress/cycles to failure (σ/N) curves alone. These predictions become possible using fracture mechanics.

Linear elastic fracture mechanics The basic concept of linear elastic fracture mechanics (LEFM) was originally developed to quantitatively evaluate sudden structural failure. LEFM, based on an analysis of the stresses near a sharp crack, assumes elastic behavior throughout the structure. The stress distribution near the crack tip depends on a single quantity, termed the

stress intensity factor, K_I . LEFM assumes that unstable propagation of existing flaws occurs when the stress intensity factor becomes critical; this critical value is the fracture toughness of the material K_{IC} .

The theory of linear elastic fracture mechanics, LEFM, is based on the assumption that, at fracture, stress σ and defect size a are related to the fracture toughness K_{IC} , as follows:

$$K_I = C \sigma \sqrt{\pi a} \quad (42a)$$

and

$$K_I \geq K_{IC} \text{ at failure} \quad (42b)$$

The critical material property, K_{IC} , is compared to the stress intensity factor of the cracked structure, K_I , to identify failure potential. K_I should not be confused with the *stress intensity* used elsewhere in ASME design codes for analysis of unflawed structures. The term C , accounting for the geometry of the crack and structure, is a function of the crack size and relevant structure dimensions such as width or thickness.

C is exactly 1.0 for an infinitely wide center cracked panel with a through-wall crack length $2a$, loaded in tension by a uniform remote stress σ . The factor C varies for other crack geometries illustrated in Fig. 11. Defects in a structure due to manufacture, in-service environment, or in-service cyclic fatigue are usually assumed to be flat, sharp, planar discontinuities where the planar area is normal to the applied stress.

ASME Code procedures for fracture mechanics design/analysis are presently given in Sections III and XI which are used for component thicknesses of at least 4 in. (102 mm) for ferritic materials with yield strengths less than 50,000 psi (344.7 MPa) and for simple geometries and stress distributions. The basic concepts of the Code may be extended to other ferritic materials (including clad ferritic materials) and more complex geometries; however, it does not apply to austenitic or high nickel alloys. These procedures provide methods for designing against brittle fractures in structures and for evaluating the significance of flaws found during in-service inspections.

Fig. 10 Economizer tube and fin (quarter symmetry model) deformed shape plots before (upper) and after (lower) design modifications.

The ASME Code, Section III uses the principles of linear elastic fracture mechanics to determine allowable loadings in ferritic pressure vessels with an assumed defect. The stress intensity factors (K_I) are calculated separately for membrane, bending, and thermal gradient stresses. They are further subdivided into primary and secondary stresses before summing and comparison to the allowable toughness, K_{IR} . K_{IR} is the reference critical stress intensity factor (toughness). It accounts for temperature and irradiation embrittlement effects on toughness. A safety factor of 2 is applied to the primary stress components and a factor of 1 is applied to the secondary components.

To determine an operating pressure that is below the brittle fracture point, the following approach is used:

1. A maximum flaw size is assumed. This is a semi-elliptical surface flaw one fourth the pressure vessel wall thickness in depth and 1.5 times the thickness in length.
2. Knowing the specific material's nil ductility temperature, and the design temperature K_{IR} can be found from the Code.
3. The stress intensity factor is determined based on the membrane and bending stresses, and the appropriate correction factors. Additional determinants include the wall thickness and normal stress to yield strength ratio of the material.
4. The calculated stress intensity is compared to K_{IR} .

The ASME Code, Section XI provides a procedure to evaluate flaw indications found during in-service inspection of nuclear reactor coolant systems. If an indication is smaller than certain limits set by Section XI, it is considered acceptable without further analysis. If the indication is larger than these limits, Section XI provides information that enables the following procedure for further evaluation:

1. Determine the size, location and orientation of the flaw by NDE.
2. Determine the applied stresses at the flaw location (calculated without the flaw present) for all normal (including upset), emergency and faulted conditions.
3. Calculate the stress intensity factors for each of the loading conditions.
4. Determine the necessary material properties, including the effects of irradiation. A reference temperature shift procedure is used to normalize the lower bound toughness versus temperature curves. These curves are based on crack arrest and static initiation values from fracture toughness tests. The temperature shift procedure accounts for heat to heat variation in material toughness properties.
5. Using the procedures above, as well as a procedure for calculating cumulative fatigue crack growth, three critical flaw parameters are determined:
 - a_f = maximum size to which the detected flaw can grow during the remaining service of the component
 - a_{crit} = maximum critical size of the detected flaw under normal conditions
 - a_{init} = maximum critical size for nonarresting growth initiation of the observed flaw under emergency and faulted conditions

Fig. 11 Types of cracks.

6. Using these critical flaw parameters, determine if the detected flaw meets the following conditions for continued operation:

$$\begin{aligned} a_f &< 0.1 a_{crit} \\ a_f &< 0.5 a_{init} \end{aligned} \quad (43)$$

Elastic-plastic fracture mechanics (EPFM) LEFM provides a one parameter failure criterion in terms of the crack tip stress intensity factor (K_I), but is limited to analyses where the plastic region surrounding the crack tip is small compared to the overall component dimensions. As the material becomes more ductile and the structural response becomes nonlinear, the LEFM approach loses its accuracy and eventually becomes invalid.

A direct extension of LEFM to EPFM is possible by using a parameter to characterize the crack tip region that is not dependent on the crack tip stress. This parameter, the path independent J -integral, can characterize LEFM, EPFM, and fully plastic fracture mechanics. It is capable of characterizing crack initiation, growth, and instability. The J -integral is a measure of the potential energy rate of change for nonlinear elastic structures containing defects.

The J -integral can be calculated from stresses around a crack tip using nonlinear finite element analysis. An alternate approach is to use previously calculated deformation plasticity solutions in terms of the J -integral from the Electric Power Research Institute (EPRI) *Elastic-Plastic Fracture Analysis Handbook*.⁴

The onset of crack growth is predicted when:

$$J_I \geq J_{IC} \quad (44)$$

The material property J_{IC} is obtained using American Society for Testing and Materials (ASTM) test E813-89, and J_I is the calculated structural response.

Stable crack growth occurs when:

$$J_I(a, P) = J_R(\Delta a)$$

and

$$a = a_o + \Delta a \quad (45)$$

where

- a = current crack size
- P = applied remote load
- $J_R(\Delta a)$ = material crack growth resistance (ASTM test standard E1152-87)
- Δa = change in crack size
- a_o = initial crack size

For crack instability, an additional criterion is:

$$\partial J / \partial a \geq \partial J_R / \partial a \quad (46)$$

Failure assessment diagrams Failure assessment diagrams are tools for the determination of safety margins, prediction of failure or plastic instability and leak-before-break analysis of flawed structures. These diagrams recognize both brittle fracture and net section collapse mechanisms. The failure diagram (see Fig. 12) is a safety/failure plane defined by the stress intensity factor/toughness ratio (K_r) as the ordinate and the applied stress/net section plastic collapse stress ratio (S_r) as the abscissa. For a fixed applied stress and defect size, the coordinates K_r , S_r are readily calculable. If the assessment point denoted by these coordinates lies inside the failure assessment curve, no crack growth can occur. If the assessment point lies outside the curve, unstable crack growth is predicted. The distance of the assessment point from the failure assessment curve is a measure of failure potential of the flawed structure.

In a leak-before-break analysis, a through-wall crack is postulated. If the resulting assessment point lies inside the failure assessment curve, the crack will leak before an unstable crack growth occurs.

The deformation plasticity failure assessment diagram (DPFAD)⁵ is a specific variation of a failure assessment diagram. DPFAD follows the British PD 6493 R-6⁶ format, and incorporates EPFM deformation plasticity J -integral solutions. The DPFAD curve is determined by normalizing the deformation plasticity J -

Fig. 12 Deformation plasticity failure assessment diagram in terms of stable crack growth.

integral response of the flawed structure by its elastic response. The square root of this ratio is denoted by K_r . The S_r coordinate is the ratio of the applied stress to the net section plastic collapse stress. Various computer programs are available which automate this process for application purposes.

Subcritical crack growth Subcritical crack growth refers to crack propagation due to cyclic fatigue, stress corrosion cracking, creep crack growth or a combination of the three. Stress corrosion cracking and creep crack growth are time based while fatigue crack growth is based on the number of stress cycles.

Fatigue crack growth Metal fatigue, although studied for more than 100 years, continues to plague structures subjected to cyclic stresses. The traditional approach to prevent fatigue failures is to base the allowable fatigue stresses on test results of carefully made laboratory specimens or representative structural components. These results are usually presented in cyclic stress versus cycles to failure, or σ/N , curves.

The significant events of metal fatigue are crack initiation and subsequent growth until the net section yields or until the stress intensity factor of the structure exceeds the material resistance to fracture. Traditional analysis assumes that a structure is initially crack free. However, a structure can have cracks that originate during fabrication or during operation. Therefore, fatigue crack growth calculations are required to predict the service life of a structure.

Fatigue crack growth calculations can 1) determine the service life of a flawed structure that (during its lifetime) undergoes significant in-service cyclic loading, or 2) determine the initial flaw size that can be tolerated prior to or during a specified operating period of the structure.

The most useful way of presenting fatigue crack growth rates is to consider them as a function of the stress intensity difference, ΔK , which is the difference between the maximum and minimum stress intensity factors.

To calculate fatigue crack growth, an experimentally determined curve such as Fig. 13 is used. The vertical axis, da/dN , is the crack growth per cycle. ASME Code, Section XI contains similar growth rate curves for pressure vessel steels.

Creep crack growth Predicting the remaining life of fossil power plant components from creep rupture data alone is not reliable. Cracks can develop at critical locations and these cracks can then propagate by creep crack growth.

At temperatures above 800F (427C), creep crack growth can cause structural components to fail. Operating temperatures for certain fossil power plant components range from 900 to 1100F (482 to 593C). At these temperatures, creep deformation and crack growth become dependent on strain rate and time exposure. Macroscopic crack growth in a creeping material occurs by nucleation and joining of microcavities in the highly strained region ahead of the crack tip. In time dependent fracture mechanics (TDFM), the energy release rate (power) parameter C_t correlates⁷ creep crack growth through the relationship:

$$da/dt = bC_t^q \quad (47)$$

By using the energy rate definition, C_t can be determined experimentally from test specimens. The constants b and q are determined by a curve fit technique. Under steady-state creep where the crack tip stresses no longer change with time, the crack growth can be characterized solely by the path independent energy rate line integral C^* , analogous to the J -integral.

C^* and C_t can both be interpreted as the difference in energy rates (power) between two bodies with incrementally differing crack lengths. Furthermore, C^* characterizes the strength of the crack tip stress singularity in the same manner as the J -integral characterizes the elastic-plastic stress singularity.

The fully plastic deformation solutions from the EPRI *Elastic-Plastic Fracture Handbook* can then be used to estimate the creep crack tip steady-state parameter, C^* .

Significant data support C_t as a parameter for correlating creep crack growth behavior represented by Equation 47. An approximate expression⁸ for C_t is as follows:

$$C_t = C^* \left[(t_T / t)^{\frac{n-3}{n-1}} + 1 \right] \quad (48)$$

where t_T is the transition time given by:

$$t_T = \frac{(1 - \mu^2) K_I^2}{(n+1) E C^*} \quad (49)$$

and μ is Poisson's ratio, and n is the secondary creep rate exponent.

For continuous operation, Equation 48 is integrated over the time covering crack growth from the initial flaw size to the final flaw size. The limiting final flaw size is chosen based on fracture toughness or instability considerations, possibly governed by cold startup conditions. For this calculation, fracture toughness data such as K_{IC} , J_{IC} or the J_R curve would be used in a failure assessment diagram approach to determine the limiting final flaw size.

Construction features

All pressure vessels require construction features such as fluid inlets and outlets, access openings, and structural attachments at support locations. These shell areas must have adequate reinforcement and gradual geometric transitions which limit local stresses to acceptable levels.

Openings Openings are the most prevalent construction features on a vessel. They can become areas of weakness and may lead to unacceptable local distortion, known as bell mouthing, when the vessel is pressurized. Such distortions are associated with high local membrane stresses around the opening. Analytical studies have shown that these high stresses are confined to a distance of approximately one hole diameter, d , along the shell from the axis of the opening and are limited to a distance of $0.37 (dt_{\text{nozzle}})^{1/2}$ normal to the shell.

Reinforcement to reduce the membrane stress near an opening can be provided by increasing the vessel

wall thickness. An alternate, more economical stress reduction method is to thicken the vessel locally around the nozzle axis of symmetry. The reinforcing material must be within the area of high local stress to be effective.

The ASME Code provides guidelines for reinforcing openings. The reinforcement must meet requirements for the amount and distribution of the added material. A relatively small opening [approximately $d < 0.2 (Rt_s)^{1/2}$ where R is mean radius of shell and t_s is thickness of shell] remote from other locally stressed areas does not require reinforcement.

Larger openings are normally reinforced as illustrated in Figs. 14a and 14b. It is important to avoid excessive reinforcement that may result in high secondary stresses. Fig. 14c shows an opening with over reinforcement and Fig. 14a shows one with well proportioned reinforcement. Fig. 14b also shows a balanced design that minimizes secondary stresses at the nozzle/shell juncture. Designs a and b, combined with generous radii r , are most suitable for cyclic load applications.

The *ligament efficiency* method is also used to compensate for metal removed at shell openings. This method considers the load carrying ability of an area between two points in relation to the load carrying ability of the remaining ligament when the two points become the centers of two openings. The ASME Code guidelines used in this method only apply to cylindri-

Fig. 13 Relationship between da/dN and ΔK as plotted on logarithmic coordinates.

cal pressure vessels where the circumferential stress is twice the longitudinal stress. In determining the thickness of such vessels, the allowable stress in the thickness calculation is multiplied by the ligament efficiency.

Nozzle and attachment loadings When external loadings are applied to nozzles or attachment components, local stresses are generated in the shell. Several types of loading may be applied, such as sustained, transient and thermal expansion flexibility loadings. The local membrane stresses produced by such loadings must be limited to avoid unacceptable distortion due to a single load application. The combination of local membrane and bending stresses must also be limited to avoid incremental distortion under cyclic loading.

Fig. 14 Nozzle opening reinforcements.

Finally, to prevent cyclic load fatigue failures, the nozzle or attachment should include gradual transitions which minimize stress concentrations.

Pressure vessels may require local thickening at nozzles and attachments to avoid yielding or incremental distortion due to the combined effects of external loading, internal pressure, and thermal loading. Simple procedures to determine such reinforcement are not available, however FEA methods can be used. The Welding Research Council (WRC) Bulletin No. 107 also provides a procedure for determining local stresses adjacent to nozzles and rectangular attachments on cylindrical and spherical shells.

The external loadings considered by the WRC are longitudinal moment, transverse moment, torsional moment, and axial force. Stresses at various inside and outside shell surfaces are obtained by combining the stresses from the various applied loads. These external load stresses are then combined with internal pressure stresses and compared with allowable stress limits.

Use of the WRC procedure is restricted by limitations on shell and attachment parameters; however, experimental and theoretical work continues in this area.

Structural support components

Pressure vessels are normally supported by saddles, cylindrical support skirts, hanger lugs and brackets, ring girders, or integral support legs. A vessel has concentrated loads imposed on its shell where these supports are located. Therefore, it is important that the support arrangements minimize local stresses in the vessel. In addition, the components must provide support for the specified loading conditions and withstand corresponding temperature requirements.

Design criteria

Structural elements that provide support, stiffening, and/or stabilization of pressure vessels or components may be directly attached by welding or bolting. They can also be indirectly attached by clips, pins, or clamps, or may be completely unattached thereby transferring load through surface bearing and friction.

Loading conditions In general, loads applied to structural components are categorized as dead, live, or transient loads. Dead loads are due to the force of gravity on the equipment and supports. Live loads vary in magnitude and are applied to produce the maximum design conditions. Transient loads are time dependent and are expected to occur randomly for the life of the structural components. Specific loadings that are considered in designing a pressure component support include:

1. weight of the component and its contents during operating and test conditions, including loads due to static and dynamic head and fluid flow,
2. weight of the support components,
3. superimposed static and thermal loads induced by the supported components,
4. environmental loads such as wind and snow,
5. dynamic loads including those caused by earthquake, vibration, or rapid pressure change,
6. loads from piping thermal expansion,

7. loads from expansion or contraction due to pressure, and
8. loads due to anchor settlement.

Code design/analysis requirements Code requirements for designing pressure part structural supports vary. The ASME Code, Section I, only covers pressure part attaching lugs, hangers or brackets. These must be properly fitted and must be made of weldable and comparable quality material. Only the weld attaching the structural member to the pressure part is considered within the scope of Section I. Prudent design of all other support hardware is the manufacturer's responsibility.

The ASME Code, Section VIII, Division 1, does not contain design requirements for vessel supports; however, suggested rules of good practice are presented. These rules primarily address support details which prevent excessive local shell stresses at the attachments. For example, horizontal pressure vessel support saddles are recommended to support at least one third of the shell circumference. Rules for the saddle design are not covered. However, the Code refers the designer to the *Manual of Steel Construction*, published by the American Institute of Steel Construction (AISC). This reference details the allowable stress design (ASD) method for structural steel building designs. When adjustments are made for elevated temperatures, this specification can be used for designing pressure vessel support components. Similarly, Section VIII, Division 2, does not contain design methods for vessel support components. However, materials for structural attachments welded to pressure components and details of permissible attachment welds are covered.

Section III of the ASME Code contains rules for the material, design, fabrication, examination, and installation of certain pressure component and piping supports. The supports are placed within three categories:

1. plate and shell type supports, such as vessel skirts and saddles, which are fabricated from plate and shell elements,
2. linear supports which include axially loaded struts, beams and columns, subjected to bending, and trusses, frames, rings, arches and cables, and
3. standard supports (catalog items) such as constant and variable type spring hangers, shock arresters, sway braces, vibration dampers, clevises, etc.

The design procedures for each of these support types are:

1. design by analysis including methods based on maximum shear stress and maximum stress theories,
2. experimental stress analysis, and
3. load rating by testing full size prototypes.

The analysis required for each type of support depends on the class of the pressure component being supported.

Typical support design considerations

Design by analysis involves determining the stresses in the structural components and their connections by accepted analysis methods. Unless specified in an

applicable code, choosing the analysis method is the designer's prerogative. Linear elastic analysis (covered in depth here), using the maximum stress or maximum shear stress theory, is commonly applied to plate, shell type and linear type supports. As an alternate, the method of limit (plastic) analysis can be used for framed linear structures when appropriate load adjustment factors are applied.

Plate and shell type supports Cylindrical shell skirts are commonly used to support vertical pressure vessels. They are attached to the vessel with a minimum offset in order to reduce local bending stresses at the vessel skirt junction. This construction also permits radial pressure and thermal growth of the supported vessel through bending of the skirt. The length of the support is chosen to permit this bending to occur safely. See Fig. 15 for typical shell type support skirt details.

In designing the skirt, the magnitudes of the loads that must be supported are determined. These normally include the vessel weight, the contents of the vessel, the imposed loads of any equipment supported from the vessel, and loads from piping or other attachments. Next a skirt height is set and the forces and moments at the skirt base, due to the loads applied, are determined. Treating the cylindrical shell as a beam, the axial stress in the skirt is then determined from:

$$\sigma = \frac{-P_v}{A} \pm \frac{Mc}{I} \quad (50)$$

where

- σ = axial stress in skirt
- P_v = total vertical design load
- A = cross-sectional area
- M = moment at base due to design loads
- c = radial distance from centerline of skirt
- I = moment of inertia

For thin shells ($R/t > 10$), the equation for the axial stress becomes:

$$\sigma = \frac{-P_v}{2\pi R t} \pm \frac{M}{\pi R^2 t} \quad (51)$$

where

- R = mean radius of skirt
- t = thickness of skirt

Because the compressive stress is larger than the tensile stress, it usually controls the skirt design. Using the maximum stress theory for this example, the skirt thickness is obtained by:

$$t = \frac{P_v}{2\pi R F_A} + \frac{M}{\pi R^2 F_A} \quad (52)$$

where

- F_A = allowable axial compressive stress

The designer must also consider stresses caused by transient loadings such as wind or earthquakes. Finally, skirt connections at the vessel and support base must be checked for local primary and secondary

Fig. 15 Support skirt details.²

bending stresses. The consideration of overall stress levels provides the most accurate design.

Local thermal bending stresses often occur because of a temperature difference between the skirt and support base. The magnitudes of these bending stresses are dependent upon the severity of this axial thermal gradient; steeper gradients promote higher stresses. To minimize these stresses, the thermal gradient at the junction can be reduced by full penetration welds at the skirt to shell junction, which permit maximum conduction heat flow through the metal at that point, and by selective use of insulation in the crotch region to permit heat flow by convection and radiation. Depending on the complexity of the attachment detail, the discontinuity stress analysis or the linear elastic finite element method is used to solve for the thermal bending stresses.

Linear type supports Utility fossil fuel-fired steam generators contain many linear components that support and reinforce the boiler pressure parts. For example, the furnace enclosure walls, which are constructed of welded membraned tube panels, must be reinforced by external structural members (buckstays) to resist furnace gas pressure as well as wind and seismic forces. (See Chapter 23.) Similarly, chambers, such as the burner equipment enclosure (windbox), require internal systems to support the enclosure and its contents as well as to reinforce the furnace walls. The design of these structural systems is based on linear elastic methods using maximum stress theory allowable limits.

The buckstay system is typically comprised of horizontally oriented beams or trusses which are attached

to the outside of the furnace membraned vertical tube walls. As shown in Fig. 16, the buckstay ends are connected to tie bars that link them to opposing wall buckstays thereby forming a self-equilibrating structural system. The furnace enclosure walls are continuously welded at the corners creating a water-cooled, orthotropic plate, rectangular pressure vessel. The strength of the walls in the horizontal direction is considerably less than in the vertical direction, therefore the buckstay system members are horizontally oriented.

The buckstay spacing is based on the ability of the enclosure walls to resist the following loads:

1. internal tube design pressure (P),
2. axial dead loads (DL),
3. sustained furnace gas pressure (PL_s),
4. transient furnace gas pressure (PL_T),
5. wind loads (WL), and
6. seismic loads (EQ).

The buckstay elevations are initially established based on wall stress checks and on the location of necessary equipment such as sootblowers, burners, access doors, and observation ports. These established buckstay elevations are considered as horizontal supports for the continuous vertical tube wall. The wall is then analyzed for the following load combinations using a linear elastic analysis method:

1. $DL + PL_s + P$,
2. $DL + PL_s + WL + P$,
3. $DL + PL_s + EQ + P$, and
4. $DL + PL_T + P$.

Buckstay spacings are varied to assure that the wall stresses are within allowable design limits. Additionally, their locations are designed to make full use of the structural capability of the membraned walls.

The buckstay system members, their end connections, and the wall attachments are designed for the maximum loads obtained from the wall analysis. They are designed as pinned end bending members according to the latest AISC ASD specification. This specification is modified for use at elevated temperatures and uses safety factors consistent with ASME Code, Sections I and VIII. The most important design considerations for the buckstay system include:

1. stabilization of the outboard beam flanges or truss chords to prevent lateral buckling when subjected to compression stress,
2. the development of buckstay to tie bar end connections and buckstay to wall attachments that provide load transfer but allow differential expansion between connected elements, and
3. providing adequate buckstay spacing and stiffness to prevent resonance due to low frequency combustion gas pressure pulsations common in fossil fuel-fired boilers.

Fig. 16 Typical buckstay elevation, plan view.

Section II

Steam Generation from Chemical Energy

This section containing 17 chapters applies the fundamentals of steam generation to the design of boilers, superheaters, economizers and air heaters for steam generation from chemical or fossil fuels (coal, oil and natural gas). As discussed in Chapter 1, the fuel and method of combustion have a dramatic impact on the size and configuration of the steam producing system. Therefore, Chapters 9 and 10 begin the section by exploring the variety and characteristics of chemical and fossil fuels, and summarize the combustion calculations that are the basis for system design.

The variety of combustion systems available to handle these fuels and the supporting fuel handling and preparation equipment are then described in Chapters 11 through 18. These range from the venerable stoker in its newest configurations to circular burners used for pulverized coal, oil and gas, to fluidized-bed combustion and coal gasification. A key element in all of these systems is the control of atmospheric emissions, in particular oxides of nitrogen (NO_x) which are byproducts of the combustion process. Combustion NO_x control is discussed as an integral part of each system. It is also discussed in Section IV, Chapter 34.

Based upon these combustion systems, Chapters 19 through 22 address the design and performance evaluation of the major steam generator heat transfer components: boiler, superheater, reheater, economizer and air heater. These are configured around the combustion system selected with special attention to properly handling the high temperature, often particle-laden flue gas. The fundamentals of heat transfer, fluid dynamics, materials science and structural analysis are combined to provide the tradeoffs necessary for an economical steam generating system design. The boiler setting and auxiliary equipment, such as sootblowers, ash handling systems and fans, which are key elements in completing the overall steam system, conclude this section in Chapters 23 through 25.

Chapter 9

Sources of Chemical Energy

World energy consumption continues to grow with the primary resources being the fossil fuels. Between 1991 and 2000, world production of primary energy increased at an annual rate of 1.4%. Production of primary energy increased from 351×10^{15} Btu (370×10^{18} J) in 1991 to 397×10^{15} Btu (419×10^{18} J) in 2000. The trend in energy production by source from 1970 to 2000 is shown in Fig. 1. World energy production and fossil fuel reserves by region are shown in Figs. 2 and 3.

The United States (U.S.), former Soviet Union (FSU) and China were the leading producers and consumers of world energy in 2000. They produced 38% and consumed 41% of the world's energy. Energy use in the developing world is expected to continue to increase with demand in developing Asia and Central and South America more than doubling between 1999 and 2020. Projected world energy consumption through the year 2025 is shown in Fig. 4.

Annual energy production in the U.S. rose to 71.6×10^{15} Btu (75.5×10^{18} J) in 2000, which is about 18% of world production. Approximately 81% of this energy is in the form of fossil fuels. U.S. energy production by source is given in Fig. 5.

The relative U.S. production of coal compared to other fossil fuels has increased since 1976, when 26% was coal, 29% was crude oil and 33% was natural gas. In 1999, coal production accounted for 32%, crude oil was 17% and natural gas was 28%. Coal production

Fig. 1 Trends in world energy production by source (NGL = natural gas liquids).

Fig. 2 World primary energy production by region, 2001.

for 1999 and 2000 represented the first time in forty years that production declined for two consecutive years. On an annual basis, the average utility price per ton of coal delivered to utilities dropped by 1.8% in 2000, continuing a downward trend started in 1978.

Overall energy consumption in the U.S. was approximately 99×10^{15} Btu (104×10^{18} J) in 2000. About 28% of this energy was consumed by electric utilities in the form of fossil fuels.

Overall U.S. fossil fuel consumption continues to increase and grew to 84×10^{15} Btu (88.6×10^{18} J) in 2000. In spite of the decline in the cost of crude oil in the 1980s, it continues to be the most dominant and costly fuel in the fossil fuel mix. The trends in coal, oil and natural gas prices are given in Fig. 6.

World availability of coal

Coal is the second leading source of fuel, supplying 23% of the world's primary energy in 2000. It is also the most used fossil fuel for utility and industrial power gen-

Fig. 3 Fossil fuel reserves by world region.

eration. Major reserves by coal type and location are lignite in the U.S. and the former Soviet Union (FSU); sub-bituminous in China, the FSU, Australia and Germany; and bituminous in China, the U.S. and the FSU.

Reserves of coal by regions of the world are given in Fig. 3. Of those regions, China consumed the most (25%) in 2000, followed by the U.S. (21%) and the FSU (9%). Because of its worldwide availability and low price, the demand for coal has grown and world coal trade has expanded by about 40% since 1980. The largest coal exporters are Australia, China, Indonesia, South Africa, the U.S., Canada, the FSU and Poland.¹

U.S. availability of coal

The coal reserves of the U.S. constitute a vast energy resource, accounting for about 25% of the world's total recoverable coal.² According to the Energy Information Administration (EIA), the national estimate of the Demonstrated Reserve Base coal resources remaining as of 2002, is 498 billion short tons. Reserves that are likely to be mined are estimated at 275×10^9 t (249

Fig. 4 World primary energy consumption by fuel.¹

$\times 10^9$ t_m).³ The U.S. produced 1.074×10^9 t (0.974×10^9 t_m) of coal in 2000. Fig. 7 summarizes U.S. production from 1978 to 2000. U.S. coal consumption has steadily increased from 0.7 billion short tons in 1980 to 1.05 billion in 1999. The states with the largest coal reserves in the ground as of January, 2000, are shown in Table 1.⁴ States with large reserves, such as Montana and Illinois, do not necessarily rank as high in production as Wyoming, Kentucky or West Virginia.

Because of the resulting sulfur dioxide (SO₂) emissions, coal sulfur levels are important production criteria and have been a factor in the growth of production from the western region, particularly the Powder River Basin. Table 2 shows the distribution of coal reserves by state at various sulfur levels.

Coal fields in the U.S. are shown in Fig. 8. The two largest producing regions are the western region consisting of Arizona, Colorado, Montana, New Mexico, North Dakota, Utah, Washington, and Wyoming and the Appalachian region including Pennsylvania, West Virginia, Ohio, western Maryland, eastern Kentucky, Virginia, Tennessee and Alabama. In 2000, these regions produced 510.7×10^6 t (463×10^6 t_m) and 419×10^6 t (380×10^6 t_m), respectively. Two-thirds of the re-

Fig. 5 U.S. energy production by source, 2002.

Fig. 6 Trends in U.S. fossil fuel prices.

Fig. 7 U.S. coal production trends.

serves lie in the Great Plains, the Rocky Mountains and the western states. These coals are mostly subbituminous and lignitic, which have low sulfur content. Therefore, these fields have been rapidly developed to meet the increasing demands of electric utilities. The low sulfur coal permits more economical conformance to the Federal Clean Air Act, its Amendments, and acid rain legislation. (See Chapter 32.)

U.S. electric utilities used coal to generate 51% of the net electrical power in 2000, and remain the largest coal consumers. Continuing the downward trend since 1982, the average delivered cost of coal decreased 27% in current dollars per million Btu.

Environmental concerns about SO_2 , nitrogen oxides (NO_x), carbon dioxide (CO_2) and mercury (Hg) emissions could limit the growth of coal consumption. However, the U.S., as well as Japan and several European countries, is researching clean coal technologies to reduce these emissions while boosting power production efficiency. These technologies are rapidly approaching commercialization in the U.S. They are expected to be integrated into current and future power plants.

How coal is formed

Coal is formed from plants by chemical and geological processes that occur over millions of years. Layers of plant debris are deposited in wet or swampy regions under conditions that prevent exposure to air and complete decay as the debris accumulates. Bacterial action, pressure and temperature act on the organic matter over time to form coal. The geochemical process that transforms plant debris to coal is called *coalification*. The first product of this process, peat, often contains partially decomposed stems, twigs, and bark

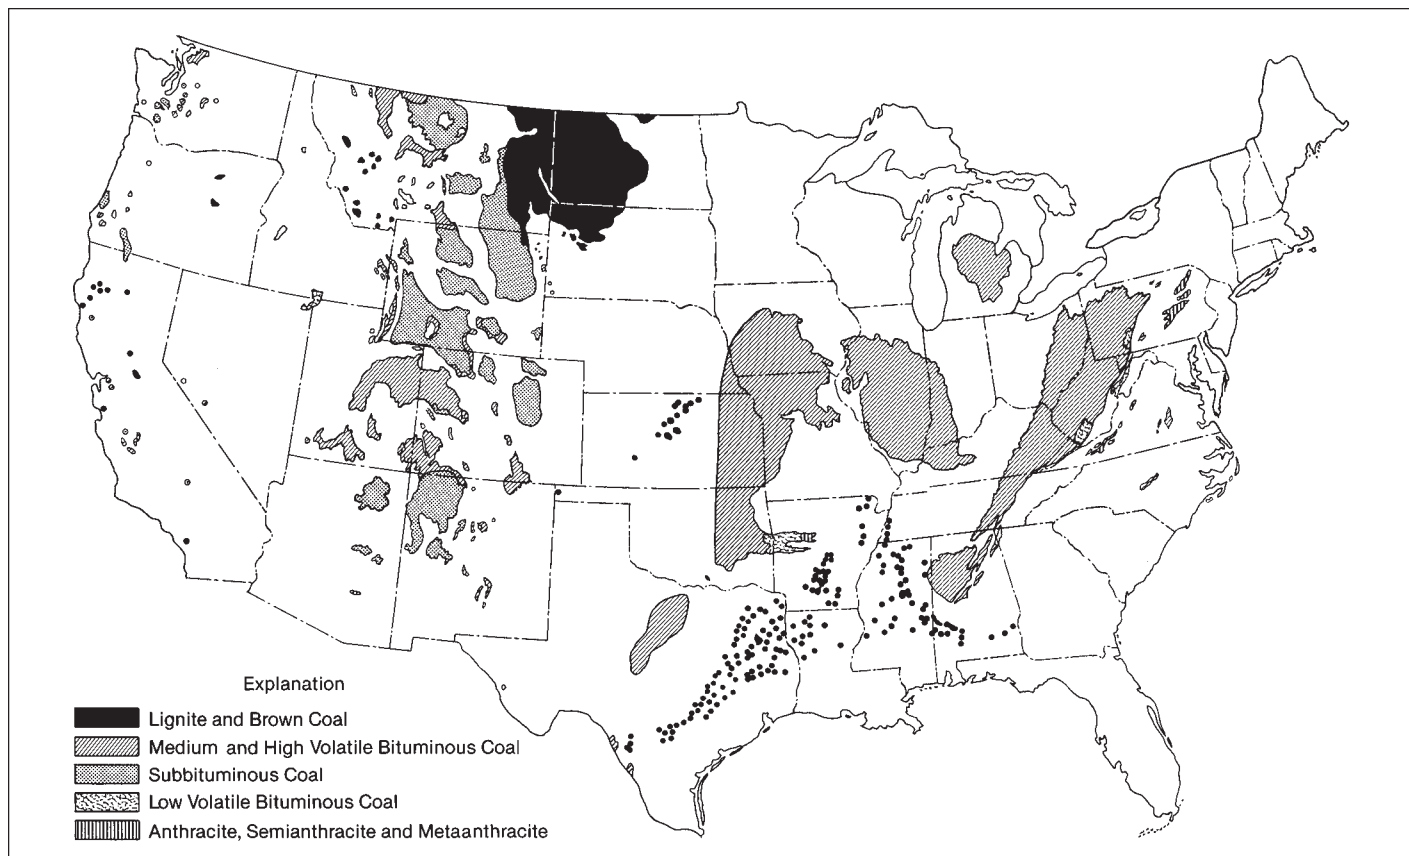

Fig. 8 U.S. coal reserves.

and is not classified as coal. However, peat is progressively transformed to lignite that eventually can become anthracite, given the proper progression of geological changes.

Various physical and chemical processes occur during coalification. The heat and pressure to which the organic material is exposed cause chemical and structural changes. These changes include an increase in carbon content; loss of water, oxygen and hydrogen; and resistance to solvents. The coalification process is shown schematically in Fig. 9.

Coal is very heterogeneous and can vary in chemical composition by location. In addition to the major organic ingredients (carbon, hydrogen and oxygen), coal also contains impurities. The impurities that are of major concern are ash and sulfur. The ash results from mineral or inorganic material introduced during coalification. Ash sources include inorganic substances, such as silica, that are part of the chemical structure of the plants. Dissolved inorganic ions and mineral grains found in swampy water are also captured by the organic matter during early coalification. Mud, shale and pyrite are deposited in pores and cracks of the coal seams.

Sulfur occurs in coal in three forms: 1) organic sulfur, which is part of the coal's molecular structure, 2) pyritic sulfur, which occurs as the mineral pyrite, and 3) sulfate sulfur, primarily from iron sulfate. The principal sulfur source is sulfate ion, found in water. Fresh water has a low sulfate concentration while salt water has a high sulfate content. Therefore, bituminous

coal, deposited in the interior of the U.S. when seas covered this region, are high in sulfur. Some Iowa coals contain as much as 8% sulfur.

Although coal is a complex, heterogeneous mixture and not a polymer or biological molecule, it is sometimes useful for chemists to draw an idealized structural formula. These formulas can serve as models that illustrate coal reactions. This can aid the further development of coal processes such as gasification, combustion and liquefaction.

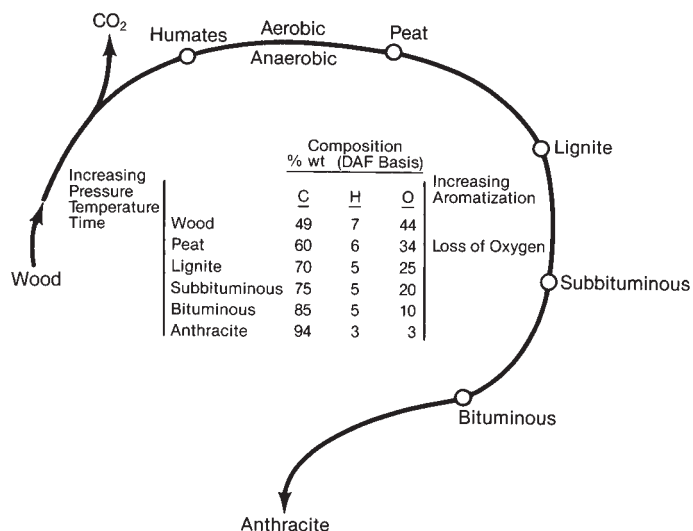

Fig. 9 The coalification process (DAF = dry ash-free).

Classifying coal

A coal classification system is needed because coal is a heterogeneous substance with a wide range of composition and properties. Coals are typically classified by rank. This indicates the progressive alteration in the coalification process from lignite to subbituminous, bituminous and anthracite coals. The rank indicates a coal's geological history and broad characteristics.

ASTM classification by rank

The system used in the U.S. for classifying coal by rank was established by the American Society for Testing and Materials (ASTM).⁵ ASTM classification is a system that uses the volatile matter (VM) and fixed carbon (FC) results from the proximate analysis and the heating value of the coal as ranking criteria. This system aids in identifying commercial uses of coals and provides basic information regarding combustion characteristics.

The classification system is given in Table 3 and described in section D 388 of the ASTM standards. Proximate analysis is based on the laboratory procedure described in ASTM D 3172. In this procedure,

moisture content, ash remaining after complete burning, amount of gases released when heated to a prescribed temperature, and fixed carbon remaining after volatilization are determined.

Table 4 gives a typical as-received proximate analysis of a West Virginia coal. An as-received analysis includes the total moisture content of the coal as it is received at the power plant.

For older or higher rank coals, FC and VM are used as the classifying criteria. These criteria are determined on a dry, mineral-matter-free basis using formulas developed by S.W. Parr in 1906 (shown in Equations 1 through 6).⁶ The younger or low rank coals are classified by Btu content on a moist, mineral-matter-free basis. Agglomerating or weathering indices, as described in ASTM D 388, are used to differentiate adjacent groups.

Parr Formulas

Dry, mineral-free FC =

$$\frac{FC - 0.15 S}{100 - (M + 1.08A + 0.55 S)} \times 100, \% \quad (1)$$

Table 3
Classification of Coals by Rank^a (ASTM D 388)

Class	Group	Fixed Carbon	Volatile Matter		Calorific Value		Agglomerating Character	
		Limits, %	Limits, %		Limits, Btu/lb			
		(Dry, Mineral- Matter-Free Basis)	(Dry, Mineral- Matter-Free Basis)	(Moist, ^b Mineral-Matter- Free Basis)	(Moist, ^b Mineral-Matter- Free Basis)			
		Equal or Greater Than	Less Than	Greater Than	Equal or Less Than	Equal or Greater Than	Less Than	
I. Anthracitic	1. Meta-anthracite	98	—	—	2	—	—	} Nonagglomerating
	2. Anthracite	92	98	2	8	—	—	
	3. Semianthracite ^c	86	92	8	14	—	—	
II. Bituminous	1. Low volatile bituminous coal	78	86	14	22	—	—	} Commonly agglomerating ^e
	2. Medium volatile bituminous coal	69	78	22	31	—	—	
	3. High volatile A bituminous coal	—	69	31	—	14,000 ^d	—	
	4. High volatile B bituminous coal	—	—	—	—	13,000 ^d	14,000	
	5. High volatile C bituminous coal	—	—	—	—	{ 11,500 10,500 ^e	{ 13,000 11,500	
III. Subbituminous	1. Subbituminous A coal	—	—	—	—	10,500	11,500	} Nonagglomerating
	2. Subbituminous B coal	—	—	—	—	9,500	10,500	
	3. Subbituminous C coal	—	—	—	—	8,300	9,500	
IV. Lignitic	1. Lignite A	—	—	—	—	6,300	8,300	} Nonagglomerating
	2. Lignite B	—	—	—	—	—	6,300	

^aThis classification does not include a few coals, principally nonbanded varieties, which have unusual physical and chemical properties and which come within the limits of fixed carbon or calorific value of the high volatile bituminous and subbituminous ranks. All of these coals either contain less than 48% dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu/lb.

^bMoist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal.

^c If agglomerating, classify in low volatile group of the bituminous class.

^d Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of calorific value.

^e It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in high volatile C bituminous group.

Table 4
Coal Analyses on As-Received Basis
(Pittsburgh Seam Coal, West Virginia)

Proximate Analysis		Ultimate Analysis	
Component	% by wt	Component	% by wt

 S = sulfur, %

all for coal on a moist basis.

Table 5 lists 16 selected U.S. coals, arranged in order of ASTM classification. The following descriptions briefly summarize the characteristics of each coal rank.

Peat Peat, the first product in the formation of coal, is a heterogeneous material consisting of partially decomposed plant and mineral matter. Its color ranges from yellow to brownish-black, depending on its geologic age. Peat has a moisture content up to 70% and a heating value as low as 3000 Btu/lb (6978 kJ/kg).

Lignite Lignite is the lowest rank coal. Lignites are

relatively soft and brown to black in color with heating values of less than 8300 Btu/lb (19,306 kJ/kg). The deposits are geologically young and can contain recognizable remains of plant debris. The moisture content of lignites is as high as 30% but the volatile content is also high; consequently, they ignite easily. Lignite coal dries when exposed to air and spontaneous combustion during storage is a concern. Long distance shipment of these coals is usually not economical because of their high moisture and low Btu content. The largest lignite deposit in the world spreads over the regions of North and South Dakota, Wyoming, and Montana in the U.S. and parts of Saskatchewan and Manitoba in Canada.

Subbituminous Subbituminous coals are black, having little of the plant-like texture and none of the brown color associated with the lower rank lignite coal. Subbituminous coals are non-coking (undergo little swelling upon heating) and have a relatively high moisture content which averages from 15 to 30%. They also display a tendency toward spontaneous combustion when drying.

Although they are high in VM content and ignite easily, subbituminous coals generally have less ash and are cleaner burning than lignite coals. Subbituminous coals in the U.S. in general have a very low sulfur content, often less than 1%. Because they have reasonably high heating values [8300 to 11,500 Btu/lb (19,306 to 26,749 kJ/kg)] and low sulfur content, switching to subbituminous coal has become an attractive option for many power plants to limit SO₂ emissions.

Bituminous Bituminous coal is the rank most commonly burned in electric utility boilers. In general, it appears black with banded layers of glossy and dull black. Typical bituminous coals have heating values of 10,500 to 14,000 Btu/lb (24,423 to 32,564 kJ/kg) and a fixed carbon content of 69 to 86%. The heating value is higher, but moisture and volatile content are lower than the subbituminous and lignite coals. Bituminous coals rarely experience spontaneous combustion in storage. Furthermore, the high heating value and fairly high volatile content enable bituminous coals to burn easily when pulverized to a fine powder. Some types of bituminous coal, when heated in the absence of air, soften and release volatiles to form the porous, hard, black product known as *coke*. Coke is used as fuel in blast furnaces to make iron.

Anthracite Anthracite, the highest rank of coal, is shiny black, hard and brittle, with little appearance of layers. It has the highest content of fixed carbon, 86 to 98%. However, its low volatile content makes it a slow burning fuel. Most anthracites have a very low moisture content of about 3%; heating values of 15,000 Btu/lb (34,890 kJ/kg) are slightly lower than the best quality bituminous coals. Anthracite is low in sulfur and volatiles and burns with a hot, clean flame. These qualities make it a premium fuel used mostly for domestic heating.

Other classification systems

There are other classifications of coal that are currently in limited use in Europe. These are the International Classification of Hard Coals by Type and the

Table 5
Sixteen Selected U.S. Coals Arranged in Order of ASTM Classification

No.	Coal Rank		State	County	Coal Analysis, Bed Moisture Basis						Rank	Rank

Notes: For definition of Rank Classification according to ASTM requirements, see Table 3.

Data on Coal (Bed Moisture Basis)

M = equilibrium moisture, %; VM = volatile matter, %;
FC = fixed carbon, %; A = ash, %; S = sulfur, %;
Btu = Btu/lb, higher heating value.

Rank FC = dry, mineral-matter-free fixed carbon, %;
Rank Btu = moist, mineral-matter-free Btu/lb.
Calculations by Parr formulas.

International Classification of Brown Coals. These systems were developed by the Coal Committee of the Economic Commission for Europe in 1949.

Coal characterization

As previously described, the criteria for ranking coal are based on its proximate analysis. In addition to providing classifications, coal analysis provides other useful information. This includes assistance in selecting coal for steam generation, evaluation of existing handling and combustion equipment, and input for design. The analyses consist of standard ASTM procedures and special tests developed by The Babcock & Wilcox Company (B&W). The following briefly summarizes some of these tests.

Standard ASTM analyses^{5,7}

Bases for analyses Because of the variability of moisture and ash content in coals, the composition determined by proximate analysis can be reported on several bases. The most common include as-received, moisture-free or dry, and mineral-matter-free. The as-received analysis reports the percentage by weight of each constituent in the coal as it is received at the laboratory. As-received samples contain varying levels of moisture. For analysis on a dry basis, the moisture of the sample is determined and then used to correct each

constituent to a common dry level. As previously mentioned, the ash in coal as determined by proximate analysis is different than the mineral matter in coal. This can cause problems when ranking coals by the ASTM method. Formulas used to correct for the mineral matter and to determine volatile matter, fixed carbon and heating value on a mineral-matter-free basis are provided in Equations 1 to 6 above.

Moisture determination Coal received at an electric power plant contains varying amounts of moisture in several forms. There is *inherent* and *surface* moisture in coal. Inherent moisture is that which is a naturally combined part of the coal deposit. It is held tightly within the coal structure and can not be removed easily when the coal is dried in air. The surface moisture is not part of the coal deposit and has been added externally. Surface moisture is more easily removed from coal when exposed to air. It is not possible to distinguish, by analysis, inherent and surface moisture.

There are many other moistures that arise when characterizing coal including equilibrium, free and air dry moisture. Their definitions and use depend on the application. Equilibrium moisture is sometimes used as an estimate of bed moisture. The ASTM standard terminology of coal and coke, D 121, defines the total coal moisture as the loss in weight of a sample under controlled conditions of temperature, time and air flow. Using ASTM D 3302, the total moisture is calculated

from the moisture lost or gained in air drying and the residual moisture. The residual moisture is determined by oven drying the air dried sample. Because subsequent ASTM analyses (such as proximate and ultimate) are performed on an air dried sample, the residual moisture value is required to convert these results to a dry basis. In addition, the moisture lost on air drying provides an indication of the drying required in the handling and pulverization portions of the boiler coal feed system.

Proximate analysis Proximate analysis, ASTM D 3172, includes the determination of volatile matter, fixed carbon and ash. Volatile matter and fixed carbon, exclusive of the ash, are two indicators of coal rank. The amount of volatile matter in a coal indicates ease of ignition and whether supplemental flame stabilizing fuel is required. The ash content indicates the load under which the ash collection system must operate. It also permits assessing related shipping and handling costs.

Ultimate analysis Ultimate analysis, described in ASTM D 3176, includes measurements of carbon, hydrogen, nitrogen and sulfur content, and the calculation of oxygen content. Used with the heating value of the coal, combustion calculations can be performed to determine coal feed rates, combustion air requirements, heat release rates, boiler performance, and sulfur emissions from the power plant. (See Table 4.)

Heating value The gross calorific value of coal, determined using an adiabatic bomb calorimeter as described in ASTM D 2015, is expressed in Btu/lb (kJ/kg) on various bases (dry, moisture and ash free, etc.).

This value determines the maximum theoretical fuel energy available for the production of steam. Consequently, it is used to determine the quantity of fuel which must be handled, pulverized and fired.

Gross (higher) heating value (HHV) is defined as the heat released from combustion of a unit fuel quantity (mass), with the products in the form of ash, gaseous CO_2 , SO_2 , nitrogen and liquid water, exclusive of any water added as vapor. The net (lower) heating value (LHV) is calculated from the HHV. It is the heat produced by a unit quantity of fuel when all water in the products remains as vapor. This LHV calculation (ASTM Standard D 407) is made by deducting 1030 Btu/lb (2396 kJ/kg) of water derived from the fuel, including the water originally present as moisture and that formed by combustion. In the U.S., the gross calorific value is commonly used in heat balance calculations, while in Europe the net value is generally used.

Grindability The Hardgrove Grindability Test, developed by B&W, is an empirical measure of the relative ease with which coal can be pulverized. The ASTM D 409 method has been used for the past 30 years to evaluate the grindability of coals. The method involves grinding 50 g of air-dried 16×30 mesh (1.18 mm \times 600 μm) test coal in a small ball-and-race mill. The mill is operated for 60 revolutions and the quantity of material that passes a 200 mesh (75 micron) screen is measured. From a calibration curve relating -200 mesh (-75 micron) material to the grindability of standard samples supplied by the U.S. Department of Energy, the Hardgrove Grindability Index (HGI) is determined for the test coal. Pulverizer manufacturers have de-

veloped correlations relating HGI to pulverizer capacity at desired levels of fineness.

Sulfur forms The sulfur forms test, ASTM D 2492, measures the amounts of sulfate sulfur, pyritic sulfur and organically bound sulfur in a coal. This is accomplished by measuring the total sulfur, sulfate, and pyritic sulfur contents and obtaining the organic sulfur by difference. The quantity of pyritic sulfur is an indicator of potential coal abrasiveness.

Free swelling index The free swelling index can be used to indicate caking characteristics. The index is determined by ASTM D 720 which consists of heating a one gram coal sample for a specified time and temperature. The shape of the sample or button formed by the swelling coal is then compared to a set of standard buttons. Larger formed buttons indicate higher free swelling indices. Oxidized coals tend to have lower indices. The free swelling index can be used as a relative measurement of a coal's caking properties and extent of oxidation.

Ash fusion temperatures Coal ash fusion temperatures are determined from cones of ash prepared and heated in accordance with ASTM method D 1857. The temperatures at which the cones deform to specific shapes are determined in oxidizing and reducing atmospheres. Fusion temperatures provide ash melting characteristics and are used for classifying the slagging potentials of the lignitic-type ashes.

Ash composition Elemental ash analysis is conducted using a coal ash sample produced by the ASTM D 3174 procedure. The elements present in the ash are determined and reported as oxides. Silicon dioxide (SiO_2), aluminum oxide (Al_2O_3), titanium dioxide (TiO_2), ferric hydroxide (Fe_2O_3), calcium oxide (CaO), magnesium oxide (MgO), sodium oxide (Na_2O) and potassium oxide (K_2O) are measured using atomic absorption per ASTM D 3682. The results of the ash analyses permit calculations of fouling and slagging indices and slag viscosity versus temperature relationships. The nature, composition and properties of coal ash and their effects on boiler performance are described further in Chapter 21.

Special B&W tests⁷

Burning profiles The burning profile technique was originated by B&W for predicting the relative combustion characteristics of fuels. The technique and application of results were described by Wagoner and Duzy,⁸ and are routinely applied to liquid and solid fuels. The test uses derivative thermogravimetry in which a sample of fuel is oxidized under controlled conditions. A 300 mg sample of solid fuel with a particle size less than 60 mesh (250 microns) is heated at 27F/min (15C/min) in a stream of air. Weight change is measured continuously and the burning profile is the resulting plot of rate of weight loss versus furnace temperature.

Coals with similar burning profiles would be expected to behave similarly in large furnaces. By comparing the burning profile of an unknown coal with that of a known sample, furnace design, residence time, excess air and burner settings can be predicted. In comparing profiles, key information is provided by

the start and completion temperatures of oxidation. The area under the temperature curve is proportional to the amount of combustible material in the sample; the height of the curve is a measure of the combustion intensity. Burning profiles are particularly useful for preliminary evaluations of new boiler fuels such as chars, coal-derived fuels and processed refuse. Fig. 10 shows burning profiles of coals of various ranks.

Abrasiveness index The abrasiveness of coal affects pulverizer grinding element life, and quartz particles in the coal can significantly contribute to its abrasiveness. A procedure for determining a coal's quartz count has been developed at B&W. This procedure consists of burning the coal, collecting and washing the ash to remove acid soluble constituents, and screening to separate size fractions. In each size fraction, 1000 particles are counted and the number of quartz particles is determined by a microscopic technique. From these data, the relative quartz value, an indicator of the coal's relative abrasiveness, is calculated.

Another abrasion index is determined using the Yancey-Geer Price apparatus. In this test, a sample of coal, sized 0.25 in. \times 0 (6.35 mm \times 0), is placed in contact with four metal test samples or *coupons* attached to a rotating shaft. The shaft is rotated at 1440 rpm (150.8 rad/s) for a total of 12,000 revolutions (75,400 rad). The weight loss of the metal coupons is then determined, from which a relative abrasion index is calculated. Indices from the test coals can be compared to those for other fuels. B&W has used the Yancey-Geer Price Index to determine wear in full scale pulverizers. The quartz count procedure and the Yancey-Geer Price procedures can provide some relative information and insight when comparing the abrasiveness of different coals; however, they have limited value in predicting actual field wear rates. (See Chapter 13.)

Erosiveness index Erosion occurs in boilers due to the impact of pulverized particles on burner lines and other components between the pulverizers and burners. The erosiveness test, developed by B&W, subjects a steel coupon to a stream of pulverized coal under controlled conditions. The measured weight loss of the coupon indicates the erosiveness of the coal.

Slag viscosity The viscosity of a coal ash slag is measured at various temperatures under oxidizing and reducing conditions using a high temperature rotational bob viscometer. This viscometer and its application are described in more detail in Chapter 21. The data obtained from slag viscosity measurements are used to predict a coal's slagging behavior in pulverized coal-fired boiler applications. The results also indicate the suitability of a coal for use in B&W's slagging and Cyclone furnaces.

Properties of selected coals

Table 6 gives basic fuel characteristics of typical U.S. coals. The coals are identified by state and rank, and the analytical data include proximate and ultimate analyses and HHVs. Table 7 provides similar fuel properties of coals mined outside the U.S. The source of this information, B&W's Fuels Catalogue, contains more than 10,000 fuel analyses performed and compiled since the 1950s.

Fuels derived from coal

Because of abundant supplies and low prices, the demand for coal as the prime or substitute fuel for utility boilers will most likely continue to increase. In addition, the future use of coal-derived fuels, such as coal refined liquids and gases, coal slurries, and chars, as inexpensive substitutes for oil and natural gas, is also possible. Therefore, methods to obtain clean and efficiently burning fuels derived from coal are continually being investigated. A few of these fuels that apply to steam generation are discussed below.

Coke

When coal is heated in the absence of air or with a large deficiency of air, the lighter constituents are volatilized and the heavier hydrocarbons crack, liberating gases and tars and leaving a residue of carbon. Some of the volatilized portions crack on contact with the hot carbon, leaving an additional quantity of carbon. The carbonaceous residue containing the ash and some of the original coal sulfur is called *coke*. The amount of sulfur and ash in the coke mainly depends on the coal from which it is produced and the coking process used. The principal uses for coke are the production of pig iron in blast furnaces and the charging of iron foundry cupolas. Because it is smokeless when burned, considerable quantities have been used for space heating.

Undersized coke, called *coke breeze*, usually passing a 0.625 in. (15.875 mm) screen, is unsuitable for charging blast furnaces and is often used for steam generation. A typical analysis of coke breeze appears in Table 8. Approximately 4.5% of the coal supplied to slot-type coke ovens is recovered as coke breeze. A portion of the coal tars produced as byproducts of the various coking processes may be burned in equipment similar to that used for heavy petroleum oil.

Gaseous fuels from coal

A number of gaseous fuels are derived from coal as process byproducts or from gasification processes. (See

Fig. 10 Coal burning profiles.

Chapter 18.) Table 9 lists selected analyses of these gases. They have currently been largely supplanted by natural gas and oil. However, improvements in coal gasification and wider use of coal in the chemical and liquid fuel industries could reverse this trend.

Coke oven gas A considerable portion of coal is converted to gases in the production of coke. Valuable products recovered from these gaseous portions include ammonium sulfate, oils and tars. The non-condensable portion is called *coke oven gas*. Constituents depend on the nature of the coal and the coking process used (Table 9).

Part of the sulfur from coal may be present in coke oven gas as hydrogen sulfide and carbon disulfide. These may be removed by scrubbing. Coke oven gas often contains other impurities that deposit in pipelines and burners. The gas burns readily because of its high free hydrogen content and presents minimal problems when used as steam generation fuel.

Blast furnace gas The gas discharged from steel mill blast furnaces is used at the mills in furnaces, in gas engines and for steam generation. Blast furnace gas has variable quality but generally has a high carbon monoxide (CO) content and low heating value (Table 9). This gas may be burned for steam generation. However, blast furnace gas deposits adhere firmly and provisions must be made for cleaning boiler heating surfaces.

Water gas The gas produced by passing steam through a bed of hot coke is known as *water gas*. Carbon in the coke combines with the steam to form H₂ and CO. This is an endothermic reaction that cools the coke bed. Water gas is often enriched with oil by passing the gas through a checkerwork of hot bricks sprayed with oil. The oil, in turn, is cracked to a gas by the heat. Refinery gas is also used for enrichment. It may be mixed with the steam and passed through the coke bed or may be mixed directly with the water gas. Such enriched gas is called *carbureted water gas*.

(Table 9). In many areas, carbureted water gas has been replaced by natural gas.

Producer gas When coal or coke is burned with a deficiency of air and a controlled amount of moisture (steam), a product known as *producer gas* is obtained. This gas, after removal of entrained ash and sulfur compounds, is used near its source because of its low heating value (Table 9).

Byproduct gas from gasification

Coal gasification processes are a source of synthetic natural gas. There are many processes under development. The effluent gas from steam-oxygen coal gasification consists principally of H₂, CO, CH₄, CO₂ and unreacted steam. The gas will also be diluted with N₂ if air is used as the oxygen source. Although the competing chemical reactions that coal undergoes during gasification are complex, they usually include the reaction of steam and carbon to produce H₂ and CO.

Some CH₄ is produced by the reaction of carbon with H₂ and by thermal cracking of the heavy hydrocarbons in the coal. CO₂ and heat needed for the process are produced by reaction of carbon with O₂. Final gas composition is modified by reaction between CO and steam to produce H₂ and CO₂.

The products of coal gasification are often classified as low, intermediate and high Btu gases. Low Btu gas has a heating value of 100 to 200 Btu/SCF (3.9 to 7.9 MJ/Nm³) and is produced by gasification with air rather than oxygen. Typically, the gas is used as a boiler fuel at the gasification plant site or as feed to a turbine in combined cycles. Intermediate Btu gas has a heating value of 300 to 450 Btu/SCF (11.8 to 17.7 MJ/Nm³) and is produced by gasification with oxygen or by a process that produces a nitrogen-free product. The applications of intermediate Btu gas are similar to low Btu gas. High Btu gas has a heating value greater than 900 Btu/SCF (35.4 MJ/Nm³) and is used as a fuel

in place of natural gas. High Btu gas is produced by the same gasification process as intermediate Btu gas and then upgraded by methanation. (See also Chapter 18.)

Fuel oil

One of the most widely accepted theories explaining the origin of oil is the organic theory. Over millions of years, rivers carried mud and sand that deposited and ultimately became sedimentary rock formations. Along with this inorganic material, tiny marine organisms were buried with the silt. Over time, in an airless and high pressure environment, the organic material containing carbon and hydrogen was converted to the hydrocarbon molecules of petroleum (oil). Because of the porosity of sedimentary rock formations, the oil flowed and collected in *traps*, or locations where crude oil is concentrated. This phenomenon greatly assists the economic recovery of crude oil.

Fig. 11 U.S. petroleum end users.

Fuel oil consumption for steam generation accounts for a minor share of U.S. domestic petroleum fuel usage. Industrial users, excluding transportation, account for about 25% of all petroleum use; electric utilities consume about 2% of the total.² The end users of petroleum products for the years 1975 to 2000 are shown in Fig. 11. Crude oil reserves and world petroleum consumption are shown in Figs. 12 and 13.

Compared to coal, fuel oils are relatively easy to handle and burn. There is less bulk ash to dispose of and the ash discharged is correspondingly small. In most oil burners, the fuel is atomized and mixed with combustion air. In the atomized state, the characteristics of oil approach those of natural gas. (See Chapter 11.)

Because of its relatively low cost, No. 6 fuel oil is the most widely used for steam generation. It can be considered a byproduct of the refining process. Its ash content ranges from 0.01 to 0.5% which is very low compared to coal. However, despite this low ash content, compounds of vanadium, sodium and sulfur in the ash can pose operating problems. (See Chapter 21.)

Fuel oil characterization

Fuel oils include virtually all petroleum products that are less volatile than gasoline. They range from light oils, suitable for use in internal combustion or turbine engines, to heavy oils requiring heating. The

Fig. 12 Major world crude oil reserves, 2000 (OPEC = Organization of Petroleum Exporting Countries).

heavier fuels are primarily suited for steam generation boilers. The ASTM specifications for fuel oil properties are given in Table 10.

Fuel oils can be divided into two classes: distillate and residual. Distillate fuels are those that are vaporized in a petroleum refining operation. They are typically clean, essentially free of sediment and ash, and relatively low in viscosity. These fuels fall into the No. 1 or No. 2 category in ASTM D 396. Although No. 2 oil is sometimes used as a premium steam generation fuel, it best lends itself to applications where cleanliness and ease of handling outweigh its cost. Examples include home heating and industrial applications where low ash and/or sulfur are important. Steam generating applications are primarily limited to use as a startup or support fuel.

The residual fuel oils are those that are not vaporized by heating. They contain virtually all the inorganic constituents present in the crude oil. Frequently, residual oils are black, high viscosity fluids that require heating for proper handling and combustion.

Fuel oils in grades No. 4 and 5 are less viscous and therefore more easily handled and burned than is No. 6 oil. Depending on the crude oil used, a fuel meeting the No. 4 specification may be a blend of residual oil and lighter distillate fractions. This oil does not usually require heating for pumping and handling.

No. 5 oils may require heating, depending on the firing equipment and the ambient temperature. No. 6 oils usually require heating for handling and burning. (See Chapter 11 for oil storage, handling and use requirements.)

Table 10
ASTM Standard Specifications for Fuel Oils^a

No. 1 A distillate oil intended for vaporizing pot-type burners and other burners requiring this grade of fuel

No. 2 A distillate oil for general purpose domestic heating for use in burners not requiring No. 1 fuel oil

No. 4 Preheating not usually required for handling or burning

No. 5 (Light) Preheating may be required depending on climate and equipment

No. 5 (Heavy) Preheating may be required for burning and, in cold climates, may be required for handling

No. 6 Preheating required for burning and handling

Notes:

a. Recognizing the necessity for low sulfur fuel oils used in connection with heat treatment, nonferrous metal, glass, and ceramic furnaces and other special uses, a sulfur requirement may be specified in accordance with the following table:

Grade of Fuel Oil	Sulfur, Max, %
No. 1	0.5
No. 2	0.7
No. 4	no limit
No. 5	no limit
No. 6	no limit

Other sulfur limits may be specified only by mutual agreement between the purchaser and the seller.

b. It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in

the next lower grade unless, in fact, it meets all requirements of the lower grade.

c. Lower or higher pour points may be specified whenever required by conditions of storage or use.

d. The 10% distillation temperature point may be specified at 440F (226C) maximum for use in other than atomizing burners.

e. When pour point less than 0F is specified, the minimum viscosity shall be 1.8 cs (32.0 s, Saybolt Universal) and the minimum 90% point shall be waived.

f. Viscosity values in parentheses are for information only and not necessarily limiting.

g. The amount of water by distillation plus the sediment by extraction shall not exceed 2.00%. The amount of sediment by extraction shall not exceed 0.50%. A deduction in quantity shall be made for all water and sediment in excess of 1.0%.

Source, ASTM D 396.

Fig. 13 Major petroleum consumption.

Fuel analyses

A typical analysis of a fuel oil or waste liquid contains the following information:

1. ultimate analysis
2. API gravity
3. heating value
4. viscosity
5. pour point
6. flash point
7. water and sediment

Ultimate analysis The ultimate analysis for an oil is similar to that for a coal. The results indicate the quantities of sulfur, hydrogen, carbon, nitrogen, oxygen and ash. Ultimate analyses for various fuel oils are given in Table 11.

The sulfur content of the oil is an indicator of its corrosiveness and is oxidized to sulfur oxides during combustion. These oxides can react with water vapor or ash constituents to form corrosive acids, salts, or boiler fouling potassium sulfate. When molten, these ash deposits are corrosive. Furthermore, vanadium can combine with the sulfur oxides to form a corrosive product. (See Chapter 21.)

API gravity The petroleum industry uses the API gravity scale to determine the relative density of oil. The scale was devised jointly by the American Petroleum Institute (API) and the National Bureau of Standards. The relationship between the *API gravity* and the *specific gravity* is given by the following formula:

$$\text{Deg API Gravity} = \frac{141.5}{\text{Specific gravity at 60/60F}} - 131.5$$

Given this relationship, heavier liquid fuels are denoted by lower API gravity values.

Heating value The heating value of a liquid fuel indicates the heat released by the complete combustion of one unit of fuel [lb (kg)]. As for coal, there are two calculated heating values, higher (HHV) and lower (LHV). In computing the HHV, it is assumed that any water vapor formed by burning the hydrogen constitu-

ent is condensed and cooled to its initial temperature. Therefore, the heat of vaporization of the water formed is included in the HHV. For the LHV, it is assumed that none of the water vapor condenses. Both heating values are determined by using an oxygen bomb calorimeter.

Viscosity The viscosity of a liquid is the measure of its internal resistance to flow. Although there are numerous viscosity scales, those most commonly used in the U.S. are:

1. Saybolt Universal Seconds (SUS),
2. Saybolt Furol Seconds (SFS),
3. absolute viscosity (centipoise), and
4. kinematic viscosity (centistokes).

The *kinematic viscosity* of oil is related to the *absolute viscosity* by the following formula:

$$\text{Kinematic viscosity (centistokes)} = \frac{\text{Absolute viscosity (centipoise)}}{\text{Specific gravity}}$$

Pour point The pour point is the lowest temperature at which a liquid fuel flows under standardized conditions.

Flash point The flash point is the temperature to which a liquid must be heated to produce vapors that flash but do not burn continuously when ignited. There are two instruments used to determine the flash point: the Pensky-Martens or closed cup flash tester, and the Cleveland or open cup tester. The closed cup tester indicates a lower flash point because it retains light vapors which are lost by the open cup unit.

Water and sediment The water and sediment level, also called bottom sediment and water (BSW), is a measure of the contaminants in a liquid fuel. The sediment normally consists of calcium, sodium, magnesium and iron compounds. For heavy fuels, the sediment may also contain carbon.

The basic analyses described are important in designing oil-fired boilers. The HHV determines the quantity of fuel required to reach a given heat input. The ultimate analysis determines the theoretical air required for complete combustion and therefore indicates the size of the burner throat. Also available from the ultimate analysis is the carbon/hydrogen ratio, which shows the ease with which a fuel burns. This ratio also indicates the expected level of carbon particulate emissions. A carbon/hydrogen ratio in excess of 7.5 is usually indicative of troublesome burning.

Considering the percentages of nitrogen and sulfur in conjunction with the HHV, an estimate of NO_x and SO₂ emissions can be made. The ash percentage has a similar bearing on particulate emissions. The ash constituent analysis and ash content indicate fouling and corrosion tendencies.

Additional information, which is often required when designing a boiler, includes:

1. carbon residue,
2. asphaltenes,
3. elemental ash analysis,
4. burning profile, and
5. distillation curve.

*Estimated

Properties of fuel oils

Analytical results for various fuel oil properties are given in Table 11.

Fuel oil heating values are closely related to their specific gravities. The relationships between the *HHV* of various fuel oils and their API gravities are shown in Fig. 14.

A more accurate estimate of the heating value for an oil is obtained by correcting the *HHV* from Fig. 14 as follows:

$$\text{Apparent heating value} = \frac{HHV [100 - (A + M + S)]}{100} + 40.5 S \quad (7)$$

where

A = % weight of ash
M = % weight of water
S = % weight of sulfur

The volume percentages of water and sediment can be used without appreciable error in place of their weight percentages.

Fuel oils are generally sold on a volume basis using 60F (16C) as the base temperature. Correction factors are given in Fig. 15 for converting volumes at

Fig. 14 Relationship between HHV of various fuel oils and their API gravities.

Fig. 15 Oil volume-temperature correction factors.

other temperatures to this standard base. This correction is also dependent on the API gravity range, as illustrated by the three lines of Fig. 15.

Handling and burning equipment are usually designed for a maximum oil viscosity. If the viscosities of heavy oils are known at two temperatures, their viscosities at other temperatures can be closely predicted by a linear interpolation between these two values on the standard ASTM chart (Fig. 16). Viscosity-temperature variations for certain light oils can also be found using the ASTM chart. In this case, however, the designer only needs to know the viscosity at one temperature. For example, the viscosity of a light oil at a given temperature within the No. 2 fuel oil range can be found by drawing a line parallel to the No. 2 boundary lines through the point of known temperature.

Natural gas

Past consumption and availability

Natural gas is found in porous rock in the earth's crust. World natural gas production for 1999 is shown in Fig. 17.

Electric power generation is the fastest growing segment of U.S. natural gas consumption. By 2000, electric generators had overtaken the residential segment as the second largest user of natural gas with a 22% share of U.S. consumption (Table 12). Environmental regulations, higher efficiency gas turbines, and a large base of simple and combined cycle gas turbine plants installed in the late 1990s and early 2000s drove the annual usage of natural gas in the U.S., for electric power generation, from 3.8 trillion cubic feet in 1996 to 5.5 trillion cubic feet in 2002. The Department of Energy (DOE) expects that the volatile price of natural gas will hold growth to about 1.8% per year to 2025.

Note: On the Y axis, find the SUS viscosity at 100F (standard test temperature) for the given oil; move horizontally to the vertical line for 100F. From this intersection, move parallel to the diagonal lines to the viscosity required for atomization; the temperature necessary to achieve this viscosity can be read on the X axis. The chart, based on U.S. Commercial Standard 12-48, has been developed from data for many fuels and should be sufficiently accurate for most applications.

Fig. 16 Approximate viscosity of fuel oil at various temperatures (courtesy of ASTM).

Natural gas characteristics

Natural gas can be found with petroleum reserves or in separate reservoirs. Methane is the principal component of natural gas; smaller components include ethane, propane and butane. Other hydrocarbons, such as pentane through decane, can also be found in natural gas. Furthermore, other gases such as CO_2 , nitrogen, helium and hydrogen sulfide (H_2S) may be present.

Gas containing mostly methane is referred to as *lean* gas. *Wet* gas contains appreciable amounts of the higher hydrocarbons (5 to 10% C). Gas containing H_2S is *sour* gas; conversely, *sweet* gas contains little or no H_2S .

Fig. 17 World natural gas production, 1999.

Note: Total may not equal sum of components due to independent rounding. Source: Energy Information Administration, *Annual Energy Review*, 2003.

Of all chemical fuels, natural gas is considered to be the most desirable for steam generation. It is piped directly to the consumer, eliminating the need for storage. It is substantially free of ash and mixes easily with air, providing complete combustion without smoke. Although the total hydrogen content of natural gas is high, its free hydrogen content is low. Because of this, natural gas burns less easily than some manufactured gases with high free hydrogen content.

The high hydrogen content of natural gas compared to that of oil or coal results in more water vapor being produced in the combustion gases. This results in a correspondingly lower efficiency of the steam generating equipment. (See Chapter 10.) This can readily be taken into account when designing the equipment.

Properties of natural gas

Analyses of natural gas from several U.S. fields are given in Table 13.

Other fuels

While coal, oil and gas are the dominant fuel sources, other carbonaceous fuels being used for boiler applications include petroleum byproducts and heavy hydrocarbon emulsions; wood, its byproducts and wastes from wood processing industries; certain types of vegetation, particularly bagasse; and municipal solid waste.

Coke from petroleum

The heavy residuals from petroleum cracking processes are presently used to produce a higher yield of lighter hydrocarbons and a solid residue suitable for fuel. Characteristics of these residues vary widely and depend on the process used. Solid fuels from oil include delayed coke, fluid coke and petroleum pitch. Some selected analyses are given in Table 14.

The delayed coking process uses residual oil that is

heated and pumped to a reactor. Coke is deposited in the reactor as a solid mass and is subsequently stripped, mechanically or hydraulically, in the form of lumps and granular material. Some cokes are easy to pulverize and burn while others are difficult.

Fluid coke is produced by spraying hot residual feed onto externally heated seed coke in a fluidized bed. The fluid coke is removed as small particles, which are built up in layers. This coke can be pulverized and burned, or it can be burned in a Cyclone furnace or in a fluidized bed. All three types of firing require supplemental fuel to aid ignition.

The petroleum pitch process is an alternate to the coking process and yields fuels of various characteristics. Melting points vary considerably, and the physi-

cal properties vary from soft and gummy to hard and friable. The low melting point pitches may be heated and burned like heavy oil, while those with higher melting points may be pulverized or crushed and burned.

Oil emulsions

With the discovery of large reserves of heavy hydrocarbon and bitumen in Venezuela, considerable effort has been devoted to developing these sources as commercial fuels. This has led to the formulation of bitumen oil emulsions. Generically, these emulsions are liquid fuels composed of micron-size oil droplets dispersed in water. Droplet coalescence is prevented by adding a small amount of a proprietary chemical. The fuel is characterized by relatively high levels of sulfur, asphaltene and metals. The heating value, ash content and viscosity of the emulsions are similar to residual fuel oil as are their handling and combustion performance characteristics. The emulsions can contain vanadium which forms corrosive compounds during combustion. Vanadium can also catalyze the oxidation of SO₂ to SO₃ and require the use of specific emission controls to avoid stack plumes of sulfuric acid aerosol.

Orimulsion® is the trade name of a proprietary bitumen emulsion produced by Bitor, a part of Petroleos de Venezuela SA (PDVSA), the Venezuelan national oil company. It is prepared from approximately 30% water and 70% bitumen from the Orinoco basin. Combined with other performance enhancing chemicals, a stable emulsified fuel for application in boilers and other combustion equipment is produced. A typical Orimulsion composition compared to fuel oil is shown in Table 15.

As of 2000, Orimulsion was being utilized worldwide at the rate of 6.2 million tons per year at boiler installations in Denmark, Japan, Italy and Canada. The fuel can offer cost advantage over No. 6 fuel oil. Environmental control equipment is required to address sulfur oxides, nitrogen oxides, and particulate emissions.

Wood

Selected analyses and heating values of wood and wood ash are given in Table 16. Wood is composed primarily of carbohydrates. Consequently, it has a relatively low heating value compared with bituminous coal and oil.

Wood bark may pick up impurities during transportation. It is common practice to drag the rough logs to central loading points and sand is often picked up.

* Salt water stored.

Where the logs are immersed in salt water, the bark can absorb the salt. Combustion temperatures from burning dry bark may be high enough for these impurities to cause fluxing of refractory furnace walls and fouling of boiler heating surfaces, unless sufficient furnace cooling surface is provided. Sand passing through the boiler banks can cause erosion of the tubes, particularly if the flue gas sand loading is increased by returning collected material to the furnace. Such collectors may be required with some bark burning equipment to reduce the stack discharge of incompletely burned bark.

Wood or bark with a moisture content of 50% or less burns quite well; however, as the moisture increases above this amount, combustion becomes more difficult. With a moisture content above 65%, a large part of the heat is required to evaporate the inherent moisture and little remains for steam generation. Burning this wet bark becomes a means of disposal rather than a source of energy.

Hogged wood and bark are very bulky and require relatively large handling and storage equipment. Uninterrupted flow from bunkers or bins through chutes is difficult to maintain. (Also see Chapter 30.)

Wood wastes There are several industries using wood as a raw material where combustible byproducts or wastes are available as fuels. The most important of these are the pulp and turpentine industries. The nature and methods of utilization of the combustible byproducts from the pulp industry are discussed in Chapter 28.

The residue remaining after the steam distillation of coniferous woods for the production of turpentine is usable as a fuel. Some of the more easily burned constituents are removed in the distillation process; as a result, the residue is somewhat more difficult to burn. Other than this, fuel properties are much the same as those of the raw wood and the problems involved in utilization are similar.

Bagasse

Mills grinding sugar cane commonly use bagasse for steam production. Bagasse is the dry pulp remaining after the juice has been extracted from sugar cane. The mills normally operate 24 hours per day during the grinding season. The supply of bagasse will easily meet the plant steam demands in mills where the sugar is not refined. Consequently, where there is no other market for the bagasse, no particular effort is made to burn it efficiently, and burning equipment is provided that will burn the bagasse as-received from the grinders. In refining plants, supplemental fuels are required to provide the increased steam demands. Greater efforts to obtain higher efficiency are justified in these plants. A selected analysis of bagasse is given in Table 8.

Other vegetation wastes

Food and related industries produce numerous vegetable wastes that are usable as fuels. They include such materials as grain hulls, the residue from the

Table 17
Analyses of MSW and RDF Compared to Bituminous Coal

production of furfural from corn cobs and grain hulls, coffee grounds from the production of instant coffee, and tobacco stems. Fuels of this type are available in such small quantities that they are relatively insignificant in total energy production.

Municipal solid waste

Municipal solid waste (MSW), or refuse, is an energy source in the U.S., Europe and Japan. MSW is the combined residential and commercial waste generated in a given municipality. It is burned as-received, called mass burning, or processed using size reduction and material recovery techniques to produce refuse-derived fuel (RDF). Much MSW continues to be landfilled, since siting and acceptance of waste-to-energy boilers have been greatly limited by the public's concern over environmental issues.

Table 17 shows a typical analysis of raw refuse and RDF compared to bituminous coal. The relatively low calorific value and high heterogeneous nature of MSW provide a challenge to the combustion system design engineer. The design of MSW handling and combustion systems is discussed in Chapter 29.

Coal remains the dominant fuel source for electric power generation worldwide.

Chapter 10

Principles of Combustion

A boiler requires a source of heat at a sufficient temperature to produce steam. Fossil fuel is generally burned directly in the boiler furnace to provide this heat although waste energy from another process may also be used.

Combustion is defined as the rapid chemical combination of oxygen with the combustible elements of a fuel. There are just three combustible elements of significance in most fossil fuels: carbon, hydrogen and sulfur. Sulfur, usually of minor significance as a heat source, can be a major contributor to corrosion and pollution problems. (See Chapters 21 and 32.)

The objective of good combustion is to release all of the energy in the fuel while minimizing losses from combustion imperfections and excess air. System requirement objectives include minimizing nitrogen oxides (NO_x), carbon monoxide (CO), volatile organic compounds (VOC) and, for more difficult to burn fuels, minimizing unburned carbon (UBC) and furnace corrosion. The combination of the combustible fuel elements and compounds in the fuel with all the oxygen requires *temperatures* high enough to ignite the constituents, mixing or *turbulence* to provide intimate oxygen-fuel contact, and sufficient *time* to complete the process, sometimes referred to as the *three Ts of combustion*.

Table 1 lists the chemical elements and compounds found in fuels generally used in commercial steam generation.

Concept of the mole

The mass of a substance in pounds equal to its molecular weight is called a pound-mole (lb-mole) of the substance. The molecular weight is the sum of the atomic masses of a substance's constituent atoms. For example, pure elemental carbon (C) has an atomic mass and molecular weight of 12 and therefore a lb-mole is equal to 12. In the case of carbon dioxide (CO_2), carbon still has an atomic mass of 12 and oxygen has an atomic mass of 16 giving CO_2 a molecular weight and

a lb-mole equal to $(1 \times 12) + (2 \times 16)$ or 44. In SI, a similar system is based upon the molecular weight in kilograms expressed as kg-mole or kmole. In the United States (U.S.) power industry it is common practice to replace lb-mole with mole.

In the case of a gas, the volume occupied by one mole is called the molar volume. The volume of one mole of an ideal gas (a good approximation in most combustion calculations) is a constant regardless of its composition for a given temperature and pressure. Therefore, one lb-mole or mole of oxygen (O_2) at 32 lb and one mole of CO_2 at 44 lb will occupy the same volume equal to 394 ft³ at 80F and 14.7 psi. The volume occupied by one mole of a gas can be corrected to other pressures and temperatures by the ideal gas law.

Because substances combine on a molar basis during combustion but are usually measured in units of mass (pounds), the lb-mole and molar volume are important tools in combustion calculations.

Fundamental laws

Combustion calculations are based on several fundamental physical laws.

Conservation of matter

This law states that matter can not be destroyed or created. There must be a mass balance between the sum of the components entering a process and the sum of those leaving: X pounds of fuel combined with Y pounds of air always results in X + Y pounds of products (see Note below).

Conservation of energy

This law states that energy can not be destroyed or created. The sum of the energies (potential, kinetic, thermal, chemical and electrical) entering a process must equal the sum of those leaving, although the proportions of each may change. In combustion, chemical energy is converted into thermal energy (see Note below).

For clarity, this chapter is provided in English units only. Appendix 1 provides a comprehensive list of conversion factors. Selected factors of particular interest here include: $\text{Btu/lb} \times 2.326 = \text{kJ/kg}$; $5/9 (\text{F}-32) = \text{C}$; $\text{lb} \times 0.4536 = \text{kg}$. Selected SI constants include: universal gas constant = 8.3145 kJ/kmole K; one kmole at 0C and 1.01 bar = 22.4 m³.

Note: While the laws of conservation of matter and energy are not rigorous from a nuclear physics standpoint (see Chapter 47), they are quite adequate for engineering combustion calculations. When a pound of a typical coal is burned releasing 13,500 Btu, the equivalent quantity of mass converted to energy amounts to only 3.5×10^{-10} lb.

g Gas Processors Suppliers Association (GPSA) Data Book, Fig 23-2, Physical Constants, 1987.

h Either the density or the compressibility factor has been assumed.

Ideal gas law

This law states that the volume of an ideal gas is directly proportional to its absolute temperature and inversely proportional to its absolute pressure.

The proportionality constant is the same for one mole of any ideal gas, so this law may be expressed as:

$$v_M = \frac{RT}{P} \quad (1)$$

where

v_M = volume, ft³/mole

R = universal gas constant, 1545 ft lb/mole R

T = absolute temperature, R = F + 460

P = absolute pressure, lb/ft²

Most gases involved in combustion calculations can be approximated as ideal gases.

Law of combining weights

This law states that all substances combine in accordance with simple, definite weight relationships. These relationships are exactly proportional to the molecular weights of the constituents. For example, carbon (molecular weight = 12) combines with oxygen (molecular weight of O₂ = 32) to form carbon dioxide (molecular weight = 44) so that 12 lb of C and 32 lb of O₂ unite to form 44 lb of CO₂. (See *Application of fundamental laws* below.)

Avogadro's law

Avogadro determined that equal volumes of different gases at the same pressure and temperature contain the same number of molecules. From the concept of the mole, a pound mole of any substance contains a mass equal to the molecular weight of the substance. Therefore, the ratio of mole weight to molecular weight is a constant and a mole of any chemically pure substance contains the same number of molecules. Because a mole of any ideal gas occupies the same volume at a given pressure and temperature (ideal gas law), equal volumes of different gases at the same pressure and temperature contain the same number of molecules.

Dalton's law

This law states that the total pressure of a mixture of gases is the sum of the partial pressures which would be exerted by each of the constituents if each gas were to occupy alone the same volume as the mixture. Consider equal volumes V of three gases (a, b and c), all at the same temperature T but at different pressures (P_a , P_b and P_c). When all three gases are placed in the space of the same volume V , then the resulting pressure P is equal to $P_a + P_b + P_c$. Each gas in a mixture fills the entire volume and exerts a pressure independent of the other gases.

Amagat's law

Amagat determined that the total volume occupied by a mixture of gases is equal to the sum of the volumes which would be occupied by each of the constituents when at the same pressure and temperature as the mixture. This law is related to Dalton's law, but it

considers the additive effects of volume instead of pressure. If all three gases are at pressure P and temperature T but at volumes V_a , V_b and V_c , then, when combined so that T and P are unchanged, the volume of the mixture V equals $V_a + V_b + V_c$.

Application of fundamental laws

Table 2 summarizes the molecular and weight relationships between fuel and oxygen for constituents commonly involved in combustion. The heat of combustion for each constituent is also tabulated. Most of the weight and volume relationships in combustion calculations can be determined by using the information presented in Table 2 and the seven fundamental laws.

The combustion process for C and H₂ can be expressed as follows:

C	+	O ₂	=	CO ₂
1 molecule	+	1 molecule	→	1 molecule
1 mole	+	1 mole	=	1 mole
(See Note below)	+	1 ft ³	→	1 ft ³
12 lb	+	32 lb	=	44 lb
2H ₂	+	O ₂	=	2H ₂ O
2 molecules	+	1 molecule	→	2 molecules
2 moles	+	1 mole	=	2 moles
2 ft ³	+	1 ft ³	→	2 ft ³
4 lb	+	32 lb	=	36 lb

Note: When 1 ft³ of oxygen (O₂) combines with carbon (C), it forms 1 ft³ of carbon dioxide (CO₂). If carbon were an ideal gas instead of a solid, 1 ft³ of carbon would be required.

It is important to note that there is a mass or weight balance according to the law of combining weights but there is not necessarily a molecular or volume balance.

Molar evaluation of combustion

Gaseous fuel

Molar calculations have a simple and direct application to gaseous fuels, where the analyses are usually reported on a percent by volume basis. Consider the following fuel analysis:

Fuel Gas Analysis, % by Volume

CH ₄	85.3
C ₂ H ₆	12.6
CO ₂	0.1
N ₂	1.7
O ₂	0.3
Total	100.0

The mole fraction of a component in a mixture is the number of moles of that component divided by the total number of moles of all components in the mixture. Because a mole of every ideal gas occupies the same volume, by Avogadro's Law, the mole fraction of a component in a mixture of ideal gases equals the volume fraction of that component.

Table 2
Common Chemical Reactions of Combustion

Combustible	Reaction	Moles	Mass or weight, lb	Heat of Combustion (High) Btu/lb of Fuel
Carbon (to CO)	$2C + O_2 = 2CO$	$2 + 1 = 2$	$24 + 32 = 56$	3,967
Carbon (to CO ₂)	$C + O_2 = CO_2$	$1 + 1 = 1$	$12 + 32 = 44$	14,093
Carbon monoxide	$2CO + O_2 = 2CO_2$	$2 + 1 = 2$	$56 + 32 = 88$	4,342
Hydrogen	$2H_2 + O_2 = 2H_2O$	$2 + 1 = 2$	$4 + 32 = 36$	61,029
Sulfur (to SO ₂)	$S + O_2 = SO_2$	$1 + 1 = 1$	$32 + 32 = 64$	3,980
Methane	$CH_4 + 2O_2 = CO_2 + 2H_2O$	$1 + 2 = 1 + 2$	$16 + 64 = 80$	23,891
Acetylene	$2C_2H_2 + 5O_2 = 4CO_2 + 2H_2O$	$2 + 5 = 4 + 2$	$52 + 160 = 212$	21,482
Ethylene	$C_2H_4 + 3O_2 = 2CO_2 + 2H_2O$	$1 + 3 = 2 + 2$	$28 + 96 = 124$	21,643
Ethane	$2C_2H_6 + 7O_2 = 4CO_2 + 6H_2O$	$2 + 7 = 4 + 6$	$60 + 224 = 284$	22,334
Hydrogen sulfide	$2H_2S + 3O_2 = 2SO_2 + 2H_2O$	$2 + 3 = 2 + 2$	$68 + 96 = 164$	7,094

$$\frac{\text{Moles of component}}{\text{Total moles}} = \frac{\text{Volume of component}}{\text{Volume of mixture}} \quad (2)$$

This is a valuable concept because the volumetric analysis of a gaseous mixture automatically gives the mole fractions of the components.

Accordingly, the previous fuel analysis may be expressed as 85.3 moles of CH₄ per 100 moles of fuel, 12.6 moles of C₂H₆ per 100 moles of fuel, etc.

The elemental breakdown of each constituent may also be expressed in moles per 100 moles of fuel as follows:

$$\begin{aligned} \text{C in CH}_4 &= 85.3 \times 1 = 85.3 \text{ moles} \\ \text{C in C}_2\text{H}_6 &= 12.6 \times 2 = 25.2 \text{ moles} \\ \text{C in CO}_2 &= 0.1 \times 1 = \underline{0.1 \text{ moles}} \\ \text{Total C per 100 moles fuel} &= 110.6 \text{ moles} \end{aligned}$$

$$\begin{aligned} \text{H}_2 \text{ in CH}_4 &= 85.3 \times 2 = 170.6 \text{ moles} \\ \text{H}_2 \text{ in C}_2\text{H}_6 &= 12.6 \times 3 = \underline{37.8 \text{ moles}} \\ \text{Total H}_2 \text{ per 100 moles fuel} &= 208.4 \text{ moles} \end{aligned}$$

$$\begin{aligned} \text{O}_2 \text{ in CO}_2 &= 0.1 \times 1 = 0.1 \text{ moles} \\ \text{O}_2 \text{ as O}_2 &= 0.3 \times 1 = \underline{0.3 \text{ moles}} \\ \text{Total O}_2 \text{ per 100 moles fuel} &= 0.4 \text{ moles} \end{aligned}$$

$$\text{Total N}_2 \text{ per 100 moles fuel} = 1.7 \text{ moles}$$

The oxygen/air requirements and products of combustion can now be calculated for each constituent on an elemental basis. These requirements can also be calculated directly using Table 1. Converting the gaseous constituents to an elemental basis has two advantages. It provides a better understanding of the combustion process and it provides a means for determining an elemental fuel analysis on a mass basis. This is boiler industry standard practice and is convenient for determining a composite fuel analysis when gaseous and solid/liquid fuels are fired in combination.

The following tabulation demonstrates the conversion of the gaseous fuel constituents on a moles/100 moles gas basis to a lb/100 lb gas (percent mass) basis.

Constituent	Moles/100 Moles	Mol Wt lb/Mole	lb/100 Moles	lb/100 lb
C	110.6×12.011	$= 1328.4$	$/1808.9 \times 100$	$= 73.5$
H ₂	208.4×2.016	$= 420.1$	$/1808.9 \times 100$	$= 23.2$
O ₂	0.4×31.999	$= 12.8$	$/1808.9 \times 100$	$= 0.7$
N ₂	1.7×28.013	$= 47.6$	$/1808.9 \times 100$	$= 2.6$
Total		1808.9		100.0

Solid/liquid fuel

The ultimate analysis of solid and liquid fuels is determined on a percent mass basis. The mass analysis is converted to a molar basis by dividing the mass fraction of each elemental constituent by its molecular weight.

$$\frac{\frac{\text{lb Constituent}}{100 \text{ lb Fuel}}}{\text{Mole constituent}} = \frac{\text{Mole constituent}}{100 \text{ lb Fuel}} \quad (3)$$

The calculation is illustrated in Table 3.

The products of combustion and moles of oxygen required for each combustible constituent are shown. Note that when a fuel contains oxygen, the amount of theoretical O₂/air required for combustion is reduced (as designated by the brackets).

Composition of air

So far, combustion has been considered only as a process involving fuel and oxygen. For normal combustion and steam generator applications, the source of oxygen is air. Atmospheric air is composed of oxygen, nitrogen and other minor gases. The calculations and derivation of constants which follow in this text are based upon a U.S. standard atmosphere³ composed of 0.20946 O₂, 0.78102 N₂, 0.00916 argon (Ar) and 0.00033 CO₂ moles per mole of dry air, which has an

Table 3

H ₂ O	8.0	18.015	= 0.444	H ₂ O	0.000
Ash	9.0				
Total	100.0		8.835		7.023

* Column 6 is based upon moles of oxygen as O₂ needed for combustion. Therefore, the moles of H₂O need to be divided by 2 to obtain equivalent moles of O₂.

average molecular weight of 28.9625. To simplify the calculations, N₂ includes argon and other trace elements; it is referred to as atmospheric nitrogen (N_{2a}) having an equivalent molecular weight of 28.158. (See Table 4.)

Air normally contains some moisture. As standard practice, the American Boiler Manufacturers Association (ABMA) considers moisture content to be 0.013 lb water/lb dry air, which corresponds to approximately 60% relative humidity at 80°F. For combustion calculations on a molar basis, multiply the mass basis moisture by 1.608 (molecular weight of air divided by molecular weight of water). Therefore, 0.013 lb water/lb dry air becomes 0.0209 moles water/mole dry air.

The moisture content in air is normally determined from wet and dry bulb temperatures or from relative humidity using a psychrometric chart, as shown in Fig. 1. Air moisture may also be calculated from:

$$MFWA = 0.622 \times \frac{P_v}{(P_b - P_v)} \quad (4)$$

where

MFWA = moisture content in air, lb/lb dry air
P_b = barometric pressure, psi
P_v = partial pressure of water vapor in air, psi
= 0.01 (*RH*) (*P_{vd}*), psi
P_{vd} = saturation pressure of water vapor at dry bulb temperature, psi
RH = relative humidity, %

P_v may also be calculated from Carrier's equation:

Table 4
Air Composition

	Composition of Dry Air % by vol	% by wt
Oxygen, O ₂	20.95	23.14
Atmospheric nitrogen, N _{2a}	79.05	76.86

Fig. 1 Psychrometric chart – water content of air for various wet and dry bulb temperatures.

$$P_v = P_{vw} - \frac{(P_b - P_{vw})(T_d - T_w)}{2830 - (1.44T_w)} \quad (5)$$

where

T_d = dry bulb temperature, F
T_w = wet bulb temperature, F
P_{vw} = saturation pressure of water vapor at wet bulb temperature, psi

The following constants, with values from Table 4, are frequently used in combustion calculations:

$$\text{moles air/mole O}_2 = \frac{100}{20.95} = 4.77$$

or
ft³ air/ft³ O₂

$$\text{moles N}_{2a} / \text{mole O}_2 = \frac{79.05}{20.95} = 3.77$$

$$\text{lb air (dry)/lb O}_2 = \frac{100}{23.14} = 4.32$$

$$\text{lb N}_{2a} / \text{lb O}_2 = \frac{76.86}{23.14} = 3.32$$

The calculations in Table 2 can be converted to combustion with air rather than oxygen by adding 3.77 moles of N_{2a}/mole of O₂ to the left and right side of each equation. For example, the combustion of carbon monoxide (CO) in air becomes:

or for methane, CH₄:

Theoretical air requirement

Theoretical air is the minimum air required for complete combustion of the fuel, i.e., the oxidation of car-

bon to CO₂, hydrogen to water vapor (H₂O) and sulfur to sulfur dioxide (SO₂). In the combustion process, small amounts of sulfur trioxide (SO₃), nitrogen oxides (NO_x), unburned hydrocarbons and other minor species may be formed. While these may be of concern as pollutants, their impact is negligible with regard to the quantity of air and combustion products and, therefore, they are not normally considered in these calculations.

In practice, it is necessary to use more than the theoretical amount of air to assure complete combustion of the fuel. For the example shown in Table 3, consider completing the combustion calculations on a molar basis using 20% excess air. These calculations are summarized in Table 5.

Now consider the portion of the combustion products attributable to the air. The oxygen in the theoretical air is already accounted for in the products of combustion: CO₂, H₂O (from the combustion of hydrogen) and SO₂. That leaves N_{2a} in the theoretical air, N_{2a} in the excess air, O₂ in the excess air and H₂O in air (as calculated in Table 5) as the products in the combustion gas attributable to the wet combustion air. These constituents are in addition to the combustion products from fuel shown in Table 3.

Table 5
Calculation of Wet Air Requirements
for Combustion – Molar Basis

* Standard combustion air: 80F, 60% relative humidity; 0.013 lb H₂O/lb dry air; 0.0209 moles H₂O/mole dry air.

Products of combustion – mass/mass fuel basis

Table 6 shows a tabulation of the flue gas products and combustion air on a molar (or volumetric) basis and the conversion to a mass basis (wet and dry). The products of combustion calculated on a molar basis in Tables 3 and 5 are itemized in column A. The moisture (H₂O) sources are separated from the dry products for convenience of calculating the flue gas composition on a wet and dry basis.

The water products shown in column A are from the combustion of hydrogen in the fuel, from moisture in the fuel and from moisture in the air. The N_{2a} is the sum of nitrogen in the theoretical air plus the nitrogen in the excess air. The N_{2a} is tabulated separately from the elemental nitrogen in the fuel to differentiate the molecular weight of the two. In practice, the nitrogen in the fuel is normally small with respect to the N_{2a} and can be included with the nitrogen in air. For manufactured gases that are formed when combustible products oxidize with air (blast furnace gas, for example), the nitrogen in the fuel is predominately atmospheric nitrogen.

Flue gas products are normally measured on a volumetric basis. If the sample includes water products, it is measured on a *wet basis*, typical of in situ analyzers. Conversely, if water products are excluded, measurements are done on a *dry basis*, which is typical of extractive gas sample systems. (See *Flue gas analysis*.) Note that the flue gas products are summed on a dry and wet basis to facilitate calculation of the flue gas constituents on a dry and wet percent by volume basis in columns B and C. The molecular weight of each constituent is given in column D. Finally, the mass of each constituent on a lb/100 lb fuel basis is the product of the moles/100 lb fuel and the molecular weight.

The calculation of the mass of air on a lb/100 lb fuel basis, shown at the bottom of Table 6, follows the same principles as the flue gas calculations.

For most engineering calculations, it is common U.S. practice to work with air and flue gas (combustion products) on a mass basis. It is usually more convenient to calculate these products on a mass basis directly as discussed later. The mole method described above is the fundamental basis for understanding and calculating the chemical reactions. It is also the basis for deriving certain equations that are presented later. For those who prefer using the mole method, Table 7 presents this method in a convenient calculation format.

Alternate units – Btu method

It is customary within the U.S. boiler industry to use units of mass rather than moles for expressing the quantity of air and flue gas. This is especially true for heat transfer calculations, where the quantity of the working fluid (usually steam or water) is expressed on a mass basis and the enthalpy of the hot and cold fluids is traditionally expressed on a Btu/lb basis. Therefore, if the combustion calculations are performed on the mole basis, it is customary to convert the results to lb/100 lb fuel.

Table 6
Calculation of Flue Gas and Air Quantities –
Mass Basis

Constituent	Flue Gas or Combustion Product				
	A (From Tables 3 and 5) Moles/100 lb Fuel	B (A/A6) % Vol dry	C (A/A11) % Vol wet	D (From Table 1) Molecular weight	E (A x D) lb/100 lb Fuel
1 CO ₂	5.995	15.25	14.02	44.010	263.8
2 SO ₂	0.050	0.13	0.115	64.065	3.2

8 H ₂ O fuel	+0.444				
9 H ₂ O air	+0.841				
10 Total H ₂ O	<u>3.468</u>		<u>8.11</u>	18.015	<u>62.5</u>
11 Total, wet combustion products	42.768		100.00		1271.3
Air					
12 Dry air	40.228			28.963	1165.1
13 H ₂ O	<u>0.841</u>			18.015	<u>15.2</u>
14 Total wet air					<u>1180.3</u>

Items that are expressed on a unit of fuel basis (mole/100 lb fuel, mass/mass fuel, etc.) can be normalized by using an input from fuel basis. For example, knowing that a coal has 10% ash only partly defines the fuel. For a 10,000 Btu/lb fuel, there are 10 lb ash per million Btu input, but for a 5000 Btu/lb fuel there would be 20 lb ash per million Btu input. Considering that fuel input for a given boiler load does not vary significantly with heating value, a boiler firing the lower heating value fuel would encounter approximately twice the amount of ash.

The mass per unit input concept is valuable when determining the impact of different fuels on combustion calculations. This method is particularly helpful in theoretical air calculations. Referring to Table 8, in the first column, theoretical air has been tabulated for various fuels on a mass per mass of fuel basis. The resulting values have little significance when comparing the various fuels. However, when the theoretical air is converted to a mass per unit heat input from fuel basis, the theoretical air varies little between fuels. Also refer to the discussion on the Btu Method in the *Combustion calculations* section. The common units are lb/10,000 Btu, abbreviated as lb/10KB. The fuel labeled MSW/RDF refers to municipal solid waste and refuse derived fuel. Note that the theoretical air is in the same range as that for fossil fuels on a heat input basis. Carbon and hydrogen, the principal combustible fuel elements, are shown for reference. Note that the coals listed in the table are limited to those with a volatile matter (moisture and ash free) greater than

30%. As volatile matter decreases, the carbon content increases and requires more excess air. To check the expected theoretical air for low volatile coals, refer to Fig. 2. The theoretical air of all coals should fall within plus or minus 0.2 lb/10,000 Btu of this curve. Table 9 provides the fuel analysis and theoretical air requirements for a typical fuel oil and natural gas.

Heat of combustion

In a boiler furnace (where no mechanical work is done), the heat energy evolved from combining combustible elements with oxygen depends on the ultimate products of combustion; it does not rely on any intermediate combinations that may occur.

For example, one pound of carbon reacts with oxygen to produce about 14,093 Btu of heat (refer to Table 2). The reaction may occur in one step to form CO₂ or, under certain conditions, it may take two steps. In this process, CO is first formed, producing only 3967 Btu per pound of carbon. In the second step, the CO joins with additional oxygen to form CO₂, releasing 10,126 Btu per pound of carbon (4342 Btu per pound of CO). The total heat produced is again 14,093 Btu per pound of carbon.

Measurement of heat of combustion

In boiler practice, a fuel's *heat of combustion* is the amount of energy, expressed in Btu, generated by the complete combustion, or oxidation, of a unit weight of fuel. *Calorific value*, *fuel Btu value* and *heating value* are terms also used.

The amount of heat generated by complete combustion is a constant for a given combination of combustible elements and compounds. It is not affected by the manner in which the combustion takes place, provided it is complete.

A fuel's heat of combustion is usually determined by direct calorimeter measurement of the heat evolved. Combustion products within a calorimeter are cooled to the initial temperature, and the heat absorbed by the cooling medium is measured to determine the higher, or gross, heat of combustion (typically referred to as the higher heating value, or HHV).

For all solid and most liquid fuels, the bomb type calorimeter is the industry standard measurement device. In these units, combustible substances are burned in a constant volume of oxygen. When they

* VM = volatile matter, moisture and ash free basis
MSW = municipal solid waste
RDF = refuse-derived fuel

are properly operated, combustion is complete and all of the heat generated is absorbed and measured. Heat from external sources can be excluded or proper corrections can be applied.

For gaseous fuels of 900 to 1200 Btu/ft³, continuous or constant flow type calorimeters are industry standards. The principle of operation is the same as for the bomb calorimeter; however, the heat content is determined at constant pressure rather than at constant volume.

For most fuels, the difference between the constant pressure and constant volume heating values is small and is usually neglected. However, because fuel is burned under essentially constant pressure conditions, the constant pressure heating value is the technically correct value.

For solid or liquid fuels, to convert the constant volume higher heating value (HHV_{CV}) measured in the bomb calorimeter to constant pressure (HHV_{CP}), an adjustment for the volume change is required. During the constant pressure combustion process:

1. Every mole of carbon combines with one mole of oxygen to form one mole of carbon dioxide. Therefore, there is no volume change.
2. Every mole of sulfur combines with one mole of oxygen to form one mole of sulfur dioxide. Therefore, there is no volume change.
3. Every mole of hydrogen combines with 1/2 mole of oxygen to form one mole of water vapor. Therefore, there is a net increase of 1/2 mole of gas produced. When the water vapor is condensed to a liquid in the bomb calorimeter, there is a net decrease of 1/2 mole of gas for each mole of hydrogen.
4. For every mole of oxygen in the fuel, there is one mole of oxygen gas produced. Therefore, there is a net increase of one mole of gas produced for each mole of oxygen in the fuel.
5. The solid or liquid nitrogen in the fuel is released as a gas. Therefore, there is a net increase of one mole of gas produced for every mole of nitrogen.

Using the ideal gas law, the energy change due to the volume change is as follows:

$$\Delta HHV = \sum_{n=1}^k N_k \left(\frac{R \times T}{J} \right), \text{ Btu/lb} \quad (6)$$

where

- N_k = number of moles of constituent k
 R = universal gas constant, 1545 ft-lb/mole-R
 T = absolute reference temperature for the bomb calorimeter, 537R
 J = mechanical equivalent of heat, 778.2 ft lbf/Btu

Substituting:

$$\Delta HHV = \left(\frac{-O_2}{31.9988} + \frac{-N_2}{28.0134} + \frac{0.5 H_2}{2.0159} \right) \times \frac{R T}{778.2} \quad (7)$$

where

- O_2 = mass fraction of oxygen in fuel
 N_2 = mass fraction of nitrogen in fuel
 H_2 = mass fraction of hydrogen in fuel

The corrections for nitrogen and oxygen in typical solid and liquid fuels are small, generally less than 1 and 2 Btu/lbm respectively, and are generally considered negligible. The fuel heating value correction from constant volume to constant pressure then becomes:

$$HHV_{CP} = HHV_{CV} + 264.4 H_2, \text{ Btu/lb} \quad (8)$$

Gas chromatography is also commonly used to determine the composition of gaseous fuels. When the composition of a gas mixture is known, its heat of combustion may be determined as follows:

Table 9
Fuel Analysis and Theoretical Air for Typical Oil and Gas Fuels

Heavy Fuel Oil, % by wt		Natural Gas, % by vol	
S	1.16	CH ₄	85.3
H ₂	10.33	C ₂ H ₆	12.6

Fuel, lb/10,000 Btu	0.543	Fuel, lb/10,000 Btu	0.440
Moisture, lb/10,000 Btu	0.502	Moisture, lb/10,000 Btu	0.912

$$hc_{\text{mix}} = v_a hc_a + v_b hc_b + \dots + v_x hc_x \quad (9)$$

where

hc_{mix} = heat of combustion of the mixture
 v_x = volume fraction of each component
 hc_x = heat of combustion of each component

For an accurate heating value of solid and liquid fuels, a laboratory heating value analysis is required. Numerous empirical methods have been published for estimating the heating value of coal based on the proximate or ultimate analyses. (See Chapter 9.) One of the most frequently used correlations is Dulong's formula which gives reasonably accurate results for bituminous coals (within 2 to 3%). It is often used as a routine check of calorimeter-determined values.

$$HHV = 14,544 C + 62,028 [H_2 - (O_2/8)] + 4050 S \quad (10)$$

where

HHV = higher heating value, Btu/lb
 C = mass fraction carbon
 H_2 = mass fraction hydrogen
 O_2 = mass fraction oxygen
 S = mass fraction sulfur

A far superior method for checking whether the heating value is reasonable in relation to the ultimate analysis is to determine the theoretical air on a mass per Btu basis. (See *Alternate units - Btu method*.) Table 8 indicates the range of theoretical air values. The equation for theoretical air can be rearranged to calculate the higher heating value, HHV , where the median range for theoretical air for the fuel from Table 8, $MQTHA$, is used:

$$HHV = 100 \times \frac{11.51 C + 34.29 H_2 + 4.31 S - 4.32 O_2}{MQTHA} \quad (11)$$

where

HHV = higher heating value, Btu/lb
 C = mass percent carbon, %
 H_2 = mass percent hydrogen, %
 S = mass percent sulfur, %
 O_2 = mass percent oxygen, %
 $MQTHA$ = theoretical air, lb/10,000 Btu

Higher and lower heating values

Water vapor is a product of combustion for all fuels that contain hydrogen. The heat content of a fuel depends on whether this vapor remains in the vapor state or is condensed to liquid. In the bomb calorimeter, the products of combustion are cooled to the initial temperature and all of the water vapor formed during combustion is condensed to liquid. This gives the HHV or gross calorific value (defined earlier) of the fuel, and the heat of vaporization of water is included in the reported value. For the lower heating value (LHV) or net calorific value (net heat of combustion at constant

pressure), all products of combustion including water are assumed to remain in the gaseous state, and the water heat of vaporization is not available.

While the high, or gross, heat of combustion can be accurately determined by established American Society for Testing and Materials (ASTM) procedures, direct determination of the lower heating value is difficult. There is no international standard for calculation of LHV from the measured HHV. The constants used for heats of combustion, and the temperature used to calculate the latent heat of vaporization (H_{FG}), may vary slightly between references. It is important that the temperature used for the calculation of H_{FG} be consistent with the basis for the boiler efficiency calculations, otherwise there can be errors in calculated fuel flow for a given boiler output. ASME Performance Test Code PTC 4 specifies a reference temperature of 77F (25C). The value given for H_{FG} at 77F in the ASME International Steam Tables for Industrial Use, based on IAWPS-IF97 is 1049.7 Btu/lb. Calculation of LHV at constant pressure from HHV at constant pressure is then as follows:

$$LHV_{CP} = HHV_{CP} - 1049.7(H_2 \times 8.937 + M), \text{ Btu/lb} \quad (12)$$

where

H_2 = mass fraction of hydrogen in fuel
 M = mass fraction of water in fuel

In some references, the calculation of LHV includes a correction for the difference between constant volume and constant pressure combustion. Combining Equations 8 and 12, the calculation of LHV at constant pressure from HHV at constant volume is as follows:

$$LHV_{CP} = HHV_{CV} - 1049.7(H_2 \times 8.937 + M) + 264.4H_2, \text{ Btu/lb} \quad (13)$$

Ignition temperatures

Ignition temperatures of combustible substances vary greatly, as indicated in Table 10. This table lists minimum temperatures and temperature ranges in air for fuels and for the combustible constituents of fuels commonly used in the commercial generation of heat. Many factors influence ignition temperature, so any tabulation can be used only as a guide. Pressure, velocity, enclosure configuration, catalytic materials, air/fuel mixture uniformity and ignition source are examples of the variables. Ignition temperature usually decreases with rising pressure and increases with increasing air moisture content.

The ignition temperatures of coal gases vary considerably and are appreciably higher than those of the fixed carbon in the coal. However, the ignition temperature of coal may be considered as the ignition temperature of its fixed carbon content, because the gaseous constituents are usually distilled off, but not ignited, before this temperature is attained.

Table 10
Ignition Temperatures of Fuels in Air
(Approximate Values or Ranges
at Atmospheric Pressure)

Combustible	Formula	Temperature, F
Sulfur	S	470
Charcoal	C	650
Fixed carbon (bituminous coal)	C	765
Fixed carbon (semi-anthracite)	C	870
Fixed carbon (anthracite)	C	840 to 1115
Acetylene	C ₂ H ₂	580 to 825
Ethane	C ₂ H ₆	880 to 1165
Ethylene	C ₂ H ₄	900 to 1020
Hydrogen	H ₂	1065 to 1095
Methane	CH ₄	1170 to 1380
Carbon monoxide	CO	1130 to 1215
Kerosene	—	490 to 560
Gasoline	—	500 to 800

Adiabatic flame temperature

The *adiabatic flame temperature* is the maximum theoretical temperature that can be reached by the products of combustion of a specific fuel and air (or oxygen) combination, assuming no loss of heat to the surroundings and no dissociation. The fuel's heat of combustion is the major factor in the flame temperature, but increasing the temperature of the air or the fuel also raises the flame temperature. This adiabatic temperature is a maximum with zero excess air (only enough air chemically required to combine with the fuel). Excess air is not involved in the combustion process; it only acts as a dilutant and reduces the average temperature of the products of combustion.

The adiabatic temperature is determined from the adiabatic enthalpy of the flue gas:

$$H_g = \frac{HHV - \text{Latent heat H}_2\text{O} + \text{Sensible heat in air}}{\text{Wet gas weight}} \quad (14)$$

where

H_g = adiabatic enthalpy, Btu/lb

Knowing the moisture content and enthalpy of the products of combustion, the theoretical flame or gas temperature can be obtained from Fig. 3 (see pages 12 and 13).

The adiabatic temperature is a fictitiously high value that can not exist. Actual flame temperatures are lower for two main reasons:

1. Combustion is not instantaneous. Some heat is lost to the surroundings as combustion takes place. Faster combustion reduces heat loss. However, if combustion is slow enough, the gases may be cooled sufficiently and incomplete combustion may occur, i.e., some of the fuel may remain unburned.

2. At temperatures above 3000F, some of the CO₂ and H₂O in the flue gases dissociates, absorbing heat in the process. At 3500F, about 10% of the CO₂ in a typical flue gas dissociates to CO and O₂. Heat absorption occurs at 4342 Btu/lb of CO formed, and about 3% of the H₂O dissociates to H₂ and O₂, with a heat absorption of 61,029 Btu/lb of H₂ formed. As the gas cools, the dissociated CO and H₂ recombine with the O₂ and liberate the heat absorbed in dissociation, so the heat is not lost. However, the overall effect is to lower the maximum actual flame temperature.

The term *heat available* (Btu/h) is used throughout this text to define the heat available to the furnace. This term is analogous to the energy term (numerator) in the adiabatic sensible heat equation above except that one half of the radiation heat loss and the manufacturer's margin portion are not considered available to the furnace.

Practical combustion application issues

In addition to the theoretical combustion evaluation methodologies addressed above, several application issues are very important in accurate combustion calculations of actual applications. These include the impact of the injection of SO₂ sorbents and other chemicals into the combustion process, solid ash or residue, unburned carbon and excess air.

Sorbents and other chemical additives

In some combustion systems, chemical compounds are added to the gas side of the steam generator to reduce emissions. For example, limestone is used universally in fluidized-bed steam generators to reduce SO₂ emissions. (See Chapter 17.)

Limestone impacts the combustion and efficiency calculations by: 1) altering the mass of flue gas by reducing SO₂ and increasing CO₂ levels, 2) increasing the mass of solid waste material (ash residue), 3) increasing the air required in forming SO₃ to produce calcium sulfate, CaSO₄, 4) absorbing energy (heat) from the fuel to calcine the calcium and magnesium carbonates, and 5) adding energy to the system in the sulfation reaction (SO₂ + ½ O₂ + CaO → CaSO₄). The impact of sorbent/limestone is shown as a correction to the normal combustion calculations presented later.

The limestone constituents that are required in the combustion and efficiency calculations are:

Reactive constituents:

Calcium carbonate (CaCO₃)

Magnesium carbonate (MgCO₃)

Water

Inerts

Some processes may use sorbents derived from limestone. These sorbents contain reactive constituents such as calcium hydroxide [Ca(OH)₂] and magnesium hydroxide [Mg(OH)₂].

For design purposes, the amount of sorbent is determined from the design calcium to sulfur molar ratio, *MOFCAS*. The sorbent to fuel ratio, *MFSBF*, is a

Fig. 3 Enthalpy of flue gas above 77F at 30 in. Hg.

convenient equation that converts sorbent products to a mass of fuel or input from fuel basis.

$$MFSBF = \frac{MOFCAS \times S}{MOPCA \times 32.066} \quad (15)$$

and

$$MOPCA = \left(\frac{\text{CaCO}_3}{100.089} + \frac{\text{Ca(OH)}_2}{74.096} \right) \quad (16)$$

where

- $MFSBF$ = mass ratio of sorbent to fuel, lb/lb
- $MOFCAS$ = calcium to sulfur molar ratio
- S = mass percent sulfur in fuel, %
- $MOPCA$ = calcium in sorbent molar basis, moles/100 lb sorbent
- CaCO_3 = mass percent calcium carbonate in sorbent, %
- Ca(OH)_2 = mass percent calcium hydroxide in sorbent, %

When calcium carbonate and magnesium carbonate are heated, they release CO_2 , which adds to the flue gas products. This is referred to as *calcination*. Magnesium carbonate calcines readily; however, at the operating temperatures typical of atmospheric pressure fluidized beds, not all of the calcium carbonate is calcined. For design purposes, 90% calcination is appropriate for atmospheric fluidized-bed combustion. On an operating unit, the mass fraction of calcination can be determined by measuring the CO_2 in the ash residue and by assuming it exists as CaCO_3 . The quantity of CO_2 added to the flue gas may be calculated from:

$$MQGSB = 44.01 \times MOGSB \times \frac{100}{HHV} \quad (17)$$

and

$$MOGSB = MFSBF \left(\frac{MFCL \times \text{CaCO}_3}{100.089} + \frac{\text{MgCO}_3}{58.320} \right) \quad (18)$$

where

- $MQGSB$ = incremental CO_2 from sorbent, lb/10,000 Btu
- $MOGSB$ = moles CO_2 from sorbent, moles/100 lb sorbent
- HHV = higher heating value, Btu/lb fuel
- $MFCL$ = fraction of available CaCO_3 calcined, lb/lb
- CaCO_3 = mass percent calcium carbonate in sorbent, %
- MgCO_3 = mass percent magnesium carbonate in sorbent, %

The water added to the flue gas, $MQWSB$, includes the free water and water evaporated due to dehydration of calcium and magnesium hydroxide products.

$$MQWSB = 18.015 \times MOWSB \times \frac{100}{HHV} \quad (19)$$

and

$$MOWSB = \text{H}_2\text{O} + \left(\frac{\text{Ca(OH)}_2}{74.096} + \frac{\text{Mg(OH)}_2}{84.321} \right) \quad (20)$$

where

- $MQWSB$ = water added to flue gas from sorbent, lb/10,000 Btu
- $MOWSB$ = moles of water from sorbent, moles/100 lb sorbent
- HHV = higher heating value, Btu/lb fuel
- H_2O = free water from sorbent, moles/100 lb sorbent
- Ca(OH)_2 = mass percent calcium hydroxide in sorbent, %
- Mg(OH)_2 = mass percent magnesium hydroxide in sorbent, %

Spent sorbent refers to the solid products remaining due to the use of limestone. Spent sorbent is the sum of the inerts in the limestone, the mass of the reactive constituents after calcination (CaCO_3 , CaO and MgO), and the SO_3 formed in the sulfation reaction.

$$MQSSB = MFSSB \times \frac{10,000}{HHV} \quad (21)$$

and

$$MFSSB = MFSBF - (0.4401 \times MOGSB) - (0.18015 \times MOWSB) + (250 \times S \times MFSC) \quad (22)$$

where

- $MQSSB$ = solids added to flue gas, lb/10,000 Btu
- $MFSSB$ = solids added to flue gas, lb/lb fuel
- HHV = higher heating value, Btu/lb fuel
- $MFSBF$ = mass ratio of sorbent to fuel, lb/lb
- $MOGSB$ = moles CO_2 from sorbent, moles/100 lb sorbent
- $MOWSB$ = moles H_2O from sorbent, moles/100 lb sorbent
- S = mass percent sulfur in fuel, %
- $MFSC$ = mass fraction of sulfur in fuel captured, lb/lb

The combustion and efficiency values related to limestone (sorbent) are calculated separately in this text; they are treated as a supplement to the basic calculations. (See *Combustion and efficiency calculations*.)

Residue versus refuse

The term *residue* is used within this text to refer to the solid waste products that leave the steam generator envelope. This replaces the term *refuse* which is now used to refer to municipal solid waste fuels and their derivatives.

Unburned carbon

In commercial solid fuel applications, it is not always practical to completely burn the fuel. Some of the fuel may appear as unburned carbon in the residue or CO in the flue gas, although the hydrogen in the fuel is

usually completely consumed. The capital and operating (energy) costs incurred to burn this residual fuel are usually far greater than the energy lost. In addition, the evolution of combustion equipment to reduce NO_x emissions has resulted in some tradeoffs with increases in unburned carbon and CO.

Unburned carbon impacts the combustion calculations and represents an efficiency loss. Therefore, unburned carbon must be measured when present. The preferred procedure is to determine the quantity of combustible carbon in the boiler flyash and bottom ash in accordance with ASTM D-6316, *Determination of Total, Combustible, and Carbonate Carbon in Solid Residues from Coal and Coke*.

The unburned carbon determined by ASTM D-6316 is on the basis of percent carbon in the flyash/bottom ash (lb carbon/100 lb residue). The combustion calculations require unburned carbon on a lb/100 lb fuel basis (percent unburned carbon from fuel) calculated from the following equations:

$$UBC = MPCR \times MFR \quad (23)$$

and

$$MFR = \frac{AF + (100 \times MFSSB)}{(100 - MPCR)} \quad (24)$$

where

- UBC = unburned carbon, lb/100 lb fuel
- $MPCR$ = unburned carbon in residue (measured or reference), mass %
- MFR = mass fraction residue, fuel basis, lb/lb fuel
- AF = mass percent ash from fuel, %
- $MFSSB$ = mass fraction of spent sorbent, lb/lb fuel

The quantity of ash in solid fuels is variable, and therefore it is sometimes desirable to correct the measured percent unburned carbon in residue to a reference (or baseline) fuel ash content in order to evaluate combustion system performance. For given boiler operating conditions, the heat loss due to unburned carbon (UBCL) is assumed to remain constant for typical variations in fuel ash (and spent sorbent if applicable). The unburned carbon as it would appear in a residue produced by the *reference* fuel (and sorbent flow) may be calculated using the following equation:

$$MPCR_{REF} = \frac{100}{\left[\frac{14,500 \times (AF_{REF} + 100 \times MFSSB_{REF})}{UBCL_{MEAS} \times HHV_{REF}} \right] + 1} \quad (25)$$

where

- $MPCR_{REF}$ = unburned carbon in residue corrected to reference fuel ash (and spent sorbent), %
- AF_{REF} = mass percent ash from reference fuel, %
- $MFSSB_{REF}$ = reference mass fraction of spent sorbent, lb/lb fuel

$UBCL_{MEAS}$ = measured heat loss due to unburned carbon, %

HHV_{REF} = higher heating value of reference fuel, Btu/lb

Equation 25 assumes that the unburned carbon loss, UBCL, is constant between the test and reference conditions.

Excess air

For commercial applications, more than theoretical air is needed to assure complete combustion. This *excess air* is needed because the air and fuel mixing is not perfect. Because the excess air that is not used for combustion leaves the unit at stack temperature, the amount of excess air should be minimized. The energy required to heat this air from ambient to stack temperature usually serves no purpose and is lost energy. Typical values of excess air required at the burning equipment are shown in Table 11 for various fuels and methods of firing. When substoichiometric firing is used in the combustion zone, i.e., less than the theoretical air is used, the values shown would apply to the furnace zone where the final air is admitted to

Table 11
Typical Excess Air Requirements
at Fuel Burning Equipment

Fuel	Type of Furnace or Burners	Excess Air % by wt
Pulverized coal	Completely water-cooled furnace — wet or dry ash removal	15 to 20
	Partially water-cooled furnace	15 to 40
Crushed coal	Cyclone furnace — pressure or suction	13 to 20
	Fluidized-bed combustion	15 to 20
Coal	Spreader stoker	25 to 35
	Water-cooled vibrating grate stoker	25 to 35
	Chain grate and traveling grate	25 to 35
Fuel oil	Underfeed stoker	25 to 40
	Register type burners	3 to 15
Natural, coke oven and refinery gas	Register type burners	3 to 15
	Register type burners	3 to 15
Blast furnace gas	Register type burners	15 to 30
Wood/bark	Traveling grate, water-cooled vibrating grate	20 to 25
	Fluidized-bed combustion	5 to 15
Refuse-derived fuels (RDF)	Completely water-cooled furnace — traveling grate	40 to 60
Municipal solid waste (MSW)	Water-cooled/refractory covered furnace	80 to 100
	reciprocating grate	
Bagasse	Rotary kiln	60 to 100
	All furnaces	25 to 35
Black liquor	Recovery furnaces for Kraft and soda pulping processes	15 to 20

complete combustion. The amount of excess air at the exit of the pressure parts (where it is usually monitored) must be greater than the air required at the burning equipment to account for setting infiltration on balanced draft units (or seal air on pressure-fired units). On modern units with membrane wall construction, this is usually only 1 or 2% excess air at full load. On older units, however, setting infiltration can be significant, and operating with low air at the steam generator exit can result in insufficient air at the burners. This can cause poor combustion performance.

For units with air heaters, excess air must be measured at the air heater gas inlet to determine efficiency. When equipment such as selective catalytic reduction (SCR) systems or dust collection equipment is located between the exit of the pressure parts and air heater gas inlet, additional air infiltration may occur, including SCR dilution air for ammonia transport. A typical value for SCR dilution air is 0.8% excess air.

Combustion and efficiency calculations

The combustion calculations are the starting point for all design and performance calculations for boilers and their related component parts. They establish the quantities of the constituents involved in the combustion process chemistry (air, flue gas, residue and sorbent), the efficiency of the combustion process and the quantity of heat released.⁴

The units used for the combustion and efficiency calculations are lb/10,000 Btu. The acronym MQxx also refers here to constituents on a mass per 10,000 Btu basis. For gaseous fuels, the volumetric analysis is converted to an elemental mass basis, as described in *Molar evaluation of combustion*.

Combustion air – theoretical air

The combustion air is the total air required for the burning equipment; it is the theoretical air plus the excess air. Theoretical air is the minimum air required for complete conversion of the carbon, hydrogen and sulfur in the fuel to standard products of combustion. For some fuels and/or combustion processes, all of the carbon is not converted. In addition, when limestone or other additives are used, some of the sulfur is not converted to sulfur dioxide. However, additional air is required for the conversion of sulfur dioxide to sulfur trioxide in the sulfation reaction ($\text{CaO} + \text{SO}_2 + \frac{1}{2} \text{O}_2 \rightarrow \text{CaSO}_4$). Because the actual air required is the desired calculation result, the theoretical air is corrected for unburned carbon and sulfation reactions.

$$MQTHAC = THAC \times \frac{100}{HHV} \quad (26)$$

and

$$THAC = 11.51 \times CB + 34.29 \times H_2 + [4.31 \times S \times (1 + 0.5 \times MFSC)] - 4.32 \times O_2 \quad (27)$$

where

$MQTHAC$ = theoretical air, corrected, lb/10,000 Btu

$THAC$	= theoretical air, corrected, lb/100 lb fuel
HHV	= higher heating value, Btu/lb
CB	= mass percent carbon burned
	= percent carbon in fuel – UBC , %
H_2	= mass percent hydrogen in fuel, %
S	= mass percent sulfur in fuel, %
$MFSC$	= mass fraction sulfur captured by furnace sorbent, lb/lb sulfur
O_2	= mass percent oxygen in fuel, %
UBC	= unburned carbon percent from fuel, %

For test purposes, the unburned carbon is measured. For design calculations, the unburned carbon may be calculated from the estimated unburned carbon loss, $UBCL$:

$$UBC = UBCL \times \frac{HHV}{14,500} \quad (28)$$

$MFSC$ is the sulfur capture/retention ratio or mass of sulfur captured per mass sulfur available from the fuel. It is zero unless a sorbent, e.g., limestone, is used in the furnace to reduce SO_2 emissions. See *Flue gas analysis* to determine $MFSC$ for test conditions.

The mass of dry air, $MQDA$, water in air, $MQWA$, and wet air, MQA , are calculated from the following equations:

$$MQDA = MQTHAC \times \left(1 + \frac{PXA}{100}\right) \quad (29)$$

$$MQWA = MA \times MQDA \quad (30)$$

$$MQA = MQDA + MQWA = MQDA \times (1 + MA) \quad (31)$$

where

$MQDA$	= mass dry air, lb/10,000 Btu
$MQTHAC$	= theoretical air, lb/10,000 Btu
PXA	= percent excess air, %
$MQWA$	= mass of moisture in air, lb/10,000 Btu
MA	= moisture in air, lb/lb dry air
MQA	= mass of wet air, lb/10,000 Btu

Flue gas

The total gaseous products of combustion are referred to as *wet flue gas*. Solid products or residue are excluded. The wet flue gas flow rate is used for heat transfer calculations and design of auxiliary equipment. The total gaseous products excluding moisture are referred to as *dry flue gas*; this parameter is used in the efficiency calculations and determination of flue gas enthalpy.

The wet flue gas is the sum of the wet gas from fuel (fuel less ash, unburned carbon and sulfur captured), combustion air, moisture in the combustion air, additional moisture such as atomizing steam and, if sorbent is used, carbon dioxide and moisture from sorbent. Dry flue gas is determined by subtracting the summation of the moisture terms from the wet flue gas.

Wet gas from fuel is the mass of fuel less the ash in the fuel, less the percent unburned carbon and, when

sorbent is used to reduce SO₂ emissions, less the sulfur captured:

$$MQGF = [100 - AF - UBC - (MFSC \times S)] \times \frac{100}{HHV} \quad (32)$$

where

$MQGF$	= wet gas from fuel, lb/10,000 Btu
AF	= mass percent ash in fuel, %
UBC	= unburned carbon as mass percent in fuel, %
$MFSC$	= mass fraction of sulfur captured, lb/lb sulfur
S	= mass percent sulfur in fuel, %
HHV	= higher heating value, Btu/lb

Water from fuel is the sum of the water in the fuel, H₂O and the water produced from the combustion of hydrogen in the fuel, H₂:

$$MQWFF = [(8.937 \times H_2) + H_2O] \times \frac{100}{HHV} \quad (33)$$

where

$MQWFF$	= water from fuel, lb/10,000 Btu
H_2	= mass percent hydrogen in fuel, %
H_2O	= mass percent moisture in fuel, %

Refer to *Sorbents and other chemical additives* for calculating gas from sorbent (CO₂), $MQGSB$, and water from sorbent, $MQWSB$. The total wet gas weight, MQG , is then the sum of the dry air, water in air, wet gas from fuel and, when applicable, additional water, gas from sorbent (CO₂), and water from sorbent:

$$MQG = MQDA + MQWA + MQGF + MQWAD + MQGSB + MQWSB \quad (34)$$

where

MQG	= total wet gas weight, lb/10,000 Btu
$MQDA$	= mass dry air, lb/10,000 Btu
$MQWA$	= mass of moisture in air, lb/10,000 Btu
$MQGF$	= wet gas from the fuel, lb/10,000 Btu
$MQWAD$	= additional water such as atomizing steam, lb/10,000 Btu
$MQGSB$	= gas from the sorbent, lb/10,000 Btu
$MQWSB$	= water from the sorbent, lb/10,000 Btu

The total moisture in the flue gas, $MQWG$, is the sum of the water from fuel, water in air and, if applicable, additional water and water from sorbent.

$$MQWG = MQWFF + MQWA + MQWAD + MQWSB \quad (35)$$

Dry flue gas, $MQDG$ in lb/10,000 Btu, is the difference between the wet flue gas and moisture in the flue gas:

$$MQDG = MQG - MQWG \quad (36)$$

The percent moisture in flue gas is a parameter required to determine flue gas energy heat content or enthalpy (see *Enthalpy of air and gas*) and is calcu-

lated as follows:

$$MPWG = 100 \times \frac{MQWG}{MQG}, \% \quad (37)$$

For most fuels, the mass of solids, or residue, in the flue gas is insignificant and can be ignored. Even when the quantity is significant, solids do not materially impact the volume flow rate of flue gas. However, solids add to the heat content, or enthalpy, of flue gas and should be accounted for when the ash content of the fuel is greater than 0.15 lb/10,000 Btu or when sorbent is used.

The mass of residue from fuel, $MQRF$ in lb/10,000 Btu, is calculated from the following equation:

$$MQRF = (AF + UBC) \times \frac{100}{HHV} \quad (38)$$

where

$MQRF$	= residue from fuel, lb/10,000 Btu
AF	= mass percent ash in fuel, %
UBC	= unburned carbon as mass percent in fuel, %

The mass percent of solids or residue in the flue gas is then:

$$MPRG = 100 \times \frac{MQRF + MQSSB}{MQG} \quad (39)$$

where

$MPRG$	= mass percent solids or residue in flue gas, %
$MQSSB$	= spent sorbent, lb/10,000 Btu
MQG	= mass of gaseous combustion products excluding solids, lb/10,000 Btu

Efficiency

Efficiency is the ratio of energy output to energy input and is usually expressed as a percentage. The output term for a steam generator is the energy absorbed by the working fluid that is not recovered within the steam generator envelope. It includes the energy added to the feedwater and desuperheating water to produce saturated/superheated steam, reheat steam, auxiliary steam and blowdown. It does not include the energy supplied to preheat the entering air such as air preheater coil steam supplied by the steam generator. The energy input term is the maximum energy available when the fuel is completely burned, i.e., the mass flow rate of fuel, MRF , multiplied by the higher heating value of the fuel. This is conventionally expressed as:

$$\begin{aligned} \eta_f &= 100 \times \frac{\text{Output}}{\text{Input fuel}} \\ &= 100 \times \frac{\text{Output}}{MRF \times HHV}, \% \end{aligned} \quad (40)$$

and is commonly referred to as steam generator fuel efficiency. In the U.S., it is customary to express steam generator efficiency on a higher heating value basis. Steam generator efficiency may also be expressed on

a lower heating value basis (common in Europe). For the same mass flow rate of fuel, the LHV efficiency may be 3 to 10 percentage points higher than the HHV efficiency, depending upon the amount of H_2 and H_2O in the fuel. When comparing steam generator efficiency and/or plant heat rate, they must be on the same basis, i.e., HHV or LHV.

Efficiency may be determined by measuring the mass flow rate of fuel and steam generator output, which is referred to as the input-output method, or by the energy balance method. The energy balance method is generally the preferred method. It is usually more accurate than the input-output method and is discussed below.

According to the law of conservation of energy, for steady-state conditions, the energy balance on the steam generator envelope can be expressed as:⁵

$$QRF = QRO + QHB, \text{ Btu/h} \quad (41)$$

where QRF is the input from fuel, Btu/h, QRO is the steam generator output, Btu/h, and QHB is the energy required by heat balance for closure, Btu/h. The heat balance energy associated with the streams entering the steam generator envelope and the energy added from auxiliary equipment power are commonly referred to as heat credits, QRB (Btu/h). The heat balance energy associated with streams leaving the steam generator and the heat lost to the environment are commonly referred to as heat losses, QRL (Btu/h). This steam generator energy balance may be written as:

$$\begin{aligned} QRF &= QRO + QHB \\ &= QRO + QRL - QRB, \text{ Btu/h} \end{aligned} \quad (42)$$

and the efficiency may be expressed as:

$$\eta_f = 100 \times \frac{QRO}{QRO + QRL - QRB}, \% \quad (43)$$

When losses and credits are expressed as a function of percent input from fuel, QPL and QPB , the efficiency may be calculated from:

$$\eta_f = 100 - QPL + QPB, \% \quad (44)$$

Most losses and credits are conveniently calculated on a percent input from fuel basis. However, some losses are more conveniently calculated on a Btu/h basis. The following expression for efficiency allows the use of mixed units; some of the losses/credits are calculated on a percent basis and some on a Btu/h basis.

$$\begin{aligned} \eta_f &= (100 - QPL + QPB) \\ &\times \left(\frac{QRO}{QRO + QRL - QRB} \right), \% \end{aligned} \quad (45)$$

For a more detailed understanding of losses and credits, refer to the American Society of Mechanical Engineers (ASME) Performance Test Code, PTC 4, for steam generators.

The general form for calculating losses (QPL_k) us-

ing the mass per unit of heat input basis to express the percent heat loss for individual constituents is:

$$\begin{aligned} QPL_k &= \frac{MQ_k \times MCP_k \times (TO_k - TR)}{100} \\ &= \frac{MQ_k \times (HO_k - HR_k)}{100}, \% \end{aligned} \quad (46)$$

where

$$\begin{aligned} MQ_k &= \text{mass of constituent } k, \text{ lb/10,000 Btu} \\ MCP_k &= \text{mean specific heat between } TO_k \text{ and } TR, \\ &\quad \text{Btu/lb } ^\circ\text{F} \\ TO_k &= \text{outlet temperature, } ^\circ\text{F} \\ TR &= \text{reference temperature, } ^\circ\text{F} \\ HO_k &= \text{outlet enthalpy, Btu/lb} \\ HR_k &= \text{reference enthalpy, Btu/lb} \end{aligned}$$

For units with gas to air heat exchangers, there is usually some air leakage from the air inlet to the gas outlet. This leakage lowers the gas temperature leaving the air heater (measured gas temperature) without performing any useful work. It is recommended that the calculated gas temperature leaving the air heater without leakage be used for TO_k above, in accordance with PTC 4 (see Chapter 20 for calculation). For this case, the dry gas weight is based on the excess air entering the air heater. Other codes, including the older PTC 4.1, may use the measured gas temperature leaving the air heater, in which case, the dry gas weight must be based on the excess air leaving the air heater.

The reference temperature for PTC 4 is 77F (25C) and the calculation of both losses and credits are required to determine efficiency. The energy credit will be negative for any stream entering the steam generator envelope at a temperature lower than the reference temperature. The most significant credit is generally the energy in the entering air. The entering air temperature (air temperature entering the boundary) is the air temperature leaving the forced draft fans or leaving the air pre-heater coils (entering an air to gas heat exchanger) if the source of energy (steam) is external to the steam generator. When air pre-heater coils are used and the energy is supplied by steam from the steam generator, the entering air temperature is the air temperature entering the pre-heater coils. The air temperature entering the fan(s) is usually taken as the design ambient condition, but may be some other specified condition such as when the fan inlets are supplied by air from within the building. The fan compression energy (typically 1/2 degree F per 1 in. wg fan pressure rise) may be considered to establish the fan discharge temperature. Some test codes, including the older PTC 4.1, may use some other arbitrary reference temperature or the entering air temperature as the reference temperature. An advantage of using the entering air temperature as the reference temperature is that it eliminates the need to calculate credits for entering air and moisture in air.

The general form for calculating credits (QPB_k) us-

ing the mass per unit of input basis to express the quantity of individual constituents is:

$$QPB_k = \frac{MQ_k \times MCP_k \times (TI_k - TR)}{100} = \frac{MQ_k \times (HI_k - HR_k)}{100}, \% \quad (47)$$

where

TI_k = inlet temperature, F
 HI_k = inlet enthalpy, Btu/lb

and other terms were defined in Equation 46.

The terms used to calculate losses and credits that are a function of fuel input have been discussed previously. The other losses and credits are described below.

Surface radiation and convection loss

This is the heat lost to the atmosphere from the boiler envelope between the first and the last heat trap (commonly between the steam generator air inlet and the boiler exit or air heater exit). Surfaces include the boiler casing, flues and ducts, piping and other surfaces above ambient temperature as a result of the energy entering the unit. It is a function of the average velocity and the difference between the average surface temperature and average ambient temperature. The U.S. industry and PTC 4 standard for calculating this heat loss use a temperature differential of 50F (for insulated surfaces) and a surface velocity of 100 ft/min. For PTC 4, the heat loss is based on the actual flat projected area of the unit and standard ASME Performance Test Code heat transfer coefficients. For convenience, the American Boiler Manufacturers Association (ABMA) standard radiation loss chart, shown in Chapter 23, may be used for an approximation. The ABMA curve expresses the radiation loss on a percent of gross heat input basis as a function of steam generator output (percent gross heat input may be interpreted as heat input from fuel for most applications). This curve is the basis for the surface radiation and convection loss prior to the release of PTC 4 and is approximately the same as PTC 4 for oil- and gas-fired units. For coal-fired units, due to the requirement for a larger furnace and convection surface area due to the requirement for lower gas velocities, the PTC 4 radiation loss is typically on the order of 2 to 2.5 times greater than the ABMA curve.

Unburned carbon loss

For design of a unit, this is normally estimated based on historical data and/or combustion models. For an efficiency test, this item is calculated from measured unburned carbon in the residue. (See *Unburned carbon*.)

Other losses and manufacturers' margins

When testing a unit, it is usually only economically practical to measure the major losses and credits. The other minor losses (and credits) are estimated or based on historical data. Accordingly, when designing a unit, the individual losses and credits to be tested are itemized separately and the estimated losses (and credits)

are grouped together and referred to as *Other* losses and credits (also referred to as *Unaccounted for* or *Unmeasured* losses). The most typical Other losses are CO (0.05% loss for 145 ppm or 0.12 lb/10⁶ Btu), NO_x (0.01% for 50 ppm or 0.07 lb/10⁶ Btu), radiation to the furnace ash pit (0.03% loss for a typical radiation rate of 10,000 Btu/ft² h), pulverizer rejects (0.02% loss for a reject rate of 0.25% of fuel flow at a higher heating value of 1000 Btu/lb and 170F/77C mill outlet temperature), and unburned hydrocarbons/VOCs (normally negligible and assumed to be zero). In addition, the manufacturer normally adds a margin, or safety factor, to the losses to account for unexpected performance deviations and test measurement uncertainty. Typical design values for these margins are 0 to 0.5% of heat input for gas, oil and coals with good combustion characteristics and slagging/fouling properties to 0 to 1.5% of heat input or higher for fuels with poor combustion characteristics and poor slagging/fouling characteristics. In the evaluation of actual unit efficiency, the minor or Other losses that are not measured should be estimated and agreed to.

Enthalpy

Enthalpy of air and gas

Enthalpy, H , in Btu/lb is an indication of the relative energy level of a material at a specific temperature and pressure. It is used in thermal efficiency, heat loss, heat balance and heat transfer calculations (see Chapter 2). Extensive tabulated and graphical data are available such as the ASME Steam Tables summarized in Chapter 2. Except for steam and water at high pressure, the pressure effect on enthalpy is negligible for engineering purposes.

Enthalpies of most gases used in combustion calculations can be curve-fitted by the simple second order equation:

$$H = aT^2 + bT + c \quad (48)$$

where

H = enthalpy in Btu/lb
 T = temperature in degrees, F

To determine the enthalpy of most gases used in combustion calculations at a temperature, T , Equation 48 can be used with the coefficients summarized in Table 12. Reference 6 is the source for the properties and the curve fits are in accordance with Reference 7. The curve fits are within plus or minus 0.2 Btu/lb for enthalpies less than 40 Btu/lb and within plus or minus 0.5% for larger values. If the enthalpy of a fluid is known, the temperature in degrees F can be evaluated from the quadratic equation:

$$T = \frac{-b + \sqrt{b^2 - 4a(c - H)}}{2a} \quad (49)$$

For mixtures of gases, such as dry air and water vapor or flue gas and water vapor, Equation 48 coefficient, a , b and c can be determined by a simple mass

average:

$$n_{mix} = \sum x_i n_i \quad (50)$$

where

n_{mix} = equivalent coefficient a , b or c of the mixture
 x_i = mass fraction of constituent i
 n_i = coefficient a , b or c for constituent i

For convenience, Table 12 lists coefficients for a number of gas mixtures including standard wet air with 0.013 lb H₂O per lb dry air. In addition, Figs. 3 and 4 provide graphical representations of flue gas and standard air enthalpy.

Another method of evaluating the change in specific enthalpy of a substance between conditions 1 and 2 is to consider the specific heat and temperature difference:

$$H_2 - H_1 = c_p (T_2 - T_1) \quad (51)$$

where

H = enthalpy, Btu/lb
 c_p = specific heat at constant pressure, Btu/lb F
 T = temperature, F

Enthalpy of solids and fuels

Enthalpy of coal, limestone and oil can be evaluated from the following relationships:

Coal:⁸

$$H = [(1 - W_F)(0.217 + 0.00248 VM) + W_F](T - 77) \quad (52)$$

Limestone:

$$H = [(1 - W_F)H_{LS} + W_F](T - 77) \quad (53)$$

and

$$H_{LS} = (0.179T) + (0.1128 \times 10^{-3} T^2) - 14.45 \quad (54)$$

Oil:⁹

$$H = C_1 + C_2(API) + C_3T + C_4(API)T + [C_5 + C_6(API)]T^2 \quad (55)$$

and

$$API = (141.5 - 131.5 SPGR) / SPGR \quad (56)$$

Fig. 4 Enthalpy of air assuming 0.987 mass fraction dry air plus 0.013 mass fraction of water vapor.

Measurement of excess air

One of the most critical operating parameters for attaining good combustion is excess air. Too little air can be a source of excessive unburned combustibles and can be a safety hazard. Too much excess air increases stack gas losses.

Flue gas analysis

The major constituents in flue gas are CO₂, O₂, N₂ and H₂O. Excess air is determined by measuring the O₂ and CO₂ contents of the flue gas. Before proceeding with measuring techniques, consider the form of the sample. A flue gas sample may be obtained on a wet or dry basis. When a sample is extracted from the gas stream, the water vapor normally condenses and the sample is considered to be on a dry basis. The sample is usually drawn through water near ambient temperature to ensure that it is dry. The major constituents of a dry sample do not include the water vapor in the flue gas. When the gas is measured with an in situ analyzer or when precautions are taken to keep the moisture in the sample from condensing, the sample is on a wet basis.

The amount of O₂ in the flue gas is significant in defining the status of the combustion process. Its presence always means that more oxygen (excess air) is being introduced than is being used. Assuming complete combustion, low values of O₂ reflect moderate excess air and normal heat losses to the stack, while higher values of O₂ mean needlessly higher stack losses.

The quantity of excess O₂ is very significant since it is a nearly exact indication of excess air. Fig. 5 is a dry flue gas volumetric combustion chart that is universally used in field testing; it relates O₂, CO₂ and N_{2a} (by difference). For complete uniform combustion of a specific fuel, all points should lie along a straight line drawn through the pivot point. This line is referred to as the combustion line. The combustion line should be determined by calculating the CO₂ content at zero O₂ for the test fuel (see Table 15). Lines indicating constant excess air have been superimposed on the volumetric combustion chart. Note that excess air is essentially constant for a given O₂ level over a wide range

of fuels. The O₂ is an equally constant indication of excess air when the gas is sampled on a wet or in situ basis because the calculated excess air result is insensitive to variations in moisture for specific types/sources of fuel.

The current industry standard for boiler operation is continuous monitoring of O₂ in the flue gas with in situ analyzers that measure oxygen on a wet basis.

For testing, the preferred instrument is an electronic oxygen analyzer. The Orsat unit, which measures (CO₂ + SO₂) and O₂ on a dry volumetric basis, remains a trusted standard for verifying the performance of electronic equipment. The Orsat uses chemicals to absorb the (CO₂ + SO₂) and O₂, and the amount of each is determined by the reduction in volume from the original flue gas sample. When an Orsat is used, the dry flue gas volumetric combustion chart should be used to plot the results. Valid results for any test with a consistent fuel should fall on a single combustion line (plus or minus 0.2 points of O₂/CO₂ is a reasonable tolerance). The Orsat has several disadvantages. It lacks the accuracy of more refined devices, an experienced operator is required, there are a limited number of readings available in a test, and the results do not lend themselves to electronic recording. Electronic CO₂ analyzers may be used in addition to oxygen analyzers to relate the O₂/CO₂ results to the fuel line on the volumetric combustion chart. When CO₂ is measured, by Orsat or a separate electronic analyzer, it is best to calculate excess air based on the O₂ result due to the insensitivity of excess air versus O₂ results in the fuel analysis.

Depending upon whether O₂ is measured or excess air known, the corresponding excess air, O₂, CO₂ and SO₂ can be calculated using procedures provided in ASME Performance Test Code 4, *Steam Generators*.⁵ The calculations are summarized in Table 15 at the end of this chapter in the *Combustion calculations – examples* section.

Flue gas sampling

To ensure a representative average gas sample, samples from a number of equal area points should be taken. Reference the U.S. Environmental Protection Agency (EPA) Method 1 standards and ASME Performance Test Code PTC 19.10. For normal performance testing, equal areas of approximately 9 ft² (0.8 m²) up to 24 points per flue are adequate.

For continuous monitoring, the number of sampling points is an economic consideration. Strategies for locating permanent monitoring probes should include point by point testing with different burner combinations. As a guideline, four probes per flue located at quarter points have been used successfully on large pulverized coal-fired installations.

Testing heterogeneous fuels

When evaluating the performance of a steam generator firing a heterogeneous fuel such as municipal solid waste (MSW) (see Chapter 29), it is generally not possible to obtain a representative fuel sample. Waste fuel composition may vary widely between samples and is usually not repeatable.

Fig. 5 Dry flue gas volumetric combustion chart.

For boiler design, an ultimate analysis for an average fuel and a range of the most significant components, such as moisture and ash, are used. Therefore, the design calculations are the same as those for homogeneous fuels.

When firing a heterogeneous fuel, the current industry practice used to evaluate average fuel properties and determine boiler efficiency is to test using the boiler as a calorimeter (BAC). The BAC method features the same principles for determining efficiency as those used when the fuel analysis is known. The significant difference is that the mass/volume flow rate of flue gas and moisture in the flue gas are measured directly rather than being calculated based upon the measured fuel analysis and O_2 in the flue gas.

The additional measurements that are required for the BAC test method versus conventional test methods are flue gas flow, moisture in flue gas, O_2 and CO_2 in the flue gas, and residue mass flow rates from the major extraction points.

BAC calculation method

This section describes how to calculate excess air, dry gas weight and water from fuel (water evaporated). The results are on a mass per unit of time basis and losses and credits, therefore, are calculated as Btu/h. Refer to the basic efficiency equations for application. (See Equations 42 and 43.)

The wet gas weight and water in the wet gas are measured. The dry gas weight is then calculated as the difference of the two.

The composition of flue gas is determined by measuring O_2 and CO_2 . N_{2a} is determined by difference from 100%. The nitrogen in flue gas is considered to be atmospheric with a molecular weight of 28.158 lb/mole. Because waste fuel combustors operate at high levels of excess air and the nitrogen in the fuel is small, this nitrogen can be ignored.

The moisture in the flue gas may be from vapor or liquid sources. Vapor sources include moisture in the air and atomizing steam. Water sources are moisture in the fuel, moisture formed by combustion of H_2 , water from ash quenching systems, and fuel pit water spray. The moisture in air and that from other vaporous sources must be measured, so the sensible heat efficiency loss may be differentiated from the water evaporated loss. The water evaporated is the total moisture in the flue gas less the vaporous sources. The water evaporation loss is calculated in the same manner as the water from fuel loss and is analogous to the total water from fuel loss if miscellaneous water sources are accounted for.

The total dry air flow at the point of flue gas measurement is calculated from the nitrogen in the flue gas. Excess air is determined from the measured O_2 and theoretical air is calculated by difference from the total air flow. The percent excess air is calculated from the excess air and theoretical air weight flow rates.

Combustion calculations – examples

The detailed steps in the solution of combustion problems are best illustrated by examples. The ex-

amples in this section are presented through calculation forms which are a convenient method for organizing the calculations in a logical sequence. The input required to complete the forms is located at the top of the form. An elemental fuel analysis on a mass basis is used for all of the examples. For gaseous fuels, the analysis on a volume basis must be converted to an elemental mass basis as described in *Molar evaluation of combustion*. The calculations required are shown as a combination of item numbers (enclosed in brackets) and constants.

Mole method

The mole method is the fundamental basis for all combustion calculations. It is the source for the constants used in other more simplified methods. The only constants the user needs are the molecular weights of the fuel and air constituents. The reader should understand the mole method before proceeding with the Btu method.

Table 7 is an example of the combustion calculations for a bituminous coal on a molar basis. Items 1 through 6 are the required input. If the unburned carbon is known (Item 6), the unburned carbon loss (Item 5) is calculated. Provision is made for entering the excess air to the burners and excess air leaving the boiler if the user desires to account for setting infiltration (Item 1). For this example, the excess air to the burners is assumed to be the same as that leaving the boiler. An intermediate step in the calculations on a molar basis is the volumetric flue gas analysis (Items 20 and 21). Air and gas mass flow rates are shown on a lb/10,000 Btu basis as well as a 1000 lb/h basis.

Btu method

Once the reader understands the principles of the combustion calculations on a mole basis, the Btu method is the preferred method for general combustion calculations. The calculations provided in Table 13A are more comprehensive than the simple calculation of air and gas weights shown in Table 7. Provision is made for handling the impact of sorbent on the combustion calculations, the calculation of efficiency and finally heat available to the furnace.

The inputs to Table 13A are similar to those used in Table 7. The same fuel analysis and excess air are used and the calculated input from fuel is very nearly the same. These inputs are also the same as those used in the example performance problem in Chapter 22. Items 1 through 19 are the inputs and initial calculations required for the combustion calculations. For the efficiency calculations, Items 44 through 46 must be provided. If sorbent is used, Table 14, *Combustion Calculations – Sorbent*, must be completed first. (See Items 11 through 14 and 46). Because the entering air temperature and fuel temperature are the same as the reference temperature selected (80F), the efficiency credits are zero. The total fuel heat is calculated from the efficiency, Item 53, and steam generator output, Item 10. Flue gas and air flow rates are calculated from the fuel input and the results of the combustion gas calculations.

Table 13A shows the calculation results for a typi-

cal eastern U.S. coal. A similar set of calculations can be made for a typical western subbituminous coal which has an increased moisture content (30% by weight) and reduced LHV (8360 Btu/lb).

For the same boiler rating and other boundary conditions, the results can be compared on a lb per 10,000 Btu basis:

	Eastern Bit.	Western Subbit.	No. 6 Oil	Natural Gas
Theoretical air	7.572	7.542	7.437	7.220
Dry air	9.086	9.050	8.924	8.664
Dry gas weight	9.442	9.463	8.965	8.194
Wet gas weight	9.864	10.303	9.583	9.236
H ₂ O in gas	0.422	0.840	0.618	1.042
Efficiency, %	86.91	82.10	85.30	80.79

The theoretical air, dry air and resulting dry gas weight are approximately the same for each coal. The wet gas weight and H₂O in gas are higher for the subbituminous coal due to the higher moisture content. Referring to the efficiency calculations and losses, the efficiency is lower for the subbituminous coal essentially due to the higher moisture content, not the lower heating value. However, if the actual mass flow rates for subbituminous coal versus an eastern bituminous coal are compared, it will be found that a higher air weight is required primarily due to the lower efficiency, while a higher gas weight is required due to the higher moisture in the fuel and the lower efficiency.

Table 13B is the same example as shown in Table 13A except that it is assumed that a limestone sorbent is used in a fluidized bed at a calcium to sulfur molar ratio of 2.5. A sulfur capture of 90% is expected. A

higher unburned carbon loss is used, typical of this combustion process. It is necessary to complete the calculations shown in Table 14 to develop input for this Table. The net losses due to sorbent, Item 46 in Table 13B, are not overly significant. Therefore, the difference in efficiency from the example in Table 13A is primarily due to the difference in the assumed unburned carbon loss.

When testing a boiler, the excess air required for the combustion calculations is determined from measured O₂ in the flue gas. Table 15A, *Excess Air Calculations from Measured O₂*, demonstrates the calculation of excess air from O₂ on a wet basis. The fuel analysis and unburned carbon are the same as in Tables 7 and 13A. These tables can also be used to determine the volumetric composition of wet or dry flue gas when excess air is known (Items 25 through 32). These values can be compared to the flue gas composition calculated on a molar basis, Table 7.

Table 15B is an example of calculating excess air from O₂ when a sorbent is used. All of the sulfur in the fuel will not be converted to sulfur dioxide. Therefore, the sulfur capture must first be determined from Table 16, *Sulfur Capture Based on Gas Analysis*. The example presented in Tables 13B and 14 is used as the basis for this example. The flue gas composition in Tables 13A and 13B can be compared to assess the impact of adding the sorbent.

When units firing municipal solid waste or refuse-derived fuels are tested, it is not practical to determine the ultimate analysis of the fuel. Table 17, *Combustion Calculations – Measured Gas Weight*, shows the combustion calculations for determining dry gas weight, water evaporated and excess air using measured gas weight.

Chapter 11

Oil and Gas Utilization

Before the industrial revolution, distilled petroleum products were used primarily as a source of illumination. Today, petroleum finds its primary importance as an energy source and greatly influences the world's economy. The following discusses the use of petroleum products and natural gas as energy sources for steam generation.

Fuel oil

Preparation

Petroleum or crude oil is the source of various fuel oils used for steam generation ([Fig. 1](#), facing page). Most petroleum is refined to some extent before use although small amounts are burned without processing. Originally, refining petroleum was simply the process of separating the lighter compounds, higher in hydrogen, from the heavier compounds by fractional distillation. This yielded impure forms of kerosene, gasoline, lubricating oils and fuel oils. Through the development of refining techniques, such as thermal cracking and reforming, catalytic reforming, polymerization, isomerization and hydrogenation, petroleum is now regarded as a raw material source of hydrogen and carbon elements that can be combined as required to meet a variety of needs.

In addition to hydrocarbons, crude oil contains compounds of sulfur, oxygen and nitrogen and traces of vanadium, nickel, arsenic and chlorine. Processes are used during petroleum refinement to remove impurities, particularly compounds of sulfur. Purification processes for petroleum products include sulfuric acid treatment, sweetening, mercaptan extraction, clay treatment, hydrogen treatment and the use of molecular sieves.

The refining of crude oil yields a number of products having many different applications. Those used as fuel include gasoline, distillate fuel, residual fuel oil, jet fuels, still gas, liquefied gases, kerosene and petroleum coke. Products for other applications include lubricants and waxes, asphalt, road oil, and petrochemical feedstock.

Fuel oils for steam generation consist primarily of residues from the distillation of crude oil. As refinery methods improve, the quality of residual oil available

for utility and industrial steam generation is deteriorating. High sulfur fuels containing heavy components create challenges during combustion that range from high particulate and sulfur oxide emissions to higher maintenance costs due to the corrosive constituents in the flue gas.

Transportation, storage and handling

The high heating value per unit of volume of oil, its varied applications, and its liquid form have fostered a worldwide system of distribution. The use of supertankers for the transportation of crude oil has significantly reduced transportation costs and has allowed refineries to be located near centers of consumption rather than adjacent to the oil fields. Large supertankers, up to 250,000 t (227,000 t_m), are capable of transporting nearly 2,000,000 bbl (318,000 m³) of crude oil at a time to deepwater ports.

Tanker and barge shipments on coastal and inland waterways are by far the cheapest method of transporting the various grades of oil. With the depletion of oil fields in the eastern United States (U.S.), crude oil trunk lines were developed in the early 1900s to transport oil from points west of the Mississippi River to the east coast refineries. Today, more than 170,000 mi (274,000 km) of pipeline, including small feeder lines, are used for the transportation of oil within the U.S. Much smaller quantities of oil are shipped overland by rail and truck because of the higher cost of haulage.

Fuel oil systems require either underground or surface storage tanks. Oil is usually stored in cylindrical shaped steel tanks to eliminate evaporation loss. Loss in storage of the relatively nonvolatile heavy fuel oils is negligible. Lighter products, such as gasoline, may volatilize sufficiently in warm weather to cause appreciable loss. In this instance, storage tanks with floating roofs are used to eliminate the air space above the fuel where vapors can accumulate. The National Fire Protection Association (NFPA) has prepared a standard set of codes for the storage and handling of oils (NFPA 30 and 31). These codes serve as the basis for many local ordinances and are required for the safe transportation and handling of fuel products.

Extensive piping and valving and suitable pumping and heating equipment are necessary for the

transportation and handling of fuel oil. Storage tanks, piping and heaters for heavy oils must be cleaned periodically because of fouling or sludge accumulation.

Fuel properties

Safe and efficient transportation, handling and combustion of fuel oil requires a knowledge of fuel characteristics. Principal physical properties of fuel oils, important to boiler applications, are summarized below (see Chapter 9 for typical fuel oil physical property values):

Viscosity The viscosity of an oil is the measure of its resistance to internal movement, or flow. Viscosity is important because of its effect on the rate at which oil flows through pipelines and on the degree of atomization obtained by oil firing equipment.

Ultimate analysis An ultimate analysis is used to determine theoretical air requirements for combustion of the fuel and also to identify potential environmental emission characteristics.

Heating value The heating value of a liquid fuel is the energy produced by the complete combustion of one unit of fuel [Btu/lb (J/kg)]. Heating value can be reported either as the gross or higher heating value (HHV) or the net or lower heating value (LHV). To determine HHV, it is assumed that any water vapor formed during combustion is condensed and cooled to the initial temperature (i.e., all of the chemical energy is available). The heat of vaporization of the water formed is included in the HHV. For LHV, it is assumed that the water vapor does not condense and is not available. The heating value determines the quantity of fuel necessary to achieve a specified heat input.

Specific gravity Specific gravity (sp gr) is the ratio of the density of oil to the density of water. It is important because fuel is purchased by volume, in gallons (l) or barrels (m³). The most widely used fuel oil gravity scale is degree API devised by the American Petroleum Institute; its use is recommended by the U.S. Bureau of Standards and the U.S. Bureau of Mines. The scale is based on the following formula:

$$\text{degrees API} = \frac{141.5}{\text{sp gr at } 60/60\text{F (16/16C)}} - 131.5$$

[sp gr at 60/60F (16/16C) means when both oil and water are at 60F (16C)]

Flash and fire point Flash point is the lowest temperature at which a volatile oil will give off explosive or ignitable vapors. It is important in determining oil handling and storage requirements. The fire point is the temperature to which a liquid must be heated to produce vapors sufficient for continuous burning when ignited by an external flame.

Pour point The pour point is the temperature at which a liquid fuel will first flow under standardized conditions.

Distillation Distillation determines the quantity and number of fractions which make up the liquid fuel.

Water and sediment Water and sediment are a measure of the contaminants in a liquid fuel. The sediment normally consists of calcium, sodium, magnesium, and iron compounds. Impurities in the fuel provide an indication of the potential for plugging of fuel handling and combustion equipment.

Carbon residue Residue that remains after a liquid fuel is heated in the absence of air is termed carbon residue. The tests commonly used to determine carbon residue are the Conradson Carbon Test and the Ramsbottom Carbon Test. Carbon residue gives an indication of the coking tendency of a particular fuel (i.e. the tendency of oil, when heated, to form solid compounds).

Asphaltene content Asphaltenes are long chain, high molecular weight hydrocarbon compounds. The asphaltene content of a petroleum product is the percentage by weight of wax free material insoluble in n-heptane but soluble in hot benzene. Their structure requires high temperatures and high atomization energy for the fuel to burn completely. Higher asphaltene content indicates a higher potential to produce particulate emissions.

Burning profile Burning profile is a plot of the rate at which a sample of fuel burns under standard conditions as temperature is increased at a fixed rate. The burning profile is a characteristic fingerprint of the fuel oxidized under standard conditions and is not intended to provide absolute kinetic and thermodynamic data. It helps evaluate combustion characteristics of various fuels on a relative basis to determine excess air and residence time necessary for complete combustion.

Natural gas

Preparation

Natural gas, found in crude oil reservoirs, either dissolved in the oil or as a gas cap above the oil, is called associated gas. Natural gas is also found in reservoirs that contain no oil and is termed non-associated gas.

Natural gas, directly from the well, must be treated to produce commercially marketable fuels. Initially, natural gas undergoes a process to remove condensate which is distilled to produce butane, propane and stabilized gasoline. Propane and butane are widely used as bottle gas. They are distributed and stored liquefied under pressure. When the pressure is released, the liquid boils, producing a gaseous fuel.

Natural gas may contain enough sand or gaseous sulfur compounds to be troublesome. The sand is usually removed at the source. Natural gas containing excessive amounts of hydrogen sulfide, commonly known as sour gas, can be treated by a process known as sweetening. Sweetening removes hydrogen sulfide as well as carbon dioxide. Additional treatments include the removal of mercaptan by soda fixation and the extraction of long chain hydrocarbons.

Where natural gas is used to replace or supplement manufactured gas, it is sometimes reformed to bring its heating value in line with the manufactured gas. Natural gas may also be mixed directly with manufactured gas to increase the heating value of the final product.

Transportation, storage and handling

Pipelines are an economical means of transporting natural gas in its gaseous form. The rapid increase in consumption of natural gas in areas far from the source has resulted in an extensive system of long distance pipelines. Natural gas can also be transported

by tanker when liquefied under pressure producing liquefied natural gas (LNG).

The distribution of natural gas is subject to some practical limitations because of the energy required for transportation. High pressures, in the order of 1000 psig (6895 kPa), are necessary for economic pipeline transportation over long distances. Compression stations are needed at specified intervals to boost the pressure due to losses in the line.

In general, it is not practical to vary the supply of natural gas to accommodate the hourly or daily fluctuations in consumer demand. For economic reasons, long distance pipelines operate with a high load factor. The rate of withdrawal from the wells may often be limited for conservation reasons, and the cost of the pipeline to provide the peak rate would be prohibitive. Therefore, to meet fluctuations in demand, it is usually necessary to provide local storage or to supplement the supply with manufactured gas for brief periods.

Above ground methods of storage include: 1) large water seal tanks, 2) in-pipe holders laid parallel to commercial gas lines, and 3) using the trunk transmission line as a reservoir by building up the line pressure. In consumer areas where depleted or partially depleted gas and oil wells are available, underground storage of gas pumped back into these wells provides, at minimum cost, the large storage volume required to meet seasonal variations in demand. In liquid form, natural gas can be stored in insulated steel tanks or absorbed in a granular substance, released by passing warm gas over the grains.

Fuel properties

Natural gas is comprised primarily of methane and ethane. Physical properties of practical importance to boiler applications include constituents by volume percent, heating value, specific gravity, sulfur content and flammability (see Chapter 9 for typical natural gas physical property values).

Other liquid and gaseous fuels

Numerous combustion system applications utilize liquid or gaseous fuels other than conventional fuel oils or natural gas. These fuels include Orimulsion®, blast furnace gas, coke oven gas, refinery gas, regenerator offgas, landfill gas, and other byproduct gases.

The large heavy hydrocarbon and bitumen reserves available in Venezuela have led to a bitumen oil emulsion fuel that has gained acceptability. Orimulsion is the trade name for a commercially established fossil fuel oil emulsion. It consists of natural bitumen dispersed in water, in approximately a 70/30 proportion split. The resulting emulsion is stabilized by a surfactant package. Orimulsion can be transported over land or water and stored for extended periods while maintaining a consistent quality. Although it can be handled using most of the equipment and systems originally designed for heavy fuel oil, Orimulsion requires some special handling and combustion considerations because of its emulsified state. In addition, although the fuel exhibits very good combustion characteristics, it contains relatively high levels of sulfur,

nitrogen, ash, asphaltene, vanadium and other metals. Thus, careful design and cleanup considerations are important when firing a fuel with high levels of these constituents.

Steel mill blast furnaces generate a byproduct gas containing about 25% carbon monoxide by volume. This fuel can be burned to produce steam for mill heating and power applications. Many mills also have their own coke producing plant, another source of byproduct fuel. Coke oven gas is an excellent fuel that burns readily because of its high free hydrogen content. With these gases, available supply pressures and the volumetric heating value of fuel may be different from that of natural gas. Therefore, gas components must be designed to accommodate the particular characteristics of the gas to be burned.

In the petroleum industry, refinery gas and regenerator offgas are frequently used as energy sources for boilers. Refinery gas is a mixture of gaseous hydrocarbon streams from various refinery processes. Depending on economic and technical considerations within the refinery, the compositions of these individual streams vary with process modifications and thus, the resultant refinery gas can change over time. Combustion equipment and controls for refinery gas must be suitably designed for this variability. Regenerator offgas, or CO (carbon monoxide) gas, is a high-temperature gas produced in catalytic cracking units. CO boilers have been developed to reclaim the thermal energy present in this gas (see Chapter 27).

Landfill gas is a combustible gas recovered by a gas collection system at a landfill. Its primary constituents are methane and carbon dioxide. Landfill gas processing systems filter suspended particulates and condensate from the gas stream. Additional processing may be done to further purify the gas, but trace contaminants that typically remain in the gas require special attention when designing fuel handling systems to minimize corrosion concerns.

Oil and gas combustion – system design

The burner is the principal equipment component for the combustion of oil and natural gas (Fig. 2). In utility and industrial steam generating units (both wall and corner-fired designs), the burner admits fuel and air to the furnace in a manner that ensures safe and efficient combustion while realizing the full capability of the boiler. Burner design determines mixing characteristics of the fuel and air, fuel particle size and distribution, and size and shape of the flame envelope.

The means of transporting, measuring and regulating fuel and air to the furnace, together with the burners, igniters and flame safety equipment, comprises the overall combustion system. The following factors must be considered when designing the combustion system and when establishing overall performance requirements:

1. the rate of feed of the fuel and air to comply with load demand on the boiler over a predetermined operating range,
2. the types of fuel to be fired including elemental constituents and characteristic properties of each fuel,

Fig. 2 Typical oil and gas utility boiler burner front.

3. the efficiency of the combustion process to minimize unburned combustibles and excess air requirements,
4. imposed limitations on emissions,
5. physical size and complexity of the furnace and burners to establish the most efficient and economic design,
6. hardware design and material properties of the combustion equipment to ensure reliable uninterrupted service for long firing periods, and
7. safety standards and procedures for control of the burners and boiler, including starting, stopping, load changes and variations in fuel.

The combustion system must be designed for optimum flexibility of operation, including the potential for variations in fuel type, fuel firing rate and combinations of burners in and out of service. Control must be simple and direct to ensure rapid response to varying load demands.

Combustion air is typically conveyed to the burners by forced draft fans. To improve both thermal and combustion efficiency and further ensure burner stability, combustion air is normally preheated to a temperature of 400 to 600F (204 to 316C) by air preheaters located downstream of the fans. The fans must be capable of delivering adequate quantities of air for complete combustion at a pressure sufficient to overcome losses across the air preheaters, burners, control dampers, and intervening duct work. The total combustion air is that required to theoretically burn all the fuel plus excess air necessary for complete combustion. (See Chapter 10.)

The fuel delivery system must be able to regulate fuel pressure and flow to the burners and must be safeguarded in accordance with applicable fire protection codes. Proper distribution of fuel to the burners, in multiple burner applications, is critical to safe and efficient operation of the combustion system. Piping and valves must be designed for allowable velocity limits, absolute pressure requirements, and pressure losses.

Performance requirements

Excess air

Excess air is the air supplied for combustion and cooling of idle burners in excess of that theoretically required for complete oxidation of the fuel. Excess air is generally required to compensate for imperfections in the air delivery system that results in maldistribution of combustion air to the burners. Excess air also helps compensate for imperfect mixing of the air and fuel in the furnace. At full load, with all burners in service, excess air required for gas and oil firing, expressed as a percent of theoretical air, is typically in the range of 5 to 10%, depending upon fuel type and the requirements of the combustion system. Operation at excess air levels below these values is possible if combustion efficiency does not deteriorate. Combustion efficiency is measured in terms of carbon monoxide, unburned combustibles in the ash, soot, particulate matter and stack opacity. Through careful design of the burners and the air delivery system, excess air can be held to a minimum, thereby minimizing sensible heat loss to the stack.

Operation at partial load requires additional excess air. When operating with all burners in service at reduced load, lower air velocity at the burners results in reduced mixing efficiency of the fuel and air. Increasing the excess air improves combustion turbulence and maintains overall combustion efficiency. Additional excess air and improved burner mixing also compensate for lower furnace temperature during partial load operation. In some instances, boiler performance dictates the use of higher than normal excess air at reduced loads to maintain steam temperature or to minimize cold end corrosion.

Additional excess air is also necessary when operating with burners out of service. Sufficient cooling air must be provided to idle burners to prevent overheating damage. Permanent thermocouples installed on selected burners measure metal temperatures and establish the minimum excess air necessary to maintain burner temperatures below the maximum use limits of the steel. Excess air for burner cooling varies with the percentage of burners out of service.

Stability and turndown

Proper burner and combustion system design will permit stable operation of the burners over a wide operating range. A stable burner, best determined through visual observation, is one where the flame front remains relatively stationary and the root of the flame is securely anchored near the burner fuel element. To ensure stable combustion, the burner must be designed to prevent blowoff or flashback of the flame for varying rates of fuel and air flow.

It is often desirable to operate over a wide boiler load range without taking burners out of service. This reduces partial load excess air requirements to cool idle burners. The burners must therefore be capable of operating in a turned down condition. Burner *turn-down* is defined as the ratio of full load fuel input to partial load input while still maintaining stable combustion. Limitations in burner turndown are gener-

ally dictated by fuel characteristics, fuel and air velocity, full load to partial load fuel pressures, and adequacy of the flame safety system. Automated and reliable flame safety supervision, with proper safeguards, must be available to achieve high burner turndown ratios.

With gas firing, a turndown ratio of 10:1 is not uncommon. Natural gas is easily burned and relatively easy to control. Residual oil, on the other hand, is more difficult to burn. Combustion characteristics are highly sensitive to particle size distribution, excess air and burner turbulence. A typical turndown ratio for oil is in the order of 6:1, depending upon fuel characteristics, flexibility of the delivery system and atomization technique.

Burner pulsation

Burner pulsation is a phenomenon frequently associated with natural gas firing and, to a lesser degree, with oil firing. Pulsation is thought to occur when fuel rich pockets of gas suddenly and repeatedly ignite within the flame envelope. The resultant pulsating burner flame is often accompanied by a noise referred to as *combustion rumble*. Combustion rumble may transmit frequencies that coincide with the natural frequency of the furnace enclosure resulting in apparent boiler vibration. In some instances, these vibrations may become alarmingly violent.

Boiler vibration on large furnaces can sometimes be attributed to a single burner. Minor air flow adjustment to a given burner, or removing select burners from service, may suddenly start or stop pulsations. Pulsation problems can be corrected through changes to burner hardware that affect mixing patterns of the fuel and air. Changes to the burner throat profile to correct anomalies in burner aerodynamics or changes to the fuel element discharge ports have successfully eliminated pulsation.

Historical operating data has enabled the development of empirical curves that are useful in designing burners to avoid pulsation. These curves relate the potential for burner pulsation to the ratio of burner fuel to air velocity. Together with careful consideration of furnace geometry, burner firing patterns and burner aerodynamics, problems with burner pulsation are becoming less common.

Combustion efficiency

Many factors influence combustion efficiency including excess air, burner mixing, fuel properties, furnace thermal environment, residence time, and particle size and distribution. Complete combustion occurs when all combustible elements and compounds of the fuel are entirely oxidized. In utility and industrial boilers, the goal is to achieve the highest degree of combustion efficiency with the lowest possible excess air. Thermal efficiency decreases with increasing quantities of excess air. Combustion performance is then measured in terms of the boiler efficiency loss due to incomplete combustion together with the efficiency loss due to sensible heat in the stack gases.

From the standpoint of optimum combustion efficiency, the following factors are critical to proper design:

1. careful distribution and control of fuel and air to the burners,
2. burner and fuel element design that provides thorough mixing of fuel and air and promotes rapid, turbulent combustion, and
3. proper burner arrangement and furnace geometry to provide sufficient residence time to complete chemical reactions in a thermal environment conducive to stable and self-sustained combustion.

In most cases, boiler efficiency loss due to unburned carbon loss (UCL) when firing oil and natural gas is virtually negligible. However, depending on fuel oil properties and the condition of the combustion system, the percent UCL can be in the order of 0.10% while firing oil. Combustion efficiency with these fuels is usually measured in terms of carbon monoxide (CO) emissions, particulate emissions and stack opacity. Generally, CO levels less than 200 ppm (corrected to 3% O₂) are considered satisfactory.

Emission control techniques

Ever increasing concern over atmospheric pollutants is changing the focus of wall and corner-fired boiler and combustion system designs. The combustion of fossil fuels produces emissions that have been attributed to the formation of acid rain, smog, changes to the ozone layer, and the so-called *greenhouse* effect. To mitigate these problems, federal and local regulations are currently in place that limit oxides of nitrogen, oxides of sulfur, particulate matter and stack opacity. While emission limits vary depending upon state and local regulations, the trend is toward more stringent control. (See also Chapter 32.)

Many combustion control techniques have emerged to reduce fossil fuel emissions. These techniques generally focus on the reduction of nitrogen oxides (NO_x), as changes to the combustion process can greatly influence NO_x formation and destruction.

Oxides of nitrogen

Nitrogen oxides in the form of NO and NO₂ are formed during combustion by two primary mechanisms: thermal NO_x and fuel NO_x. A secondary mechanism called prompt NO_x can also contribute to overall NO_x formation.

Thermal NO_x results from the dissociation and oxidation of nitrogen in the combustion air. The rate and degree of thermal NO_x formation is dependent upon oxygen availability during the combustion process and is exponentially dependent upon combustion temperature. Thermal NO_x reactions occur rapidly at combustion temperatures in excess of 2800F (1538C). Thermal NO_x is the primary source of NO_x formation from natural gas and distillate oils because these fuels are generally low in or devoid of fuel-bound nitrogen.

Fuel NO_x, on the other hand, results from oxidation of nitrogen organically bound in the fuel and is the primary source of NO_x formation from heavy fuel oil. Fuel bound nitrogen in the form of volatile compounds is intimately tied to the fuel hydrocarbon chains. For this reason, the formation of fuel NO_x is linked to both

fuel nitrogen content and fuel volatility. Inhibiting oxygen availability during the early stages of combustion, where the fuel devolatilizes, is the most effective means of controlling fuel NO_x formation.

Prompt NO_x is formed during the early, low temperature stages of combustion. Hydrocarbon fragments may react with atmospheric nitrogen under fuel-rich conditions to yield fixed nitrogen species. These, in turn, can be oxidized to NO in the lean zone of the flame. In most flames, especially those from nitrogen-containing fuels, the prompt mechanism is responsible for only a small fraction of the total NO_x .

Numerous combustion process NO_x control techniques are commonly used. These vary in effectiveness and cost. In all cases, control methods are mainly aimed at reducing either thermal NO_x , fuel NO_x , or a combination of both. A range of typical anticipated NO_x emission levels relative to various NO_x control mechanisms is shown in Fig. 3.

Low excess air Low excess air (LEA) effectively reduces NO_x emissions with little, if any, capital expenditure. LEA is a desirable method of increasing thermal efficiency and has the added benefit of inhibiting thermal NO_x . If burner stability and combustion efficiency are maintained at acceptable levels, lowering the excess air may reduce NO_x by as much as 5 to 15% from an uncontrolled baseline. The success of this method depends largely upon fuel properties and the ability to carefully control fuel and air distribution to the burners. Operation may require more sophisticated methods of measuring and regulating fuel and air flow to the burners and modifications to the air delivery system to ensure equal distribution of combustion air to all burners.

Burners out of service Essentially a simple form of two-stage combustion, burners out of service (BOOS) is a simple and direct method of reducing NO_x emissions. When removing burners from service in multiple burner applications, active burner inputs are typically increased to maintain load. Without changing total air flow, increased fuel input to the active burners results in a fuel rich mixture, effectively limiting oxygen availability and thereby limiting both fuel and thermal NO_x formation. Air control registers on the out of service burners remain open, essentially serving as staging ports.

While a fairly significant NO_x reduction is possible with this method, lower NO_x is frequently accompa-

nied by higher levels of CO in the flue gas and boiler back-end oxygen (O_2) imbalances. With oil firing, an increase in particulate emissions and increased stack opacity are likely. Through trial and error, some patterns of burners out of service may prove more successful than others. A limiting factor is the ability of existing burners to handle the increased input necessary to maintain full load operation. Short of derating the unit, changes to fuel element sizes may be required.

Two-stage combustion Two-stage combustion is a relatively long standing and accepted method of achieving significant NO_x reduction. Combustion air is directed to the burner zone in quantities less than that required to theoretically burn the fuel, with the remainder of the air introduced through overfire air ports. By diverting combustion air away from the burners, oxygen concentration in the lower furnace is reduced, thereby limiting the oxidation of chemically bound nitrogen in the fuel. By introducing the total combustion air over a larger portion of the furnace, peak flame temperatures are also lowered.

Appropriate design of a two-stage combustion system can reduce NO_x emissions by as much as 50% and simultaneously maintain acceptable combustion performance. The following factors must be considered in the overall design of the system.

1. **Burner zone stoichiometry** The fraction of theoretical air directed to the burners is predetermined to allow proper sizing of the burners and overfire air ports. Normally a burner zone stoichiometry in the range of 0.85 to 0.90 will result in desired levels of NO_x reduction without notable adverse effects on combustion stability and turndown.
2. **Overfire air port design** Overfire air ports must be designed for thorough mixing of air and combustion gases in the second stage of combustion. Ports must have the flexibility to regulate flow and air penetration to promote mixing both near the furnace walls and toward the center of the furnace. Mixing efficiency must be maintained over the anticipated boiler load range and the range in burner zone stoichiometries.
3. **Burner design** Burners must be able to operate at lower air flow rates and velocities without detriment to combustion stability. In a two-stage combustion system, burner zone stoichiometry is typically increased with decreasing load to ensure that burner air velocities are maintained above minimum limits. This further ensures positive windbox-to-furnace differential pressures at reduced loads.
4. **Overfire air port location** Sufficient residence time from the burner zone to the overfire air ports and from the ports to the furnace exit is critical to proper system design. Overfire air ports must be located to optimize NO_x reduction and combustion efficiency and to limit change to furnace exit gas temperatures.
5. **Furnace geometry** Furnace geometry influences burner arrangement and flame patterns, residence time and thermal environment during the first and second stages of combustion. Liberal furnace sizing is generally favorable for lower NO_x as combustion temperatures are lower and residence times are increased.

Fig. 3 Approximate NO_x emission reductions for oil and gas burners using various control techniques. (LEA = low excess air; BOOS = burner out of service; TSC = two-stage combustion; FGR = flue gas recirculation.)

6. **Air flow control** Ideally, overfire air ports are housed in a dedicated windbox compartment. In this manner, air to the NO_x ports can be metered and controlled separately from air to the burners. This permits operation at desired stoichiometric levels in the lower furnace and allows for compensation to the flow split as a result of air flow adjustments to individual burners or NO_x ports.

Additional flexibility in controlling burner fuel and air flow characteristics is required to optimize combustion under a two-stage system. Improved burner designs have addressed these needs.

In the reducing gas of the lower furnace, sulfur in the fuel forms hydrogen sulfide (H_2S) rather than sulfur dioxide (SO_2) and sulfur trioxide (SO_3). The corrosiveness of reducing gas and the potential for increased corrosion of lower furnace wall tubes is highly dependent upon H_2S concentration. Two-stage combustion is therefore not normally recommended when firing high sulfur residual fuel oils except when extra furnace wall protection measures are included.

Flue gas recirculation Flue gas recirculation (FGR) to the burners is instrumental in reducing NO_x emissions when the contribution of fuel nitrogen to total NO_x formation is small. For this reason, the use of gas recirculation is generally limited to the combustion of natural gas and fuel oils. By introducing flue gas from the economizer outlet into the combustion air stream, burner peak flame temperatures are lowered and NO_x emissions are significantly reduced. (See Fig. 4.)

Air foils are commonly used to mix recirculated flue gas with the combustion air. Flue gas is introduced in the sides of the secondary air measuring foils and exits through slots downstream of the air measurement taps. This method ensures thorough mixing of flue gas and combustion air before reaching the burners and does not affect the air flow metering capability of the foils.

In general, increasing the rate of flue gas recirculation to the burners results in an increasingly significant NO_x reduction. Target NO_x emission levels and limitations on equipment size and boiler components dictate the practical limit of recirculated flue gas for NO_x control. Other limiting factors include burner stability and oxygen concentration of the combustion air. Typically, oxygen content must be maintained at or above 17% on a dry basis for safe and reliable operation of the combustion equipment.

The expense of a flue gas recirculation system can be significant. Gas recirculation (GR) fans may be required for the desired flow quantities at static pressures capable of overcoming losses through the flues, ducts, mixing devices and the burners themselves. Additional controls and instruments are also necessary to regulate GR flow to the windbox at desired levels over the load range. In retrofit applications, significant cost is associated with routing of flues and ducts to permit mixing of the flue gas with combustion air. Also, the accompanying increase in furnace gas weight at full load operation may require modifications to convection pass surfaces or dictate changes to standard operating procedures.

From an operational standpoint, the introduction of flue gas recirculation as a retrofit NO_x control tech-

Fig. 4 Flue gas recirculation low NO_x system for oil and gas firing.

nique must, in virtually all cases, be accompanied by the installation of overfire air ports. Oil and gas burners, initially designed without future consideration to FGR, are not properly sized to accommodate the increase in burner mass flow as a result of recirculated flue gas. The quantity of flue gas necessary to significantly reduce NO_x emissions will, in all likelihood, result in burner throat velocities that exceed standard design practices. This, in turn, may cause burner instability, prohibitive burner differentials and in the case of gas firing, undesirable pulsation. Therefore, the installation of overfire air ports in conjunction with FGR serves two useful purposes, 1) lower NO_x emissions through two-stage combustion, and 2) a decrease in mass flow of air to the burners to accommodate the increased burden of recirculated flue gas.

When employing flue gas recirculation in combination with overfire air, it is desirable to house the overfire air ports in a dedicated windbox compartment separate from the burners. In this manner, it is possible to introduce recirculated flue gas to the burners only. This permits more efficient use of the GR fans and overall system design as only that portion of flue gas introduced through the burners is considered effective in controlling NO_x emissions.

An inexpensive means of recirculating lesser amounts of flue gas is *induced FGR*, or IFGR. Here, flue gas is introduced through the forced draft fan(s) and is restricted by the fans' capacity for flue gas. The effectiveness of IFGR is, as a result, limited.

Reburning Reburning is an in-furnace NO_x control technique that divides the furnace into three distinct zones (main, reburn, and burnout). By effectively staging both fuel and combustion air, NO_x emission reductions of 50 to 75% from baseline levels can be achieved. Heat input is spread over a larger portion of the furnace, with combustion air carefully regulated to the various zones to achieve optimum NO_x reduction (Fig. 5).

In reburning, the lower furnace or main burner zone provides the major portion of the total heat in-

put to the furnace. Depending on the percent NO_x reduction and the specific combustion system requirements, the main zone burners can be designed to operate at less than theoretical air to normal excess air levels. Combustion gases from the main burner zone then pass through a second combustion zone termed the reburning zone. Here, burners provide the remaining heat input to the furnace to achieve full load operation but at a significantly lower stoichiometry. By injecting reburn fuel above the main burner zone, a NO_x reducing region is produced in the furnace where hydrocarbon radicals from the partially oxidized reburn fuel strip oxygen from the NO molecules, forming nitrogen compounds and eventually molecular nitrogen (N_2). Overfire air ports are installed above the reburning zone where the remainder of air is introduced to complete combustion in an environment both chemically and thermally non-conducive to NO_x formation.

Application of this technology must consider a number of variables. System parameters requiring definition include: fuel split between the main combustion zone and the reburn zone, stoichiometry to the main and reburn burners, overall stoichiometry in the reburn and burnout zones of the furnace, residence time in the reburn zone, and residence time required above the overfire air ports to complete combustion. An optimum range of values has been defined for each of these parameters through laboratory tests and field application and is largely dependent upon the type of fuel being fired. For example, fuels with high sulfur contents (Orimulsion or some heavy fuel oils) are not as suitable in applications where operating the main combustion zone under low sub-stoichiometric conditions is required to reduce NO_x levels due to corrosion concerns. For these fuels, reburning technology can be effectively used by operating the main zone at higher stoichiometries, thus minimizing corrosion concerns while still achieving good NO_x reduction results.

Although implementation of the reburning technol-

ogy adds complexity to operation and maintenance of the overall combustion system, it also provides considerable emission performance optimization flexibility. In addition, higher initial costs for a reburn system as compared to other combustion techniques need to be factored into the evaluation process. From an economic standpoint, the potential benefits and technical merit of the reburning process must be commensurate with long term goals for NO_x abatement.

Oxides of sulfur

The sulfur content of fuel oils can range anywhere from a fraction of a percent for lighter oils to 3.5% for some residual oils. During the combustion process, sulfur contained in the fuel is converted to either sulfur dioxide, SO_2 , or sulfur trioxide, SO_3 (SO_x emissions). The control of SO_x emissions is a key environmental concern and sulfur compounds in the flue gas can also cause corrosion problems in the boiler and downstream equipment.

SO_3 will form sulfuric acid when cooled in the presence of water vapor. In addition to corrosion problems, it can produce emissions of acid smut and visible plume opacity from the stack. Emissions of SO_3 are best controlled during combustion through low excess air operation and can also be reduced by use of magnesium based fuel additives.

Techniques to control sulfur oxides during the combustion process have been investigated in laboratory and pilot scale tests with varying degrees of success. At present, however, the most effective and commercially accepted method, short of firing low sulfur fuels, is to install flue gas cleanup equipment. (See Chapter 35.)

Particulate matter

Particulate matter in the form of soot or coke is a byproduct of the combustion process resulting from carryover of inert mineral matter in the fuel and from incomplete combustion. Primarily a concern on oil-fired units, particulate matter becomes apparent when fuel oil droplets undergo a form of fractional distillation during combustion, leaving relatively large carbonaceous particles known as cenospheres.

Cenospheres are porous, hollow particles of carbon that are virtually unaffected by further combustion in a conventional furnace environment. Cenospheres can also absorb sulfur oxides in the gaseous phase and thereby further contribute to the formation of ash particles contaminated with acid.

Particulate matter from the combustion of fuel oil is, in large part, a function of the fuel properties. Ash content of the fuel oil plays a significant role in forming submicron particulate emissions. These ultrafine particulate emissions are potentially more dangerous to the environment than larger particles as they tend to stay suspended in the atmosphere. The fuel oil property most closely linked to forming cenospheres during the combustion process is asphaltene concentration. Asphaltenes are high molecular weight hydrocarbons that do not vaporize when heated. The combustion of fuel oils high in asphaltene content produces a greater quantity of large and intermediate size particulate emissions. Carbon residue, commonly

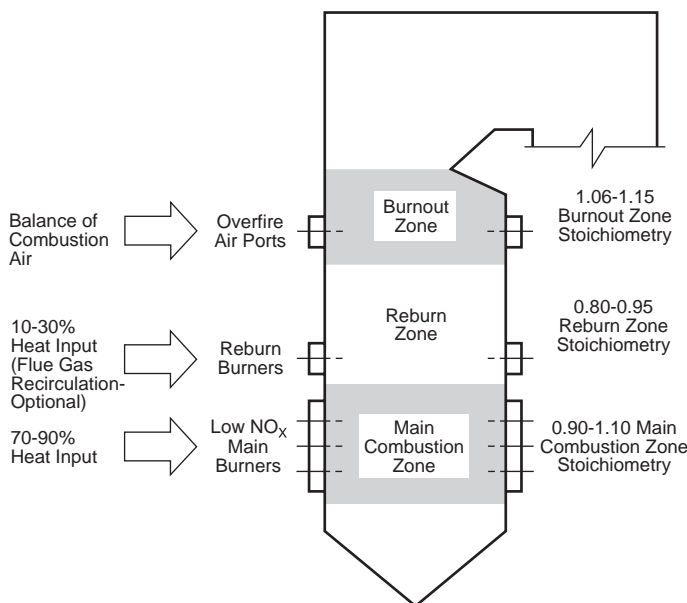

Fig. 5 Boiler side view showing reburn principle and combustion zones for a utility boiler.

determined by the Conradson Carbon Test, is also a means of evaluating the tendency to form particulate matter during combustion.

Control of particulate emissions is best achieved through proper atomization of the fuel oil and careful design of the burners and combustion control system to ensure thorough and complete mixing of fuel and air. Liberal residence time in a high temperature environment is favorable for complete combustion of fuel and low particulate emissions, although not conducive to low NO_x emissions. Oil emulsification also has a favorable impact on reducing particulate emissions. Oil emulsified with water further breaks up individual oil droplets when the water vaporizes during combustion. In addition, many fuel additives are now available to promote carbon burnout. These additives are primarily transition metals such as iron, manganese, cobalt and nickel that act as catalysts for the further oxidation of carbon particles.

Opacity

A visible plume emanating from the stack is undesirable from both a regulatory and public relations standpoint. Stack opacity is controlled in much the same manner as particulate emissions. Careful selection of fuels and complete combustion are keys to minimizing plume visibility.

Dark plumes are generally the result of incomplete combustion and can be controlled by careful attention to the combustion process and through transition metal-based additives. White plumes are frequently the result of sulfuric acid in the flue gas and can be controlled by low excess air operation or alkaline-based fuel additives that neutralize the acid.

The simultaneous control of all criteria pollutants poses a significant challenge to the burner and boiler designer. Techniques, or operating conditions, effective in reducing one form of atmospheric contaminant are frequently detrimental to controlling others or to unit performance. For this reason, hardware design and combustion controls are becoming increasingly complex. Modern boilers must have the added flexibility necessary to optimize thermal efficiency and combustion performance in conjunction with sound environmental practices.

Burner selection and design

As environmental concerns continue to dictate boiler and combustion system design, higher standards of performance are imposed on the fuel burning equipment. Control techniques to reduce NO_x emissions can conflict with proven methods of good combustion performance, e.g., time, temperature and turbulence.

Potential increases in carbon monoxide emissions, particulate emissions and stack opacity as a result of low NO_x operation suggest that the burners must be capable of continued reliable mechanical operation and of providing the flexibility necessary to optimize combustion under a variety of operating conditions.

Circular burner

Shown in Fig. 6, the circular type burner has long been the standard design for wall-fired oil and gas

applications. The tangentially disposed doors of the circular burner air register provide the turbulence necessary to mix the fuel and air and produce short, compact flames. This burner typically operates with high secondary air velocities providing rapid, turbulent combustion for high combustion efficiency. Fuel is introduced to the burner in a fairly dense mixture in the center. The direction and velocity of the air and dispersion of the fuel result in complete and thorough mixing of fuel and air.

XCL-S® type burner

The XCL-S® type oil and gas combination burner shown in Fig. 7 was originally developed to replace the circular burner. It not only met the demand for added flexibility and improved control of combustion air flow, but also incorporated the necessary design features to result in producing low NO_x emission levels. The XCL-S type burner incorporates several design features not available with the circular register. This burner has two air zones: the inner or core zone and the outer secondary air zone. When firing natural gas or oil, combustion air is introduced to the core zone through slots located around the periphery of the inner sleeve. An oil impeller or swirler is unnecessary with this burner; control of the flow entering the core zone ensures stable ignition. The core zone houses the main gas fuel element(s) and the main fuel oil atomizer.

The majority of combustion air enters the burner through the outer air zone. Axially disposed spin vanes are located in the outer sleeve to impart swirl to the combustion air and a sliding disk separately controls total air to the burner independent of swirl. An air zone swirler (AZS) device can also be incorporated into this zone to help reduce excess air and associated emission levels. The burner is equipped with an air measuring device upstream of the spin vanes. This device provides a relative indication of air flow to each burner and, on multiple burner applications, permits balancing of air flow from burner to burner. The outer zone also houses the igniter and flame detection equipment.

Because it can measure air flow to individual burners and regulate total air flow independent of swirl, the XCL-S type burner provides the added flexibility

Fig. 6 Circular register burner with water-cooled throat for oil and gas firing.

Fig. 7 XCL-S® low NO_x burner for oil and gas.

needed when employing combustion control techniques aimed at reducing NO_x emissions. This burner is ideally suited as an upgrade to existing circular (or other wall-fired type) burners as burner throat pressure part modifications can typically be avoided.

This advanced low NO_x burner achieves superior emission performance in burner only applications, as well as situations using overfire air and/or flue gas recirculation. In applications using overfire air ports, The Babcock & Wilcox Company's (B&W's) Dual Air Zone port provides maximum operating flexibility to optimize overall performance. See Chapter 14 for more details.

Corner-firing system

The general theory and configuration for corner firing of oil and/or natural gas is the same as that for pulverized coal firing described in Chapter 14.

Fuel and combustion air are introduced and distributed in each corner of the furnace through windbox assemblies similar to that shown in Fig. 8. The general arrangement of the windbox for natural gas or oil firing is essentially the same as that for coal firing in that the windbox is divided along its height into alternating compartments of fuel and air. For oil firing, a retractable oil gun is inserted into the center air nozzle of each fuel compartment. For natural gas firing, a stationary manifold gas nozzle attached to the inside of the windbox fuel compartment distributes fuel into the bellmouth of the air nozzle.

For conventional firing applications, approximately half of the total combustion air is introduced through the fuel compartments. This is known as fuel air and

is used to support combustion and stabilize flames. The balance of the air, known as auxiliary air, is used to complete combustion and is introduced through the compartments located above and below each fuel elevation. All of the combustion air enters through the corner windbox assemblies and is distributed in the windbox by a system of dampers at the inlet of each compartment. The fuel air dampers are controlled based on fuel flow rate whereas the auxiliary air dampers are controlled based on windbox to furnace differential pressure.

The most cost effective method of reducing NO_x in oil and/or natural gas corner-fired boilers is by addition of overfire air which uses the air staging or two stage combustion principle commonly used with pulverized coal firing. Application of overfire air to a corner fired system involves diverting a portion of the auxiliary air to an overfire air zone located above the combustion zone (admitted at the top of the windbox through two or more compartments and/or through separate ports located several feet above the top fuel elevation). The overfire air port compartments are typically equipped with individual dampers to control air flow, tilting mechanisms to allow for variation in separation distance for improved NO_x performance, and air flow measuring devices (e.g., pitot tubes) to facilitate air flow control. The design and arrangement of the B&W overfire air system and corresponding windbox modifications for oil and/or natural gas firing are similar to that described in Chapter 14 for pulverized coal firing.

Also, flue gas recirculation (FGR) has been used successfully and has provided significant NO_x reduc-

tions in units firing natural gas and/or heavy fuel oil. With FGR, a portion of the flue gas (typically 10 to 15% by weight) is taken from the boiler exhaust and is mixed with the combustion air. However, the use of FGR requires careful analysis as its effects on boiler operation and maintenance costs can be significant.

Fuel oil equipment

Oil for combustion must be atomized into the furnace as a fine mist and dispersed into the combustion air stream. Proper atomization is the key to efficient combustion and reduced particulate emissions. Atomization quality is measured in terms of droplet size and droplet size distribution. High quality atomization occurs when oil droplets are small, producing high surface to volume ratios and thereby exposing more surface to the combustion air. A convenient means of expressing and comparing atomization quality produced by various atomizer designs is the Sauter mean diameter (D_{sm}). This is the ratio of the mean volume of the oil droplets over the mean surface area, expressed in microns. The lower the Sauter mean diameter, the better the atomization.

For proper atomization, oil grades heavier than No. 2 must be heated by means of steam or electric heaters to reduce their viscosity to between 100 and 150 SUS (Saybolt Universal Seconds). In heating fuel oils, caution must be observed to ensure that temperatures are not raised to the point where vapor lock may occur. Vapor lock results when volatile fractions of the

fuel separate in the fuel supply system causing flow interruptions and subsequent loss of ignition. Fuel supplied to the atomizers must also be free of acid, grit and fibrous or other foreign matter likely to clog or damage hardware components.

Fuel oil is atomized by either mechanical or dual fluid atomizers that use steam or air as the medium. The choice of whether to use mechanical or steam atomization is determined by the boiler design and operating requirements. In general, steam assisted atomizers produce a higher quality spray and are more appropriate for low NO_x applications or where particulate emissions and stack opacity are of primary concern. At some installations, however, the heat balance is such that steam can not be used economically for oil atomization. Another factor to consider is the necessity to conserve boiler feedwater. In these instances, mechanical atomization may be more appropriate.

B&W's atomization test facility has been used to quantitatively and qualitatively characterize numerous atomizer designs through state-of-the-art laser diagnostic techniques. B&W's family of atomizers range from mechanical Return Flow to various dual fluid (Racer®, Y-Jet, T-Jet, and I-Jet) atomizer types. A summary of their operating characteristics is provided in Fig. 9.

Mechanical atomizers With mechanical atomizers, the pressure of the fuel itself provides the energy necessary for atomization. These atomizers require relatively high pressure oil for proper performance. Three conventional types are in common use: the Uniflow, the Return Flow and the Steam Mechanical atomizer.

The Uniflow atomizer is used in small and medium sized stationary power plants, as well as in naval and merchant marine boilers. This atomizer is simple to operate and made with as few parts as possible. Fuel is introduced into ports that discharge tangentially into a whirl chamber. The fuel is spun out of the whirl chamber and passes through an orifice into the combustion chamber as a well atomized conical spray. Required oil pressure at the atomizer is above 300 psig (2.07 MPa gauge) for heat inputs of 70 to 80×10^6 Btu/h (20.5 to 23.4 MW_t).

The Return Flow atomizer (Fig. 10) is used on either stationary or marine boilers that require wide capacity ranges. This atomizer is designed to minimize, or eliminate entirely, the need for changing sprayer plates or the number of burners in service during normal operation. A wide range of operation is possible by maintaining a high flow through the sprayer plate slots even at reduced firing rates. At reduced firing rates, because the quantity of oil supplied is greater than the required firing rate, the excess oil is returned to a low pressure point in the piping system. The required oil pressure at the atomizer must be either 600 or 1000 psig (4.14 or 6.90 MPa gauge) depending upon fuel, capacity and load range requirements. Maximum input is in the order of 200×10^6 Btu/h (58.6 MW_t).

The Steam Mechanical atomizer combines the features of steam and mechanical atomization permitting operation over wide ranges, including low loads with cold furnaces. At high loads it can be operated as a mechanical atomizer. At reduced loads mechanical

Fig. 8 Windbox assembly for corner-firing system; compartment dampers on opposite side not shown (courtesy of R-V Industries, Inc.).

Fig. 9 Operating characteristics of B&W atomizers.

atomization is augmented by the use of steam. Required oil pressure is 200 to 300 psig (1.38 to 2.07 MPa gauge) depending upon capacity requirements. Steam pressure at the atomizer must be 10 to 15 psi (0.07 to 0.10 MPa) above oil pressure not to exceed 125 psig (0.86 MPa gauge). Maximum capacity of this atomizer is in the order of $80 \text{ to } 90 \times 10^6 \text{ Btu/h}$ (23.4 to 26.4 MW_t).

Residual fuel oils contain heavy residues that may condense on cold surfaces creating potentially hazardous conditions. Improving atomization quality can help avoid this situation. A certain number of steam or air atomizers could be provided for satisfactory operation when boiling and drying out new units and for continued operation at very low capacities.

Steam atomizers Due to better operating and safety characteristics, steam assisted atomization is preferred. Steam atomization generally produces a finer spray. The steam-fuel emulsion produced in a dual fluid atomizer reduces oil droplet size when released into the furnace through rapid expansion of the steam. As a minimum, dry saturated steam at the specified pressure must be used for fuel oil atomization to avoid the potential for burner pulsation. Typically, 20 to 40F (11.1 to 22.2C) superheat is recommended to avoid such problems. If necessary, moisture free compressed air can be substituted.

Several steam atomizer designs are available in sizes up to $300 \times 10^6 \text{ Btu/h}$ (87.9 MW_t) or about 16,500 lb/h (2.08 kg/s) of fuel. Required oil pressure is much lower than for mechanical atomizers. Steam and oil pressure requirements are dependent upon the specific atomizer design. Maximum oil pressure can be as much as 300 psig (2.07 MPa gauge) with steam pressures as high as about 200 psig (1.38 MPa gauge). The four most common steam atomizer designs are the Y-jet, Racer, T-jet and I-jet. (See Fig. 11.) Each design is characterized by different operating ranges, steam

consumption rates, and atomization quality based on resultant oil droplet particle size distributions. Fig. 9 summarized these various characteristics for each of the atomizers.

The Y-jet is designed for a wide firing range without changing the number of burners in service or the size of the sprayer plate. It can be used on any type of boiler with either steam or air atomization. Fuel oil and atomizing medium flow through separate channels to the atomizer sprayer plate assembly where they mix immediately before discharging into the furnace. Required oil pressure at the atomizer for maximum capacity ranges from 65 to 90 psig (0.45 to 0.62 MPa gauge). The Y-jet is a constant differential atomizer design requiring steam pressure to be maintained at 40 psi (0.28 MPa) over the oil pressure throughout the normal operating range. Steam consumption with this design is in the order of 0.1 lb steam/lb oil.

The Racer atomizer is a refinement of the Y-jet. It was developed primarily for use where high burner turndown and low atomizing steam consumption are required. The Racer name refers to the class of merchant ship where this atomizer was first used. Required design oil pressure for maximum capacity is 300 psig (2.07 MPa gauge). Steam pressure is held constant throughout the load range at 150 psig (1.03 MPa gauge). Atomizing steam consumption at full load is approximately 0.02 lb steam/lb oil.

The T-jet and I-jet atomizers also allow a wide range of operation without the need for excessive oil pressure. These atomizer designs are unique in that the steam and oil are mixed in a chamber prior to discharging through the sprayer cap (Fig. 11). Rated capacity oil pressure for the T-jet may range from 90 to 110 psig (0.62 to 0.76 MPa gauge) depending upon fuel and capacity requirement. The I-jet atomizer rated capacity oil pressure ranges from 70 to about 170 psig (0.48 to 1.17 MPa gauge). Of the constant differential variety, the I-jet and T-jet require a steam pressure of approximately 20 to 40 psi (0.14 to 0.28 MPa) above oil pressure. Steam pressures may be adjusted to obtain optimum combustion performance. Steam consumption rates vary with these atomizer designs depending upon actual operating pressures. The standard design steam consumption rates at full atomizer

Fig. 10 Mechanical Return Flow oil atomizer assembly.

Fig. 11 I-jet atomizer assembly.

capacity for the T-jet and I-jet are 0.20 and 0.10 lb steam/lb oil, respectively. In general, higher steam consumption rates result in improved atomization quality.

A disadvantage of the steam atomizer is its consumption of steam. For a large unit, this can amount to a sizable quantity of steam and consequent heat loss to the stack. When the boiler supplies a substantial amount of steam for a process where condensate recovery is small, the additional makeup for the steam atomizer is inconsequential. However, in a large utility boiler where turbine losses are low and there is little makeup, the use of atomizing steam can have a significant effect.

Natural gas equipment

Three common types of gas element assemblies available for the combustion of commercial high Btu natural gas are the variable mix multi-spud, hemispherical multi-spud and the radial spud. The variable mix multi-spud gas element was developed for use with the circular type burner. The goal was to improve ignition stability when flue gas recirculation or two-stage combustion are implemented for NO_x control. This design uses a manifold outside the furnace, with a number of individual gas elements, or spuds, projecting through the windbox into the throat. The following is a list of the distinctive features of this gas element:

1. Individual gas spuds are removable with the boiler in service to enable cleaning or redrilling of the gas nozzles as required.
2. Individual spuds can be rotated to orient the discharge holes for optimum firing conditions with the burner in service.

3. The location of the spud tip, with respect to the burner throat, can be varied to a limited degree for optimum firing conditions.
4. Individual gas spud flame retainers provide added stability and are more conducive to lower NO_x emissions.

This gas element design adds needed flexibility for optimizing combustion under a variety of operating conditions. With proper selection of control equipment, the operator can change from one fuel to another without a drop in load or boiler pressure. Simultaneous firing of natural gas and oil in the same burner is acceptable on burners equipped with the variable-mix multi-spud arrangement.

The hemispherical gas element (Fig. 12) was developed for use with the low NO_x XCL-S and FM-XCL (package boiler application version of the XCL-S) type burners. With the exception of the flame retainers, the hemispherical gas element offers the same features as the variable mix element design. This gas element, however, can achieve lower NO_x emissions by virtue of the tip profile, drilling pattern and location within the burner.

The radial spud design consists of a manifold located inside the windbox with individual gas elements projecting into the burner throat. Unlike the variable mix and hemispherical design, the radial spud is not conducive to low NO_x emissions. Use of the radial spud is reserved for applications where coal and gas are fired in the same burner and where stringent NO_x emission limits are not an issue.

For low NO_x gas firing capability in a burner that must also be capable of firing pulverized coal, a single, high-capacity gas element (HCGE) is used (Fig. 13).

The HCGE's drilling pattern and its location on the axial centerline of the burner inside the coal nozzle promote lower NO_x emissions as a result of slower mixing of fuel and air. The gas flame associated with the HCGE tends to be somewhat longer than gas flames associated with burners having multiple spud configurations. Consequently, burner capacity and furnace size must be appropriately matched. If adequate furnace depth is available, the HCGE can also be used with the low NO_x XCL-S and FM-XCL gas or gas/oil burners to achieve lower NO_x emissions than can be achieved with hemispherical multi-spuds.

The maximum practical limit for gas input per burner is in the order of 200×10^6 Btu/h (58.6 MW_t). Frequently, physical arrangement of the gas hardware is a limiting factor in fuel input capability. With all gas element designs, the spud tip drilling is determined by adhering to empirical curves aimed at eliminating the potential for burner pulsation. Allowable gas discharge velocity criteria are established and the resulting required manifold pressure is determined. Gas pressure at the burner at rated capacity is generally in the range of 8 to 12 psig (55 to 82 kPa) for multiple spud configurations and as high as 20 psig (137 kPa) for the HCGE.

In many respects, natural gas is an ideal fuel since it requires no preparation for rapid and intimate mixing with the combustion air. However, this characteristic of easy ignition under most operating conditions has, in some cases, led to operator carelessness and damaging explosions.

To ensure safe operation, gas flames must remain anchored to the gas element discharge ports throughout the full range of allowable gas pressures and air flow conditions. Ideally, stable ignition should be possible at minimum load with full load air flow through the burner and at full load with as much as 25% excess air. With this latitude in air flow it is not likely that ignition can be lost, even momentarily, during upset conditions.

Byproduct gases

Many industrial applications utilize blast furnace gas, coke oven gas, refinery gas, regenerator offgas,

landfill gas, or other byproduct gases to produce steam. (See Chapter 27.)

Burners are designed specifically to fire these byproduct fuels. For example, blast furnace gas is a low heating value fuel that typically is available at relatively low supply pressure. Accordingly, a blast furnace gas burner utilizes a nozzle designed for low gas velocity to promote flame stability and to accommodate a high gas flow rate with minimal pressure loss. A scroll located at the nozzle inlet imparts swirl to the incoming gas stream thereby improving subsequent mixing of fuel and air. Cleanout doors in the scroll permit removal of accumulated deposits common to blast furnace gas. Similarly, the fuel element for any other byproduct gas must be designed for its particular characteristics, ignition stability, and appropriate load range.

Some byproduct gases, such as CO gas, are not of sufficient fuel quality to sustain their own flames. In CO boilers, supplementary gas and/or oil burners are used to raise the temperature of the CO gas to the ignition point and to assure complete burning of the combustibles in the CO gas stream. Supplementary fuel burners and CO gas ports are positioned to ensure thorough mixing and to promote rapid, complete combustion.

Cold start and low load operation

Cold boiler startup requires firing at low heat input for long periods of time to avoid expansion difficulties and possible overheating of superheaters or reheaters. Low pressure [200 psig (1.38 MPa gauge)] boilers without superheaters may need only about an hour of low load operation. Larger high pressure units, however, may need four to six hours for startup. During startup, combustion efficiency is typically poor, especially with residual oils, due largely to low furnace and combustion air temperatures.

Low load operation may also result in poor distribution of air to the burners in a common windbox. Low air flow and accompanying low windbox to furnace pressure differentials may result in significant stratification of air in the windbox and adversely affect combustion performance. Stack effect between the bottom and top rows of burners may further alter the quantity of air reaching individual burners. At extremely low loads, firing oil or gas, the fuel piping itself can also introduce poor distribution and accordingly affect burner operation. For a given supply pressure, some burners may have adequate fuel while others do not receive enough fuel for continuous operation.

The low ignition temperature and clean burning characteristics of natural gas make it an ideal fuel for startup and low load operation. However, extreme care must be taken to avoid a momentary interruption in the flame. Large quantities of water are generated by the combustion of gaseous fuels with a high percentage of hydrogen. For units equipped with regenerative type air heaters, the air heater should not be placed in service until the flue gas temperature to the air heater has reached 400F (204C). This prevents condensation of water from the flue gas on the air heater surface and subsequent transport of this wa-

Fig. 12 Furnace view of hemispherical gas spuds (oil atomizer not shown).

Fig. 13 High-capacity gas element (HCGE).

ter to the burners by the combustion air. Water in the combustion air may cause loss of ignition.

Fuel oil is potentially more hazardous than gas for startup and low load operation. Although ignition stability is generally not a problem, the low temperature furnace environment may result in the accumulation of soot and carbon particles on air heater and economizer surfaces and may also create a visible plume. If deposits accumulate over an extended period of time they pose a fire hazard. To reduce the incidence of fires, some operators use sootblowers that blow steam continuously on the surfaces of regenerative type air heaters as they rotate in the flue gas stream.

When oil must be used for startup, the following firing methods are listed in order of preference:

1. Use of dual fluid atomizers and light fuel oil, No. 1 or 2, with steam or compressed air as the atomizing medium. This will provide a clean stack and limit the deposit of carbonaceous residue on boiler back-end surfaces.
2. Use of dual fluid atomizers with steam atomization and fuel oil no heavier than No. 6, heated as required for reduced viscosity and proper atomization.
3. Use of dual fluid atomizers with compressed air as the atomizing medium and fuel oil no heavier than No. 6, heated as required.

Startup with oil using mechanical atomizers is not recommended due to the inherent lower atomization quality. Stationary boilers equipped with mechanical atomizers for oil firing at loads between 20 and 100% are generally started up with natural gas or a burner level of dual-fluid startup atomizers.

Igniters

Lighting a burner requires an independent source of ignition. The igniters used to provide the necessary ignition energy range from hand held torches inserted temporarily, to direct ignition electrical igniters, to automatically spark ignited oil or gas fired igniters.

Today, the boiler codes require permanently installed igniters in each burner. These are most often oil or gas fired designs that are ignited by means of high voltage or high energy spark ignition systems. The capacity of modern igniters can reach 10% or more of the main burner. This permits their use in stabilizing the combustion of difficult to burn fuels or in providing support ignition for abnormal main fuel conditions. Their high input capacity may also be used to warm the furnace prior to starting the main burner system or to synchronize the turbine. Although the igniter capacity is tailored to meet the specific requirements of the burner and flame safety system, a maximum input of approximately 25×10^6 Btu/h (7.3 MW_i) is typical.

The National Fire Protection Association (NFPA) categorizes igniters according to their input capacity relative to the burner input. Class I igniters generally provide 10% or more of the main burner heat release and may be operated continuously for support ignition when required under all boiler conditions. Specifically, the Class I igniter location and capacity will provide sufficient ignition energy to raise any credible combination of burner inputs of both fuel and air above the minimum ignition temperature. Class II igniters generally provide 4 to 10% of the burner heat release and may be operated continuously for

ignition support under well defined boiler conditions. Class III igniters generally provide a heat release less than 4% of the burner and may not be operated continuously to provide support ignition for the burner. Most modern utility boilers employ Class I igniters to warm the boiler, provide support for difficult fuels and/or poor fuel conditions, and to minimize the complexity of the flame detection system.

Gas provides the most reliable and cleanest burning fuel for high capacity igniters. Gas igniters may be operated with either natural gas or liquefied petroleum gas (LPG). When operated with LPG, it is critical that the LPG supply system provide a reliable, vapor-only flow at the required rate. Oil fired igniters may be used with both distillate and residual fuel oils. Light oils are favored as they avoid complexities of oil heating/recirculation, which can impair reliability. Distillate oil can be used with either air or steam atomization with air being preferred. Residual oil igniters require superheated steam for optimum performance.

Gas and oil igniters are available in both fixed and retractable designs. Retractable igniters are inserted to their firing position for ignition of the main burner and then retracted back into the burner when they are no longer needed. Retracting the igniter sufficiently reduces radiant heat exposure such that cooling air is not required. Fig. 14 is an example of a typical retractable igniter (B&W CFS gas igniter is shown and an oil fired version is also available).

Fixed igniters are permanently positioned in the burner throat at the proper location for ignition of the burner. Fig. 15 is an example of a stationary igniter (FPS oil igniter is shown and a gas fired version is also available). A dedicated supply of air is provided to the FPS igniter to improve combustion performance and to cool the igniter when it is out of service.

In addition to these fueled igniters, there is a special Class III igniter which does not burn fuel. These

ignite the burner directly with electrical energy. They are usually high energy, capacitive discharge, spark ignition systems similar to those that ignite oil and gas fired igniters, but usually they operate with a higher energy level. Direct electric ignition can be used on oil burners which burn distillate and residual fuel oils having specific characteristics. Direct ignition of gas burners is recommended only for burners with a single gas element. Reliable ignition of gas burners having multiple gas elements spread around the burner can often be difficult, resulting in potentially hazardous conditions, and is not normally recommended.

Direct electric ignition spark systems generally provide an ignition energy level of at least 8 joules, with 10 to 12 joules used in most applications. The small spark produced by the direct ignition spark rod must be carefully positioned in the fuel stream to ensure rapid ignition of the fuel upon opening of the burner fuel valve. Direct electric ignition spark systems must always be retractable.

Safety precautions

NFPA 85 is a standard set of operating codes (procedures, interlocks, and trips) for the safe and reliable operation of gas and oil combustion processes. Recommendations of this standard along with governing local codes and ordinances are followed in the design of gas and oil burner systems, burner interlock and trip systems, and burner sequence control systems.

Five rules of prime importance in safe and reliable operation of gas and oil fired combustion systems, whether employing a manual or automatic control system, are described below.

1. Never allow oil or gas to accumulate anywhere, other than in a tank or lines that form part of the fuel delivery system. The slightest odor of gas must be cause for alarm. Steps should be taken immediately to ventilate the area thoroughly and locate the source of the leak.
2. A minimum purge rate air flow not less than 25% of full load volumetric air flow must be maintained during all stages of boiler operation. This includes pre-purging the setting and lighting of the igniters and burners until the firing rate air requirement exceeds the purge rate air flow.
3. A spark producing device or lighted torch must be in operation before introducing any fuel into the furnace. The ignition source must be properly placed with respect to the burner and must continuously provide a flame or spark of adequate size until a stable main flame is established.
4. A positive air flow through the burners into the furnace and up the stack must be maintained at all times.
5. Adequate fuel pressure for proper burner operation must be maintained at all times. In the case of oil firing, fuel pressure and temperature must be maintained for proper atomization. In dual fluid atomizer applications, adequate steam or air pressure must be available at the atomizer.

Equipment requirements, sequence of operation, interlock systems and alarm systems are equally im-

Fig. 14 CFS retractable gas igniter with high energy spark probe.

Fig. 15 FPS oil igniter.

portant, if not more so, when implementing combustion control techniques to reduce NO_x emissions.

In observance of the recommended rules of operation, an automatic control system should include the following:

1. purge interlocks requiring a specified minimum air flow for a specific time period to purge the setting before the fuel trip valve can be opened,
2. flame detectors on each burner, connected to an alarm and interlocked to shut off the burner fuel valve upon loss of flame,
3. closed position limit switches for burner shutoff valves, requiring that individual burner shutoff valves be closed to permit opening the fuel trip valve,
4. shutoff of fuel on failure of the forced or induced draft fan,
5. shutoff of fuel in the event of low fuel pressure (and low steam or air pressure to oil atomizers),
6. shutoff of fuel in the event of low oil temperature, and
7. shutoff of fuel in gas fired units in the event of excessive fuel gas pressure.

Any of the commonly used fuels can be safely burned when using the proper equipment and operating skill. Hazards are introduced when, through carelessness or mis-operation of equipment, the fuel is no longer burned in a safe manner. While a malfunction should be corrected promptly, panic must be avoided. Investigation of explosions of boiler furnaces equipped with good recording apparatus reveal that conditions leading to the explosion had, in most cases, existed for a considerable period of time. Sufficient time was available for someone to have taken unhurried corrective action before the accident. The notion that malfunctions of safety equipment cause frequent, unnecessary unit trips is not consistent with the facts.

Chapter 12

Solid Fuel Processing and Handling

Coal remains the dominant worldwide source of energy for steam generation. However, additional solid fuels such as wood by-products and municipal wastes are also in use. The large scale continuous supply of such solid fuels for cost-effective and reliable steam power generation requires the effective integration of recovery (e.g., mining), preparation, transportation and storage technologies. The relationships between these are illustrated in Fig. 1. While each fuel offers unique challenges, a discussion of the processing and handling of coal helps identify many of the common issues and considerations for all solid fuels. Selected additional topics about the special aspects of some other solid fuels are covered in Chapters 28 through 30.

Mining is the first step in producing coal. Raw coal can be treated to remove impurities and to provide a more uniform feed to the boiler. The resulting reduction in ash and sulfur can significantly improve overall boiler performance and reduce pollutant emissions. The transportation of coal to the plant may represent a major portion of the plant's total fuel cost, although mine-mouth generating stations can minimize these

transportation costs. Storage and handling of large coal quantities at the plant site require careful planning to avoid service disruptions.

The changing nature of electric utility industry regulation, and the increasingly stringent emissions control requirements have dramatically changed the way coal is used to generate electric power in the United States (U.S.). Where once a new boiler was dedicated to one or two sources of coal over its lifetime, today active fuel management with multiple sources of coal and transport options is a core part of power plant competition and profitability. The plant objective is to meet the emission control requirements at the lowest overall power production cost.

Coal source flexibility has become necessary for economic survival. Plant owners have had to meet these new challenges by employing multiple coal sources, some very remote from the plant. This typically has required the installation of new and more flexible coal handling equipment in the plant storage facilities.

Coal mining

As discussed in Chapter 9, electric utility coal consumption for power generation dominates the market for coal produced in the U.S. and in the rest of the world. Coal production in the U.S. reached approximately 1.1 billion short tons per year at the turn of the 21st century. At the same time, electric utilities accounted for 92% of the coal consumed. Overall worldwide production and consumption of coal has been steadily increasing since the late 1980s, with the major producers being China, the U.S., India and Australia. Together these countries produced more than 65% of the total amount of coal mined.¹⁻³

U.S. coal production is split between surface mining, which produces 66% of the total and underground mining, which produces 34% of the total.² Because of the geologic locations of coal deposits or *seams*, and cost considerations, surface mining dominates coal production west of the Mississippi River and underground mining dominates in the East. In 2003, Wyoming, West Virginia and Kentucky led the nation in coal

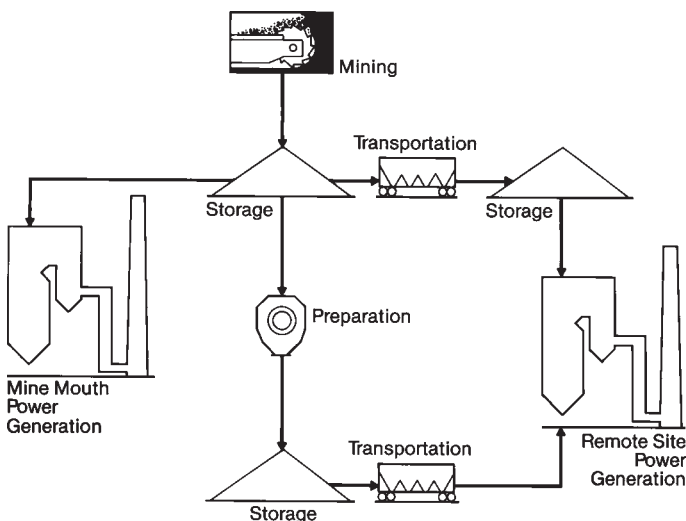

Fig. 1 Fuel supply chains for coal-fired power generation.

production with a 59% combined total. The emergence of large, high volume surface mines producing low sulfur coal in the west has resulted in a continuing shift of coal production from the eastern U.S. to the west.¹

Surface mining

Coal may be recovered from relatively shallow seams by removing the overlying earth, or *overburden*, to expose the coal seam. Typically, topsoil is first removed and stored for later use in reclamation of the site. The remaining overburden is drilled and blasted to loosen the rock for removal with a dragline or excavating shovel. The overburden is then methodically stripped away and stored for restoration of the land to the original contour following removal of the coal. A dragline is commonly used to expose the coal seam (Fig. 2). The coal may then be removed using a bulldozer and front-end loader or a shovel. A mobile crusher and screen may be set up in the mine for initial sizing of the raw coal. The coal is then loaded into trucks for delivery to a cleaning facility or steam generating plant.

The *stripping ratio* is defined as the unit amount of overburden that must be removed to access a unit amount of coal. In general, surface mines in the western U.S. have lower stripping ratios than mines in the east.

Strict environmental regulations limit the amount of land surface area that may be exposed at any one time, control water runoff, and establish land reclamation procedures.

Underground mining

Many coal reserves are accessible only by underground mining. (See Chapter 9.) Continuous mining, the most prevalent form of underground mining, makes use of machines like those in Fig. 3. It accounts for approximately 55% of the total underground production of coal.

Room and pillar mining Most underground U.S. coal is produced using a technique known as room and pillar mining. A series of headings or parallel entries are cut into the coal seam to provide passages for the

Fig. 3 Continuous mining machine in operation (courtesy of National Coal Association).

mining machinery, uncontaminated ventilation air, and conveying equipment. These headings are typically 18 to 20 ft (5.5 to 6.1 m) wide and may be several miles (km) long. Rooms are driven off of the main headings to the property limits of the mine. Typically, only about 50% of the coal is removed when the rooms are first mined. The remaining coal is left in place to support the roof. Roof bolts are installed where the coal has been removed for additional roof support. At the completion of the development cycle, the remaining coal may be removed by retreat mining, and the unsupported roof is allowed to collapse.

Longwall mining In longwall mining, shearers or plows are pulled back and forth across a panel of coal to break it loose from the seam. The coal falls onto a flight conveyor and is transported to the main haulage line. Because essentially all of the coal is removed, artificial roof supports, known as shields or chocks, are used to cover the plow and conveyor. The plow, conveyor and roof supports are advanced using hydraulic jacks as the coal is removed from the mining face. The unsupported roof is allowed to cave in behind the supports.

Although more underground mines use the room and pillar method of mining, longwall mines generally produce more coal because they are larger operations overall. Since the early 1980s, there has been a significant increase in productivity using longwall mining. Today, more than one-half of the longwall mines in the U.S. are located in Appalachia, but this type of mining is being used more widely in western coal areas as well.

A key reason for the increase in productivity involves increased panel size of longwall mining sections. The average panel face width is 759 ft (231 m), and the average panel length is 6853 ft (2089 m). Some of these operating units reaching 10,000 ft (3048 m).⁴

Longwall mining can be a very high capacity production system provided the geologic conditions are suitable and the longwall has been carefully integrated with the existing panel development scheme and coal haulage infrastructure. Production capacities exceeding 6000 t of raw coal per shift have been reported. The annual production capacity for a

Fig. 2 Large coal dragline in operation (courtesy of National Coal Association).

longwall is a function of the seam height, panel width and length, and the time required to move the equipment between operating panels.

Raw coal size reduction and classification

Sizing requirements

Size reduction operations at steam power plants are usually confined to crushing and pulverizing, although it is sometimes more economical to purchase pre-crushed coal for smaller plants, especially stoker-fired units. Screening at the plant is generally not required, except to remove large impurities and trash using simple grids (or grizzlies) and rotary breakers. Techniques for determining coal particle size distribution are discussed in Chapter 9.

Coal particle size degradation occurs in transportation and handling and must be considered when establishing supply size specifications. This may be critical where the maximum quantity of coal fines is set by firing equipment limitations.

For stoker-fired installations, it is customary to specify purchased coal sized to suit the stoker (see Chapter 16), so that no additional sizing is required at the plant [typically 1.5 in. \times 0 (38.1 mm \times 0)].

For pulverized coal-fired boilers, a maximum delivered top size is usually specified with no limitation on the percentage of fines, so that the delivered coal is suitable for crushing and pulverizing in the available equipment. The coal is crushed to reduce particle size and then ground to a very fine size in the pulverizer. (See Chapter 13.)

Crushers alone may be used to provide the relatively coarser sizes required for Cyclone furnaces. (See Chapter 15.) A properly sized crusher efficiently reduces particle size while producing minimal fines.

Size reduction equipment selection

Size reduction equipment is generally characterized by the maximum acceptable feed size and the desired product top size. The reduction ratio is defined as follows:

$$\frac{P_{\text{feed}}}{P_{\text{product}}} \quad (1)$$

where

- P_{feed} = feed particle size in which 80% of the particles pass a given screen size or mesh
- P_{product} = product particle size in which 80% of the particles pass a given screen size or mesh

Once-through crushing devices, that discharge the fines without significant re-crushing, are used to minimize the production of fines. Rotary breakers and roll crushers are commonly used to reduce the coal top size without producing a significant amount of fines.

The *rotary breaker*, illustrated in Fig. 4, reduces the coal to a predetermined maximum size and rejects larger refuse, mine timbers, trash, and some tramp metal. This equipment also breaks apart frozen coal prior to further coal processing. It consists of a large cylinder of steel screen plates that rotates at approxi-

Fig. 4 Rotary breaker for use at the mine and power plant.

mately 20 rpm. The size of the screen openings determines the top size of the coal. The coal feed at one end of the cylinder is picked up by lifting shelves and is carried up until the angle of the shelf permits the coal to drop onto the screen plate. The coal shatters and is discharged through the screen openings. The harder rock does not break as readily; it travels along the screen and is rejected at the discharge end. Wood, large rocks, and other trash that do not pass through the screen are separated from the coal. Rotary breakers may be installed at the mine, preparation plant, or steam generating plant.

The elements of a *single-roll crusher* are illustrated in Fig. 5. This crusher consists of a single, toothed roll that forces the coal against a plate to produce the crushing action. The maximum product particle size is determined by the gap between the roll and the plate. To prevent jamming by large impurities such as tramp metal, the roll is permitted to rise or the plate can swing away, allowing the impurities to pass through. This is an old type of crusher commonly used for reducing run-of-mine bituminous coal to a maximum product of 1.25 to 6 in. (31.8 to 152 mm). The abrasive action between the coal and the plate produces some fines; however, they are discharged with minimal re-breakage.

In a *double-roll crusher*, the coal is forced between two counter-rotating toothed rolls (Fig. 6). The mating faces of both rolls move in a downward direction, pulling the coal through the crusher. The size of the roll teeth and the spacing between rolls determine the

Fig. 5 Single-roll crusher – diagrammatic section.

Fig. 6 Double-roll crusher – diagrammatic section.

product top size. One of the rolls may be spring loaded to provide a means for passing large, hard impurities. Double-roll crushers are used for reducing run-of-mine coal to smaller sizes at preparation and steam generating plants.

In *retention crushers* such as *hammer mills* and *ring crushers*, coal is retained in the breakage zone until it is sufficiently fine to pass through a screen to the discharge. The re-breakage action produces considerable fines, consequently these mills are not used in applications where fines are objectionable. They are often used to reduce run-of-mine coal to an acceptable size for feed to a stoker or pulverizer, e.g., 0.75 in. \times 0 (19 mm \times 0).

A *hammer mill* is depicted in Fig. 7. In this mill, the coal is broken by impact with the hammers mounted on a central shaft and permitted to swing freely as the shaft is rotated. The coal is fed at the top of the mill and is forced down and outward to the grate bars as it is struck by the hammers. The spacing of the bars determines the maximum size of the finished product. The coal remains in the mill, and breakage continues until the particles are fine enough to pass through the grate. A trap is usually provided for collection and removal of tramp metal.

Screen selection

Screening is usually performed at the mine or preparation plant to remove unwanted material and size coal for various uses prior to shipment to the steam generating plant. The run-of-mine coal is usually passed over a grid of steel bars, or grizzly, to remove mine timbers, rocks and other trash. The raw coal may be separated into various size fractions to meet contract specifications or for further processing in a preparation plant by passing the coal through various screens. Common screen types include gravity bar screens, trommels or revolving screens, shaker screens, and vibrating screens.

A *gravity bar screen* consists of a number of sloped

parallel bars. The gaps between bars, the slope, and the length of the bars determine the separating size. The bars have tapered cross-sections; the gaps between the bars are smaller on the top side than on the bottom. This design reduces plugging.

A *revolving screen* consists of a slowly rotating cylinder with a slight downward slope parallel to the axis of coal flow. The cylinder is comprised of a perforated plate or a wire cloth, and the size of the openings determines the separating size. Because of the repeated tumbling as the coal travels along the cylinder, considerable breakage can occur. For this reason, revolving screens are not used for sizes larger than about 3 in. (76.2 mm). Because only a small portion of the screen surface is covered with coal, the capacity per area of screen surface is low.

A *shaker screen* consists of a woven wire mesh mounted in a rectangular frame that is oscillated back and forth. This screen may be horizontal or sloped slightly downward from the feed end to the discharge end. If the screen is horizontal, it is given a differential motion to help move the coal along its surface.

Bituminous coal generally fractures into roughly cubicle shapes, while commonly associated slate and shale impurities fracture to form relatively thin slabs. This shape difference enables the impurities to be separated with a *slotted shaker*.

Vibrating screens are similar to shaker screens except that an electric vibrator is used to apply a high frequency, low magnitude vibration to the screen. The screen surface is sloped downward from the feed to the discharge end. The vibration helps to keep the mesh openings clear of wedged particles and helps to stratify the coal so that fine particles come in contact with the screen surface. For screening fine, wet coal, water sprays are used to wash fine particles through the coal bed and the screen surface. Vibrating screens are the most widely used types for sizing and preliminary dewatering.

It is common practice to separate the fines from the coarse coal to improve the efficiency of subsequent cleaning and dewatering processes. The fines may be discarded, cleaned separately, or bypassed around the cleaning process and then blended back into the coarse clean coal product.

Coal cleaning and preparation

The demand for coal cleaning has increased in response to environmental regulations restricting sulfur dioxide (SO₂) emissions from coal-fired boilers. The demand is also due to a gradual reduction in run-of-mine coal quality as higher quality seams are depleted and continuous mining machines are used to increase production. Approximately 70% of coal mined for electric utility use is cleaned in some way.

Coal cleaning and preparation cover a broad range of intensity, from a combination of initial size reduction, screening to remove foreign material, and sizing discussed previously, to more extensive processing to remove additional ash, sulfur and moisture more intimately associated with the coal.

The potential benefits of coal cleaning must be bal-

Fig. 7 Ring hammer mill crusher – diagrammatic section (courtesy of Pennsylvania Crusher Corporation).

anced against the associated costs. The major costs to consider, in addition to the cleaning plant capital and operating costs, include the value of the coal lost to the refuse product through process-related inefficiencies and the cost of disposing of the refuse product. Generally, the quantity of coal lost increases with the degree of desired ash and sulfur reduction. An economic optimum level of ash and sulfur reduction can be established by balancing shipping and post-combustion cleanup costs against pre-combustion coal cleaning costs.

Coal characterization

Coal is a heterogeneous mixture of organic and inorganic materials as described in detail in Chapter 9. Coal properties vary widely between seams and within a given seam at different elevations and locations. The impurities associated with coal can generally be classified as inherent or extraneous. *Inherent impurities* such as organic sulfur can not be separated from the coal by physical processes. *Extraneous impurities* can be partly segregated from the coal and removed by physical coal cleaning processes. The extent to which these impurities can be economically removed is determined by the degree of material dissemination throughout the coal matrix, the degree of liberation possible at the selected processing particle size distribution, and physical limitations of the processing equipment.

Mineral matter associated with the raw coal forms ash when the coal is burned. Ash-forming mineral matter may also be classified as inherent or extraneous. Inherent mineral matter consists of chemical elements from plant material organically combined with coal during its formation. This mineral matter generally accounts for less than 2% of the total ash. Extraneous mineral matter consists of material introduced into the deposit during or after the coalification process, or is extracted with the coal in the mining process.

Sulfur is always present in coal and forms SO_2 when the coal is burned. If the sulfur is not removed before combustion, the SO_2 that forms is exhausted

through the stack or removed by post-combustion flue gas treatment, discussed in Chapters 32 and 35. Sulfur is generally present in coal in three forms: pyritic, organic or sulfate.

Pyritic sulfur refers to sulfur combined with iron in the minerals pyrite (FeS_2) or marcasite. Pyrite may be present as lenses, bands, balls or as finely disseminated particles. *Organic sulfur* is chemically combined with molecules in the coal structure. *Sulfate sulfur* is present as calcium or iron sulfates. The sulfate sulfur content of coal is generally less than 0.1%.

The total sulfur in U.S. coals can vary from a few tenths of a percent to more than 8% by weight. The pyritic portion may vary from 10 to 80% of the total sulfur and is usually less than 2% of the coal by weight (Table 1).

The larger pyritic sulfur particles can generally be removed by physical cleaning, but finely disseminated pyritic sulfur and organic sulfur can not. Advanced physical and chemical cleaning technologies are under development to remove these sulfur forms.

Moisture can also be considered an impurity because it reduces the heating value of raw coal. Inherent moisture varies with coal rank, increasing from 1 to 2% in anthracite to 45% or more in lignite. Surface moisture can generally be removed by mechanical or thermal dewatering. This drying requires an energy expense at the cleaning plant or the steam generating plant (in pre-drying or during combustion). Drying before shipment reduces transportation costs on a per-Btu basis. When pre-drying is used, atmospheric oxidation will tend to be increased for low rank coals because of the exposure of additional oxidation sites in the particles.

The distribution of ash and sulfur in a coal sample can be characterized by performing a *washability analysis*. This analysis consists of separating the raw coal into relatively narrow size fractions and then dividing each fraction into several specific gravity fractions. The coal in each size/specific gravity fraction is

Table 1
Distribution of Sulfur Forms in Various Coals (%)

Mine Location County, State	Coal Seam	Total Sulfur	Pyritic Sulfur	Organic Sulfur

then analyzed for ash, sulfur and heating value content. The hardness and distribution of the impurities relative to the coal determine if the impurities are concentrated in the larger or smaller size fractions. Relatively soft impurities are generally found in the finer size fractions. In general, the lowest specific gravity fractions have the lowest ash content, as indicated in Table 2.

The information generated by these *float/sink* characterization tests can be used to predict the degree of ash and sulfur reduction possible using various specific gravity based cleaning technologies discussed below. In general, the more material that is present near the desired specific gravity of separation, the more difficult it is to make an efficient separation.

Coal cleaning and preparation operations

The initial steps in the coal cleaning process include removal of trash, crushing the run-of-mine coal, and screening for size segregation. These preliminary operations and associated hardware were discussed previously. The following operations are then used to produce and dewater a reduced ash and sulfur product. Fig. 8 provides a general layout of coal cleaning unit operations.

Gravity concentration Concentration by specific gravity and the subsequent separation into multiple products is the most common means of mechanical coal cleaning. Concentration is achieved because heavier particles settle farther and faster than lighter particles of the same size in a fluid medium. Coal and impurities may be segregated by their inherent differences in specific gravity, as indicated in Table 3.

The fluid separating medium may consist of a suspension of the raw coal in water or air, a mixture of sand and water, a slurry of finely ground magnetite (iron oxide, Fe_3O_4), or an organic liquid with an intermediate specific gravity. Aqueous slurries of raw coal and magnetite are currently the most common separating media.

If the effective separating specific gravity of the media is 1.5, particles with a lower specific gravity are concentrated in the clean coal product and heavier particles are in the reject or refuse product. Several factors prevent ideal separation in practice.

Gravity separation processes concentrate particles by mass. The mass of a particle is determined by its specific gravity and particle size. Raw coal consists of particles representing a continuous distribution of

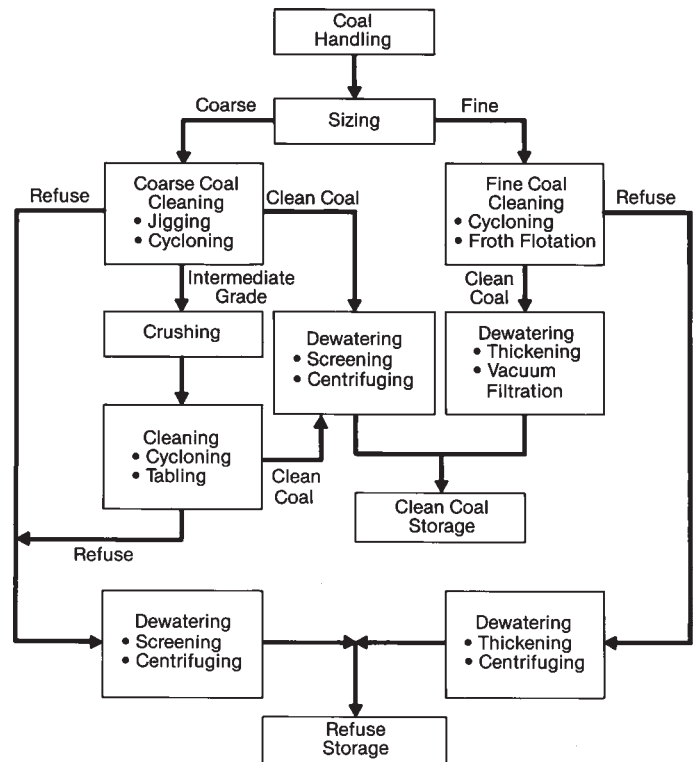

Fig. 8 General layout of coal cleaning operations.

specific gravities and sizes. It is quite possible for a larger, less dense particle to behave similarly to a smaller particle with a higher specific gravity. For example, a relatively smaller pyrite particle may settle at a similar rate as a larger coal particle. The existence of *equal settling* particles can lead to separating process inefficiency. Fine pyrite in the clean coal product and coarse coal in the refuse are commonly referred to as *misplaced material*. The amount of misplaced material is determined by the quantity and distribution of the raw coal impurities, the specific gravity of separation, and the physical separation efficiency of the segregated material.

A significant amount of material with a specific gravity close to the desired specific gravity of separation results in a more inefficient separation. If the amount of *near gravity material* exceeds approximately 15 to 20% of the total raw coal, efficient gravity separation is difficult.

The most common wet gravity concentration techniques include jigging, tabling, and dense media separation processes. Each technique offers technical and economic advantages.

Jigging In a coal jig, a pulsating current of water is pushed upward in a regular, periodic cycle through a bed of raw coal supported on a screen plate. This upward or pulsion stroke of the cycle causes the bed to expand into a suspension of individual coal and refuse particles. The particles are free to move and generally separate by specific gravity and size, with the lighter and smaller pieces of coal moving to the upper region of the expanded bed. In the downward or suction stroke of the cycle, the bed collapses, and the separation is enhanced as the larger and heavier pieces of rock settle faster than the coal. The pulsion/suction

Table 2
Typical Ash Contents of Various
Bituminous Coal Specific Gravity Fractions

Specific Gravity Fraction	Ash Content % by wt
1.3 to 1.4	1 to 5
1.4 to 1.5	5 to 10
1.5 to 1.6	10 to 35
1.6 to 1.8	35 to 60
1.8 to 1.9	60 to 75
Above 1.9	75 to 90

Table 3
Typical Specific Gravities of Coal
and Related Impurities

Material	Specific Gravity
Bituminous coal	1.10 to 1.35
Bone coal	1.35 to 1.70
Carbonaceous shale	1.60 to 2.20
Shale	2.00 to 2.60
Clay	1.80 to 2.20
Pyrite	4.80 to 5.20

cycle is repeated continuously. The separated layers are split at the discharge end of the jig to form a clean coal and a refuse product. The bed depth where the cut is made determines the effective specific gravity of separation.

The upward water pulsation can be induced by using a diaphragm or by the controlled release of compressed air in an adjacent compartment. Operation of a Baum jig is illustrated in Fig. 9. This type of jig may be used to process a wide feed size range. Typically,

the specific gravity of separation ranges from 1.4 to 1.8. The separation efficiency may be enhanced by pre-screening the feed to remove the fines for separate processing.

Tabling A concentrating, pitched table is mounted so that it may be oscillated at a variable frequency and amplitude. A slurry of coal and water is continuously fed to the top of the table and is washed across it by the oncoming feed. Diagonal bars, or *riffles*, are spaced perpendicular to the flow of particles. The coal-water mixture and oscillating motion of the table create a *hindered settling* environment where the lower gravity particles rise to the surface. Higher specific gravity particles are caught behind the riffles and transported to the edge of the table, away from the clean coal discharge.

Tables are generally used to treat 0.375 in. \times 0 (9.53 mm \times 0) coal. Three or four tables may be stacked vertically to increase throughput while minimizing plant floor space requirements.

Dense media separation In dense or heavy media separation processes, the raw coal is immersed in a fluid with a specific gravity between that of the coal and the refuse. The specific gravity differences cause

Fig. 9 Typical Baum jig for coal preparation.

the coal and refuse to migrate to opposite regions in the separation vessel. In coal preparation, the heavy media fluid is usually an aqueous suspension of fine magnetite in water.

Flotation Coal and refuse separation by *froth flotation* is accomplished by exploiting differences in coal and mineral matter surface properties rather than specific gravities. Air bubbles are passed through a suspension of coal and mineral matter in water. This suspension is agitated to prevent particles from settling out. Air bubbles preferentially attach to the coal surfaces that are generally more hydrophobic, or difficult to wet. The coal then rises to the surface where it is concentrated in a froth on top of the water. The mineral matter remains dispersed (Fig. 10). Chemical reagents, referred to as collectors and frothers, are added to enhance the selective attachment of the air bubbles to the coal and to permit a stable froth to form.

Flotation is generally used for cleaning coal finer than 48 mesh (300 microns). The efficiency of the process can be enhanced by carefully selecting the type and quantity of reagents, fine grinding to generate discrete coal and refuse particles, and generating fine air bubbles.

Dry processing Dry coal preparation processes account for a small percentage of the total coal cleaned in the U.S. In general, pneumatic processing is only applied to coal less than 0.5 in. (12.7 mm) in size with low surface moisture.

Dewatering Dewatering is a key step in the preparation of coal. Reducing the fuel's moisture content increases its heating value per unit weight. Because coal shipping charges are based on tonnage shipped, a reduction in moisture content results in lower shipping costs per unit heating value.

Coarse coal, greater than 0.375 in. (9.53 mm) particle size, can be sufficiently dewatered using vibrating screens. Intermediate size coal, 0.375 in. (9.53 mm) by approximately 28 mesh (600 microns), is normally dewatered on vibrating screens followed by centrifuges.

Fine coal dewatering often involves the use of a thickener to increase the solids content of the feed to a vacuum drum, vacuum disc filter, or high gravity

centrifuge. The filter cake may be mixed with the coarser size fractions to produce a composite product satisfying the specifications. Fine coal dewatering also serves to clarify the water for reuse in the coal preparation plant. Fines must be separated from the recycled water to maximize the efficiency of the separation processes.

Thermal dewatering may be necessary to meet product moisture specifications when the raw coal is cleaned at a fine size to maximize ash and sulfur rejection. The various types of thermal dryers include rotary, cascade, reciprocating screen, suspension and fluidized-bed dryers. Cyclones or bag filters are used to prevent fine dust emissions from the dryer. The collected fine coal may be recycled to support dryer operation. Thermal drying represents an economic tradeoff of reduced product moisture content versus heat required to fire the dryer.

Impact on steam generator system operations

The principal benefit of coal cleaning is the reduction in ash and sulfur content. Reduced ash content results in lower shipping costs and reduced storage and handling requirements at the plant on a cost per unit heating value basis. Boiler heat transfer effectiveness may increase as a result of reduced ash deposition on tube surfaces. A reduction in sulfur content leads directly to reduced SO₂ emissions. Lower sulfur feed coal may preclude the need for or reduce the performance requirements of post-combustion SO₂ emission control systems. A reduction in sulfur content may also reduce spontaneous combustion during storage, and corrosion in coal handling and storage equipment. Reduced ash content can result in reduced maintenance through removal of abrasive pyrite and quartz from the coal. Reduction of clay in the coal can improve handling and bunker or silo storage characteristics, but this may be offset by the effects of higher fines content and higher surface moisture on cleaned coal.

Coal transportation

The means of transportation and the shipping distance significantly influence the total fuel cost, reliability of supply, and fuel uniformity at the power plant. In some cases where western U.S. coal is shipped over an extended distance, freight costs may represent 75 to 80% of the total delivered fuel cost. At the other extreme, transportation costs may be negligible for mine-mouth generating stations. In transit, the coal's handling characteristics may be changed by freezing, increased moisture content, or size degradation. When open rail car, truck or barge transport is used, the moisture content of the delivered coal depends on the initial moisture level, the weather conditions in transit, and the particle size distribution. Size degradation during shipping is dependent on the coal friability (ease of crumbling) and the techniques and number of transfers. As previously stated, for pulverized coal applications, size degradation is generally not a concern.

Coal is primarily shipped by rail, barge, truck and conveyor, but can also be transported by pipelines and

Fig. 10 Flotation cell.

tramway systems. The volume and distribution of coal transported by these various means is summarized in Table 4.⁵ Combinations of these methods are often used to obtain the lowest delivery cost. Available transportation infrastructure, haulage distance, required flexibility, capital cost and operating cost are important factors in selection of a system for delivering coal to the power plant.

In general, barge transport represents the lowest unit cost per ton per mile followed by rail, truck and conveyor in terms of increasing cost. Combinations of these four transportation systems may be used to move coal to loading docks for overseas shipment.

Transportation systems are generally designed to minimize intermediate storage of coal to control inventory costs, reduce insurance costs, and minimize the effects of changes that can reduce the commercial value of coal. Potentially harmful changes include a reduction of heating value, particle size degradation, and loss due to self-ignition or wind and water erosion.

Rail

Railroads delivered approximately 70% of the coal transported to electric generating power plants in the U.S. in 2002, and nearly 95% of this total was shipped in unit trains. Unit trains travel from the loading facility to the customer without stopping and normally consist of 50 or more cars with a total of 10,000 t of coal or more. Bottom dump and rotary dump rail cars [100 t (91 t_m) capacity] are typically used. These high capacity rail cars are generally not uncoupled from the time they are loaded at the mine until they arrive at the plant. In 1999, coal accounted for 44% of the rail industry's total freight tonnage and 22% of the revenues for Class I railroads.⁶

Rail transport provides for the movement of large quantities of coal over distances ranging from 10 to 1500 mi (16 to 2414 km).⁷ Dedicated service between one mine and the steam generating plant simplifies management of coal deliveries. Improvements in coal-carrying capacity in rail cars and more powerful locomotives have resulted in higher efficiency in rail transport. In comparison to rail cars in the 1930s, today's coal car carries double the capacity.

The advantages of rail transport are offset slightly

by the restricted rail access. Generally only one rail line is available to transport coal from a mine or to a specific steam generating plant. The installation of dedicated rail lines must be included as part of the cost of the coal handling and storage system. Rail spurs to a specific mine location are useful only for the life of the mining activity. Transit time is typically on the order of 4 to 20 days.⁷ The rail car unloading system and intermediate storage facilities must be designed to quickly process the cars to avoid demurrage (delay) charges at the plant.

Railroads will continue to play a significant part in coal transportation as long as coal is used to generate electricity and remains the greatest and single-most important commodity.

Barge

Barge transport of coal is the most cost-effective alternative to rail or truck. Approximately 11% of all coal shipped to electric generating plants in the U.S. is delivered by barge. According to the U.S. Army Corps of Engineers (COE), coal is the largest single barge commodity. Coal traffic accounted for 176 million tons of the total annual barge tonnage in 1990 (623 million tons).⁸

The cargo capacity difference between the three major transportation methods for carrying coal is shown below:

$$1 \text{ Barge} = 15 \text{ Rail Cars} = 58 \text{ Trucks}$$

A key to barge efficiency is the ability of barges to carry cargo many times their own weight. Additionally, less energy is expended to move cargo by barge than by rail car or truck. There are several styles of barges used for transporting various types of cargo, but standard open-topped jumbo hopper barges are commonly applied to coal transport.⁹ (See Fig. 11.)

Export coal is shipped on the Great Lakes by large bulk carrier ships called colliers, but barges transport coal within the U.S. by using inland and intracoastal waterways. The major waterways for coal traffic in the U.S. are the Ohio, Mississippi and Black Warrior-Tombigbee Rivers. The quantity of coal shipped in a

Fig. 11 Typical barge transport for large quantities of coal.

Table 4
Distribution of Coal Transportation
Methods for Electricity Generation
(Thousand Short Tons) in the U.S. (2002)⁵

Method	10 ⁶ t/yr	10 ⁶ t _m /yr	% of Total
Rail	615	558	70
Barge	97	88	11
Truck	81	74	9
Conveyor/pipeline/ tramway	79	72	9
Other water shipping methods	11	10	1
U.S. totals	883	802	100

single tow or string of barges is determined by the lock requirements of the river system being navigated. For example, on the Ohio River system, a tow of three barges wide by five barges long is commonly used because of the River's lock requirements.¹⁰ However, on the relatively unobstructed lower Mississippi, tows of 30 barges are not uncommon.

There is a significant degree of competition and transport prices are generally stable. Some cost differences between upstream and downstream travel are common.

Barge transportation of coal to steam generating plants is constrained by the location and characteristics of the available river systems. Close proximity to waterways for direct loading and unloading is needed for efficient barge transportation. Barge delivery must be supported by truck, rail, or belt conveyor transloading at the mine location or the steam generating plant. The natural river network is not always the most direct route and may result in increased delivery time. The channel width and seasonal variability in water level are natural limitations for barge traffic. River lock sizes and condition of repair may restrict the maximum permitted tow size. Delays due to deteriorating locks and congestion may be significant on some river systems. In some areas, lock repair costs are recovered through a surcharge on tonnage shipped through the lock.

Barges are not self-unloading. Barge unloading can consist of a simple clam-shell crane discharging onto a take-away conveyor. For large capacities, high-rate automated bucket-elevator unloaders are often used. Capacities of these systems range from several hundred to several thousand tons per hour. System capacity must be considered to limit demurrage time for barge delivery and unloading at large power stations. The capital investment required for the unloading facilities may restrict barge deliveries to plants using more than 50,000 t/yr.⁷

Truck

For power plants located near mines, trucks loaded at the mine deliver coal directly to the power plant storage site. In 2002, trucking accounted for 9% of the total tonnage of coal delivered to electric generating plants.⁵ The truck deliveries may unload directly onto the coal storage pile or into hoppers feeding the automated conveying system for distribution to the storage pile or silos.

Trucking also plays an important role in both rail and barge transport. Many times coal transported by rail or barge is first trucked to the loading dock or involves truck transfer at the mine. Highway trucks typically carry 15 to 30 t (14 to 27 t_m) of coal over distances up to 70 mi (113 km). Off-road vehicles can handle 100 to 200 t (91 to 181 t_m) over a range of 5 to 20 mi (8 to 32 km) at mine-mouth generating stations.

Trucking is the most flexible mode of coal transportation. It is relatively easy to adjust to changes in demand to meet the generating plant's variable supply requirements. The short haulage distances, and therefore short delivery times, can be used to minimize storage requirements at the generating plant. Trucks are simple to unload and a minimum of on-site han-

dling and distribution is needed. Use of the existing highway infrastructure provides for flexible delivery routes and reduces travel restrictions associated with rail and river transport. Trucks are very efficient for short haulage distances and for smaller generating plants. Trucking is the least capital intensive mode of transporting coal and a high degree of competition exists.

Truck transportation is characterized by a high operating cost per ton mile relative to barge or rail transport. Practical haulage distances are usually limited to 50 mi (80 km). State and local transportation regulations often limit loads to 25 t (23 t_m) or less. A large generating plant would require a significant amount of truck traffic and congestion at the delivery site may be severe. Truck deliveries require the highest degree of monitoring at the plant. Frequently, every truck must be weighed.

Continuous transport

Coal may be transported from the mine to the generating plant by continuous belt conveyors, slurry pipelines or tramways. In 2002, continuous transport systems accounted for approximately 9% of the total coal deliveries.⁵ Belt conveyors are normally limited to lengths of 5 to 15 mi (8 to 24 km). The coal delivery rate is a function of the belt width, operating speed, and the number of transfer points. Only one major coal slurry pipeline is in operation. The 273 mi (439 km) long Black Mesa Pipeline runs from a mine in Arizona to a generating plant in Nevada. The coal transport rate is determined by the pipe diameter, slurry velocity and solids loading.¹¹

Continuous systems can move large amounts of coal cost-effectively over short distances. Often, continuous systems can be used where the terrain limits the use of other modes of transport. Social and environmental impacts are minimal.

The application of continuous transportation systems is limited by the proximity to the generating plant, a low degree of operating flexibility due to the fixed carrying capacity, the inflexibility of the loading and discharge locations, high capital cost, and a relatively high energy consumption per ton mile of coal delivered. Pipeline builders must overcome significant opposition in obtaining rights of way and water resource allocation. The added costs associated with dewatering the coal at the generating plant must also be considered.

Coal handling and storage at the power plant

Bulk storage of coal at the power plant is necessary to provide an assured continuous supply of fuel. The tonnage of coal stored at the site is generally proportional to the size of the boiler. A 100 MW plant burns approximately 950 t/d (862 t_m/d), while a 1300 MW plant requires approximately 12,000 t/d (10,887 t_m/d). For most power plants, a 30 to 90 day supply is stored at the plant to assure adequate supply through any delivery interruptions. Public utilities in the U.S. are required by law to maintain minimum supplies. How-

ever, stored coal represents substantial working capital and requires land that may be otherwise productive. Economic considerations are a key factor in determining when to purchase coal and how much coal to store at the plant. Additional considerations, such as the changes to coal characteristics due to weathering, restrict the maximum amount of coal stored on site.

For smaller, industrial boiler applications, bin or silo storage may be preferred over stockpile storage. The advantages of bin storage include shelter from the weather and ease of reclamation. Prefabricated bins with capacities holding several hundred tons are com-

mercially available as are large, field-erected concrete silos of several thousand tons capacity. In regions with severe winter weather, even large power stations use silo storage to facilitate easier reclamation.

The complexity of the coal storage and handling operations increases in proportion to the size of the steam generating plant. Efficient techniques have been developed for large and small plants. The components of a sophisticated coal storage and handling system for a large, 1000 MW electric generating plant are illustrated in Fig. 12. Coal is delivered in self-unloading rail cars and is transferred to a large stock-

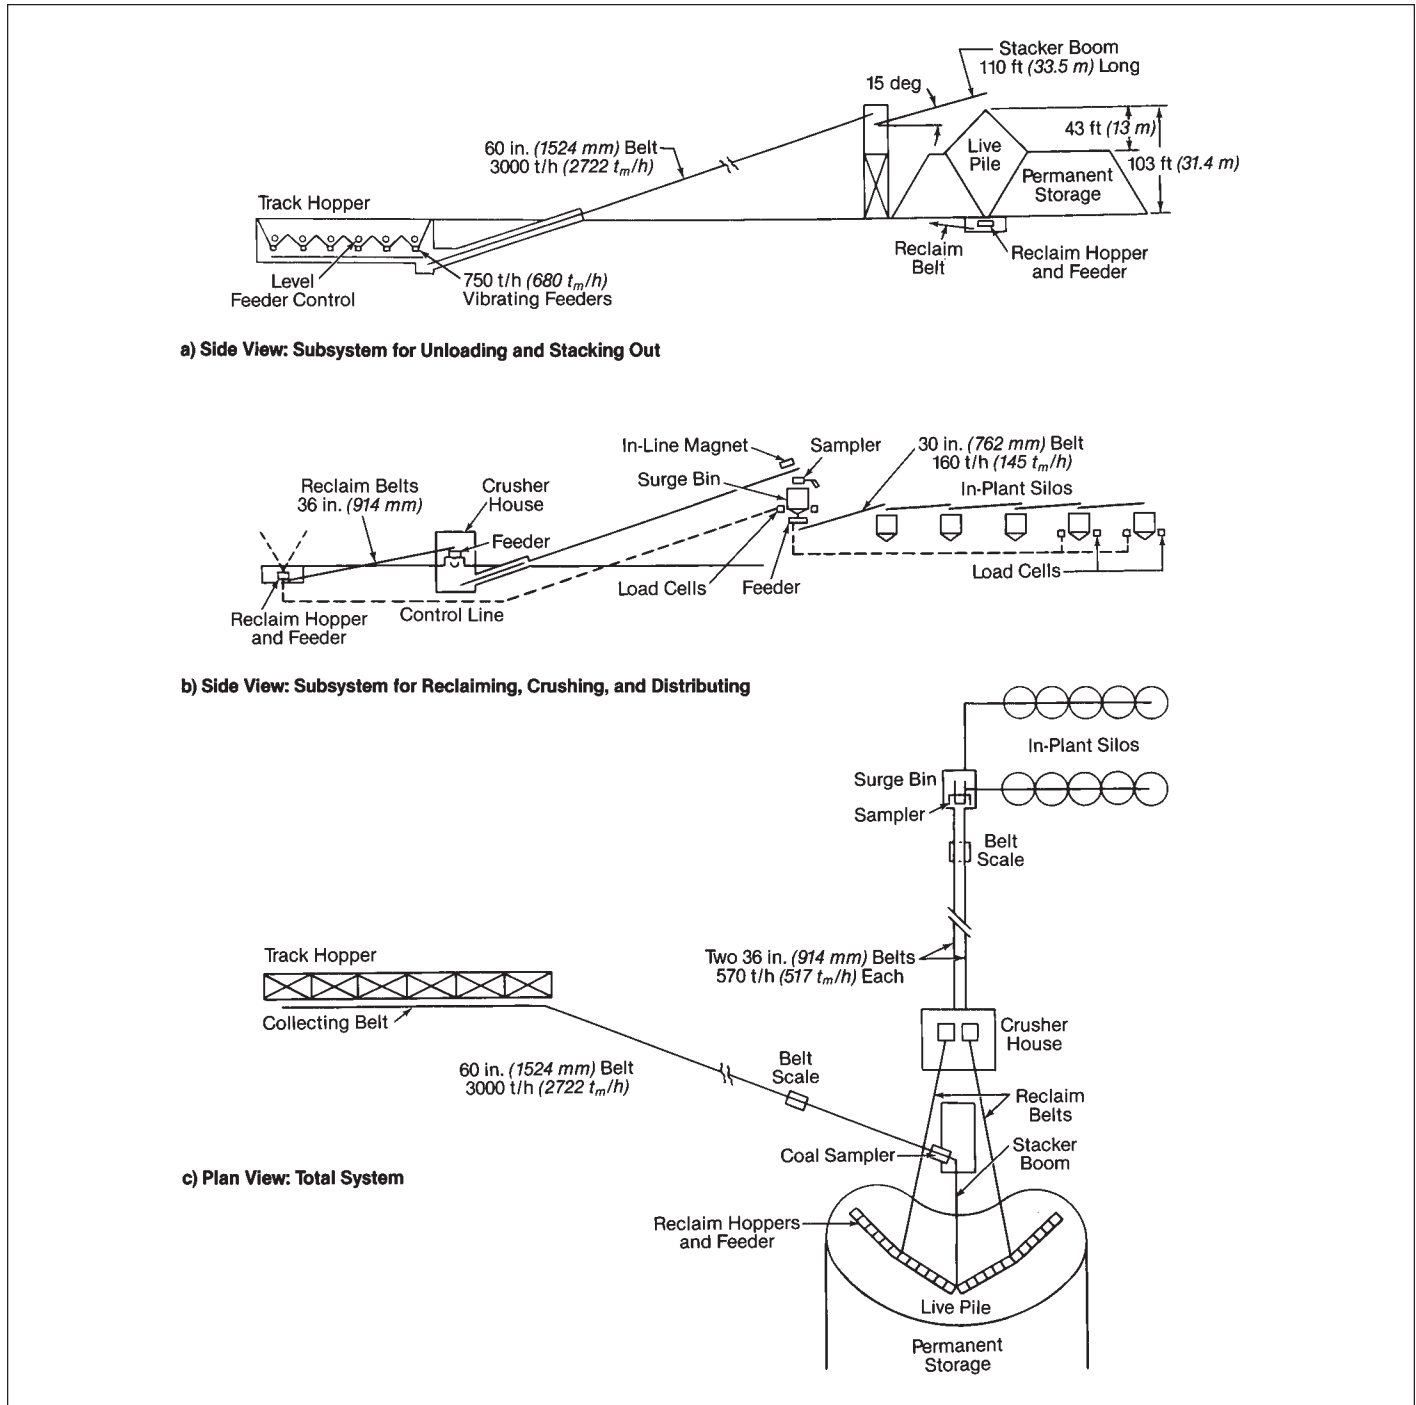

Fig. 12 Typical coal handling system and subsystems for a 1000 MW coal-fired power generation plant.

pile. An automatic reclaim system recovers coal from the stockpile for crushing and distribution to in-plant storage silos. The system is automated and a two person crew can handle 7000 t/d (6350 t_m/d) of coal. All the equipment from the reclaim feeders to the in-plant silos to the boiler is controlled by the central control room operator.

The storage and handling operations of a utility boiler are depicted in the chapter frontispiece.

Raw coal handling

An extensive array of equipment is available for unloading coal at the plant site and distributing it to stockpile and bin storage locations. Equipment selection is generally based on the method of coal delivery to the plant, the boiler type, and the required coal capacity. For small plants, portable conveyors may be used to unload rail cars, to reclaim coal from yard storage piles, and to fill bunkers. Larger plants require dedicated handling facilities to meet the demand for a continuous fuel supply. However, even relatively small plants may benefit from the improved plant appearance, cleanliness and reduced coal handling labor requirements associated with mechanical handling systems.

The coal handling system components are determined by the design and requirements of the boiler. If coal particle size is not specified to the coal supplier, then a crusher is normally integrated into the system to generate a uniform top size coal feed to the pulverizer or feeder equipment of circulating fluidized bed (CFB) or stoker-fired boilers. The system normally includes a magnetic separator to remove misplaced mining tools, roof support bolts, and other metallic debris that could damage the pulverizer or feeder equipment. Crushing and tramp metal removal needs are generally less critical for stoker-fired boilers than for pulverized coal and CFB units.

The coal handling system capacity is determined by the boiler's rate of coal use, the frequency of coal deliveries to the plant, and the time allowed for unloading. In most large plants, only four to six hours per day are dedicated to unloading of coal deliveries.

Rail car unloading

Rail cars can either be of the bottom discharge or rotary dump type. In automatic rotary car dumping systems, the rail cars are hydraulically or mechanically clamped in a cradle, and the cradle is rotated about a rotating track section so the coal falls into a hopper below the tracks. The rail cars have special swivel couplings to allow the dumping to be completed without uncoupling the cars. The rotary dump system advantages of short cycle time and high capacity are offset by a relatively high capital cost.

With bottom dump cars, unloading is relatively simple when the coal is dry and free flowing. However, high surface moisture can cause the coal to adhere within the car and, in cold weather, freeze into a solid mass. In hot, dry weather, high winds can create severe dust clouds at the unloading station unless special precautions are taken. The coal supplier frequently sprays the coal with oil or an anti-freezing chemical such as ethylene glycol as the car is loaded

to settle the fines and to improve handling in freezing weather. The treatment does not appreciably affect combustion or cause problems in the pulverizers. There is also some evidence that the treatment may reduce adherence and hangups in bunkers and chutes.

A simple bottom dump rail car unloading system that includes a crusher and magnetic separator is illustrated in Fig. 13. A screw conveyor is used to distribute coal along the length of the bunker. The capacity of the bucket elevator generally limits this system to relatively small plants.

A rotary dump rail car unloading and handling sys-

Fig. 13 Rail car dumping system for a small power plant.

Fig. 14 Rail car unloading and coal handling system for a large power plant.

tem for a larger plant is shown in Fig. 14. Coal from the car dump hopper is fed to a rotary breaker, where the coal breaks into smaller pieces as it is tumbled and passes through a screen shell. The broken coal can then be conveyed directly to the storage bunkers, or to the stockpile.

Barge unloading

The simplest barge unloader consists of a clamshell bucket mounted on a fixed tower. The barge is positioned under the bucket and is moved as necessary to allow emptying. With this type of unloader, the effective grab capacity of the buckets is only 40 to 50% of the nominal bucket capacity. A shore mounted bucket wheel or elevator unloader can increase the efficiency and capacity of this unloading operation. Modern ocean-going vessels are often equipped with a bucket wheel for self-unloading.

Truck unloading

Trucks may dump coal through a grid into a storage hopper. This grid separates large pieces of wood and other trash from the coal. At some plants, the trucks are directed to a temporary storage area, where coal from various mines can be blended prior to crushing or feeding to the boiler.

An effective truck delivery and coal handling system for a small to medium size (30 to 300 t/d) stoker coal-fired boiler is illustrated in Fig. 15. This system provides site preparation of the coal along with tramp metal removal.

Stockpile storage

Careful consideration should be given to storage pile location. The site must be conveniently accessible by barge, rail or truck. Frequently, provisions must be made for more than one method of coal delivery. The site should be free of underground power lines. Other underground utilities that would not be accessible after the storage pile is constructed must also be

avoided. A thorough evaluation and environmental survey of the proposed site topography should include analysis of the soil characteristics, bedrock structure, local drainage patterns, and flood potential. Climatic data, such as precipitation records and prevailing wind patterns, should also be evaluated. Protection from tidal action or salt water spray may be needed in coastal areas. The potential effects of water runoff and dust emissions from the pile must be considered. Site preparation includes removing foreign material, grading for drainage, compacting the soil, and providing for collection of site drainage.

The shape of a stockpile is generally dependent on the type of equipment used for pile construction and for reclaiming coal from the pile. Conical piles are generally associated with a fixed stacker while a radial stacker generates a kidney shaped pile. A rail mounted traveling stacker can be used to form a rectangular pile. Regardless of the shape of the pile, the sides should have a shallow slope.

Bituminous coal, subbituminous coal and lignite should be stockpiled in multiple horizontal layers. To reduce the potential for spontaneous combustion, coal piles are frequently compacted to minimize air channels. These channels can function as chimneys that promote increased air flow through the pile as the coal heats. For bituminous coal, an initial layer, 1 to 2 ft (0.3 to 0.6 m) thick, is spread and thoroughly packed to eliminate air spaces. A thinner layer is required for subbituminous coal and lignite to assure good compaction. Care should be taken to avoid coal pile size segregation by blending coal during pile preparation.

For long-term storage (see Fig. 16), the top of the pile may be slightly crowned to permit even rain runoff. All exposed sides and the top may be covered with a 1 ft (0.3 m) thick compacted layer of fines and then capped with a 1 ft (0.3 m) layer of screened lump coal. It is not practical to seal subbituminous and lignite piles with coarse coal because the coarse coal would

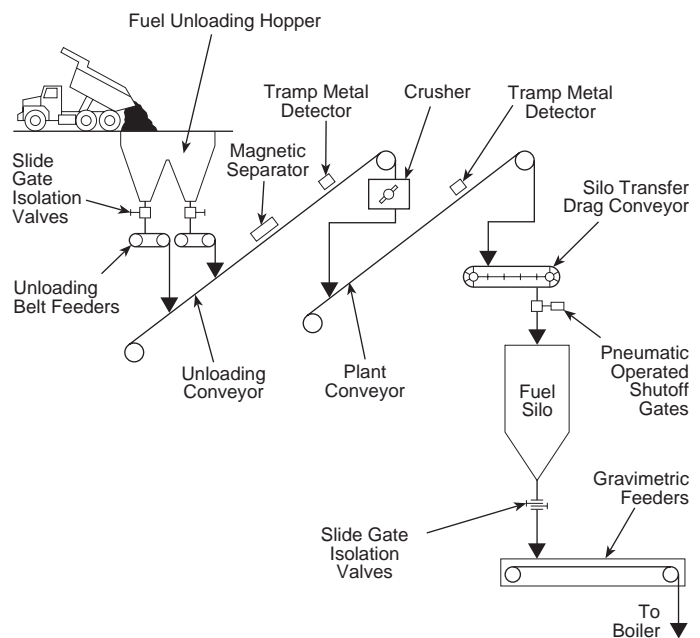

Fig. 15 Typical coal handling system for truck delivery.

Fig. 16 Long-term coal storage – typical example of thorough packing with minimal size segregation. This pile contains about 200,000 t of coal.

weather and break apart to a smaller size in a short period of time. At smaller industrial plants, where heavy equipment for compaction can not be justified, a light coating of diesel oil can help to seal off the outer surface of the pile.

The quantity of coal stored in a stockpile can be estimated using geometry and some assumptions about the characteristics of coal. The volume of the pile can be estimated based on its shape. Approximate values for the material's bulk density and its angle of repose are required to complete tonnage calculations. Both of these parameters are particle size dependent. For typical utility storage pile applications, a loose coal bulk density of 50 lb/ft³ (801 kg/m³) and a 40 deg angle of repose may be used. For well compacted piles, a bulk density of 65 to 72 lb/ft³ (1041 to 1153 kg/m³) is more appropriate.

Storage pile inspection and maintenance Visual inspections for hot spots should be made daily. In wet weather, a hot area can be identified by the lighter color of the surface coal dried by escaping heat. On cold or humid days, streams of water vapor and the odor of burning coal are signs of heating or air flowing through the pile. Hot spots may also be located by probing the pile with a metal rod. If the portion of the rod in contact with the coal is too hot to be held as it is withdrawn, the coal temperature is dangerously high.

It is also important to rotate areas of the storage pile from long to short term storage on a planned schedule. This minimizes harmful degradation of the coal.

Bulk storage reclaim and transfer The specific sys-

tem for reclaiming the stored coal from stockpiles depends upon plant size and economic evaluation of operating and capital costs. For higher capacity systems of around 200 t/h (181 t_m) and greater, automated under-pile or over-pile reclaim systems are used. Under-pile reclaim systems can consist of under-pile hoppers with vibrating or belt feeders discharging onto a take-away belt conveyor. The belt conveyor travels at an incline through an underground tunnel until exiting the ground surface and is routed to the desired elevation. Over-pile reclaimers can be a variety of traveling bucket wheels or flight reclaimers that discharge onto an above ground take-away belt conveyor. For lower capacity systems, reclaim can be by bulldozer or front loader into a hopper feeding a take-away conveyor.

A variety of mechanical conveyors are used for transfer conveying. These include belt conveyors, drag (or flight) conveyors, bucket elevators, and screw conveyors. Belt conveyors are generally limited to an incline angle of 15 to 16 deg from horizontal to avoid roll-back of coal lumps on the traveling belt. Advancements in belt conveyor technology have yielded designs capable of greater incline angles and lateral routing, however at greater capital cost. Bucket and drag conveyors provide greater elevation capabilities over short horizontal distances, but mechanical conveyors inherently have greater wear and associated maintenance costs than belt conveyors. Screw conveyors are utilized primarily for horizontal, short-length conveying in low capacity applications. Wear and maintenance costs are also higher with screw conveyors.

Silo storage

Silos are often used where severe winter conditions can justify the added cost. Power plants with limited land space for large storage piles can also justify the expense. Silos are typically large field-constructed concrete structures of the slip-form or jump-form design. Large silos at central power stations can store 10,000 to 20,000 t (9710 to 18,144 t_m) and can be grouped together for necessary storage capacity. Multiple silos also provide the ability to empty one and perform maintenance while supporting operations. The silo hopper design must ensure adequate coal flow to avoid hide-out and coal hang-ups in the silo.

Bunker storage

Coal bunkers provide intermediate, short term storage, ahead of the pulverizers or other boiler coal feed equipment. Bunkers (also known as *day-bins*) are normally sized for 8 to 24 hours of fuel supply at maximum boiler operation. Normally, there is one bunker for each pulverizer and boiler coal feed point, but it is not uncommon to see one bunker with two or more outlets, feeding multiple points.

Bunker design

Once constructed, the coal bunkers are an integral part of the boiler house structure. Any redesign or modification to the bunkers can be expensive and difficult, if not impossible. The bunkers also must be designed for reliable flow of the stored fuel. (See Fig. 17.)

Fig. 17 Four commonly used shapes in coal bunker design.

The flowability characteristics of coal are important parameters in the design of the hoppers and chutes in the coal handling system and boiler feed systems. A *shear cell* test device measures the resistance of coal to slide in shear action against itself, and measures the resistance of the material to slide on a surface such as steel, stainless steel or other common materials. This testing can be performed after the coal has consolidated for several days, to simulate storage of the coal in a silo or bunker. From this data, the optimum combination of hopper slope angle and minimum outlet opening can be determined to assure reliable flow. This data can also be used to determine critical chute angles to assure continuous sliding flow through the chute, regardless of the cohesive nature of the coal and tendency to adhere to chute walls. Other factors that are utilized in optimizing the hoppers or chutes are the flowability of the coal on varying surfaces. This information is used in determining the most economic material to use for fabrication of the hoppers or chutes, or the liners applied. Materials such as carbon steel, polished and unpolished stainless steel, abrasion resistant steels, abrasion resistant plastic liner materials, and ceramic are just some of the materials routinely tested.

In bunkers or silos without proper design, reduced flow or even pluggage can occur. This is the result of the coal adhering to the hopper walls, especially at the transition from the straight walls to the angled hopper. This build-up can form a channel of limited cross-section through which the material flows. As the material continues to build-up, this flow channel of small cross section can bridge over and total pluggage occurs. Flow aids such as air blasters and bin vibrators

can reduce this pluggage, but many times have limited success. Even with continuous flow, some residual material will remain in an emptied bunker due to the adherence in the straight wall to sloped hopper zone. This residual material can result in bunker fires due to spontaneous combustion. This is especially problematic with higher volatile coals, such as Powder River Basin coals.

With proper flow testing and design, complete emptying of the bunker or silo is assured each time the level is drawn down. The bunker or silo will be designed for *funnel flow* or *mass flow*. In funnel flow there is a stagnant zone (where the material does not flow) where the bunker vertical wall transitions to the sloped hopper wall. However, when the level in the vessel is drawn below this region and the pressure is reduced on this material, it releases from the hopper wall and collapses on the material level in the hopper. In a mass flow design, the material draws down uniformly throughout the vessel, in a pattern down the vertical walls, then transcends down the sloped hopper slopes. The cohesive nature of the coal and ability to adhere to the vessel walls determine the design. A third design, called *expanded flow*, combines these two. The hopper is in two sections, the upper section funnel flow and the lower section mass flow.

Downspout design Flow testing data can also be used to optimize downspout design. Downspouts should be circular, short and as steep as possible, preferably vertical. Reductions in cross-sectional area and sudden changes in direction should be avoided.

In pressurized pulverizer feed applications, or coal feed to the pressurized location of a CFB boiler, special consideration must be given to downspout design because the coal inside the downspout also serves as the seal against the pressurized location and air or gas backflow to the bunker. A minimum required height (*seal height*) and a sealed downspout/feeder system are required. A typical bunker to pulverizer system is shown in Fig. 18. Vertical, constant-diameter downspouts connect the bunker to the feeder and the feeder to the pulverizer. Appropriate couplings and valves complete the system.

Feeder design

Feeders are used to control coal flow from the storage bunker at a uniform rate. Feeder selection should be based on an analysis of the material properties (maximum particle size, particle size distribution, bulk density, moisture content and abrasiveness), the desired flow rate, and the degree of flow control required. A variety of feeder designs have been used for coal-fired applications with increasing sophistication as more accurate control of coal flow has become necessary. Feeders for modern pulverized coal and CFB boiler applications can generally be classified as *volumetric* or *gravimetric*.

Volumetric feeders, as the name implies, are designed to provide a controlled volume rate of coal to the pulverizer. Typical examples include drag, table, pocket, apron and belt feeders. Belt feeders, perhaps the most accurate type, have a *level bar* to maintain

Fig. 18 Arrangement of bunker discharge to pulverizer showing typical feed system.

the flow of coal at a constant height and width while the belt speed sets the velocity of the coal through the opening. As with all volumetric designs, however, the belt feeder does not compensate for changes in coal bulk density. This results in variations in the energy input to the pulverizer and ultimately to the burners, for a pulverized coal unit, or to the bed of a CFB unit.

Gravimetric feeders (see Fig. 19) compensate for variations in bulk density due to moisture, coal size and other factors. They provide a more precise weight flow rate of coal to the pulverizer or CFB boiler bed feed point and, therefore, more accurate heat input to the burners and boiler. Even variations in coal moisture have a larger relative impact on coal bulk density than on heating value. Therefore, modern gravimetric feeders offer an accurate, commercially accepted technology to control fuel and heat input to the burners and boiler. This can be a very significant issue where more accurate control of fuel/air ratios is needed to: 1) minimize the formation of nitrogen oxides (NO_x), 2) control furnace slagging, and 3) maximize boiler thermal efficiency by reducing excess air levels. (See Chapter 14.)

In the most common gravimetric feeder system, coal is carried on a belt over a *load cell* that monitors the coal weight on the belt. The feedback signal is used to maintain the weight flow by either: 1) adjusting the height of a leveling bar to control the cross-sectional coal flow area while the belt speed remains constant,

or 2) fine tuning the belt speed while the cross-sectional area remains constant. The overall set point flow rate is adjusted by varying the base belt speed.

Coal blending

When coals from two or more sources fuel a single boiler, effective coal blending or mixing is required to provide a uniform feed to the boiler. The use of multiple coals can be driven by economics, coal sulfur content to meet emission requirements, and/or the effects of different coals on boiler operation. The goal of effective blending is to provide a coal supply with reasonably uniform properties that meet the blend specification typically including sulfur content, heating value, moisture content, and grindability.

Coal blending may occur at a remote location, such as the mine or coal washing/preparation facility, or at the steam generating plant. Off-site blending eliminates the need for separate coal storage and additional fuel blending facilities. Steam plant on-site blending may be accomplished through a variety of techniques. It may be sufficient to provide separate stockpiles for each coal source and use front-end loaders to transfer the appropriate quantities to a common pile or hopper for blending prior to crushing. Coal may also be reclaimed from the various stockpiles using under-pile or over-pile reclaim systems transferring to a common conveyor belt. Coal from the various sources may be stored in separate bins with a feeder from each bin used to meter the desired quantities onto a common transfer belt. On-site blending provides more flexibility in coal sourcing and in adjusting to actual on-site coal variations.

Fig. 19 Typical gravimetric feeder (courtesy of Stock Equipment Company, Inc.).

Particular care must be maintained to ensure proper and complete blending. Significant variations in the blended coal can have a major impact on operation of the pulverizers, burners and sootblowers of a pulverized coal unit, and on bed temperature control of a CFB boiler. If uniform blending does not occur, pulverizer performance can deteriorate (see Chapter 13), the boiler may experience excessive slagging and fouling, and electrostatic precipitator particulate collection efficiency may decline, among other potential problems.

Resolution of common coal handling problems

Dust suppression

Water, oil and calcium chloride (CaCl_2) are common agents used to suppress fugitive dust emissions on open coal stock piles and during loading into open ground hoppers. A water or oil mist may be sprayed into the discharge area of rail cars as well as open discharges of conveyors onto storage piles. The water or oil spray reduces dust emissions by causing the dust to adhere to larger pieces of coal and by forming agglomerates that are less likely to become airborne. Use of CaCl_2 should be limited because of its potentially harmful side effects on boiler operation. (See Chapter 21.)

Dust collection at the transfer points from conveyor to conveyor in the coal transport system is performed by a vacuum collection system. These systems consist of a blower that draws the airborne dust from the discharge chutes, transfer chutes, and loading chutes of a transfer point. The enclosed chute arrangement is essentially maintained at a negative pressure. The dust laden air flow is routed through a bag filter to collect the dust, with the air discharging to the atmosphere. The collected dust is discharged from the bag filter hopper through a rotary seal to the continuing coal conveyer, silo or bunker. For coals with high volatility, the dust is collected with water and sluiced to waste or reclaim to avoid fire or explosion. These dust collection systems can also evacuate the methane that is generated in bunkers and silos.

Oxidation

Coal constituents begin to oxidize when exposed to air. This oxidation may be considered as a very slow, low temperature combustion process, because the end products, carbon dioxide (CO_2), carbon monoxide, water and heat, are the same as those from furnace coal combustion. Furnace combustion of coal may be viewed as a very rapid oxidation process. Although there is evidence that bacterial action causes coal heating, the heating primarily occurs through a chemical reaction process. If spontaneous combustion is to be avoided, heat from the oxidation should be minimized by retarding oxidation or removing the generated heat.

Coal oxidation is primarily a surface action. Finer coal particles have more surface area for a given volume and, therefore, oxidize more rapidly. Freshly crushed coal also has a high oxidation rate. Coal's oxygen absorption rate at constant temperature de-

creases with time. Once a safe storage pile has been established through compaction to minimize entrapped air, the rate of oxidation has been slowed considerably. Coal should be kept in dead storage undisturbed until it is to be used.

The rate of oxidation also increases with moisture content. High-moisture western coals are particularly susceptible to self-heating.

Frozen coal

The difficulties associated with handling frozen coal may be avoided by thermally or mechanically drying the fines following coal preparation. Spraying the coal with an oil or anti-freezing solution mist is one method, but this can have a negative effect on combustion and emissions performance.

Permanent installations for thawing frozen coal in rail cars include steam-heated thawing sheds, oil-fired thawing pits, and radiant electric thawing systems. Steam-heated systems are reliable and efficient, but are relatively expensive. Oil-fired systems that prevent direct flame impingement on the cars provide reliable operation and rapid thawing. Electric thawing systems are used at many plants that handle unit train coal shipments.

The coal handling system must also be protected. The chutes and bunker/silo hoppers can be fitted with heating coils to avoid hang-up due to coal freezing on the metal surfaces. Heating of the buildings enclosing these transfer chutes or hoppers should also be considered.

Frost and ice can form on belt conveyor surfaces. As coal is loaded onto the conveyor, it can skid on the ice and not convey. Systems using ethylene glycol or salt applications can help alleviate this problem.

Coal pile fires

A primary concern in coal storage is the potential for spontaneous combustion in the pile as a result of self-heating properties.

A coal pile fire may be handled in several ways depending on its size or severity. The hot region should be isolated from the remainder of the pile. This may be accomplished by trenching and sealing the sides and top of the hot area with an air tight coating of road tar or asphalt. Caution should be used in working the hot area with heavy equipment as subsurface coal combustion can affect the stability and load bearing characteristics of the pile. Water should not be used unless it is necessary to control flames. Pouring water on a smoldering pile induces more pronounced channeling and promotes greater air flow through the pile.

Bunker flow problems

Bunkers may be equipped with ports located near the outlet. These ports permit the use of air lances for restoring flow. Air lances may also be effectively used from the top of the bunker. Small boring machines can be mounted above the bunker to loosen coal jams at the outlet. Service companies can be contracted to remove flow obstructions using boring tools. Air blasters or air cannons have been successfully used to promote flow of coal in bunker hoppers. If there is any possibility of fire, these devices must be charged with

nitrogen or carbon dioxide to prevent triggering a dust explosion. Bin vibrators can be used to promote flow similar to air blasters and cannons. Air blasters and cannons along with bin vibrators must be carefully evaluated prior to installation as these devices can further consolidate coal accumulated in the vessel.

Flow testing can be performed to determine if the current hopper design can be economically modified for reliable flow of a poorer quality coal. The application of different hopper liner materials can provide a simple solution to coal flow problems.

Bunker fires

A fire in a coal bunker is a serious danger to personnel and equipment and must be dealt with promptly. The coal feed to the bunker should be stopped. An attempt should be made to smother the fire while quickly discharging the coal. Continuity and uniformity of the hot or burning coal discharge from the bunker is especially important; interruption of coal flow aggravates the danger. The bunker should be emptied completely; no fresh coal should be added until the bunker has cooled and the cause of the fire determined.

The fire may be smothered using steam or carbon dioxide. CO₂ settles through the coal and displaces oxygen from the fire zone because it is heavier than air. Permanent piping connections to the bottom of the bunker may be made to supply CO₂ on demand. The CO₂ should fill the bunker, displace the air and smother the fire.

It is highly desirable to completely extinguish the fire before emptying the bunker. This is rarely possible because of boiler load demands and the difficulty of eliminating air flow to the fire. However, the use of steam or CO₂ to smother the fire can minimize the danger.

Bunker flow problems that result in dead zones may contribute to fires. Thermocouples installed in the bunker can monitor the temperature of the stored coal. The coal feed to the bunkers may also be monitored to prevent loading the bunker with hot coal.

Additional remarks on dealing with bunker fires in pulverized coal plants are provided in Chapter 13.

Environmental concerns

Water percolating through the coal storage pile can become a source of acidic drainage that may contaminate local streams. Runoff water must be isolated by directing the drainage to a holding pond where the pH may be adjusted. (See also Chapter 32.)

Airborne fugitive dust from stockpiles and adjacent haul roads creates a public nuisance, has potentially harmful effects on surrounding vegetation, and may violate regulated dust emission standards. To satisfy environmental regulations, plant haul roads are normally watered frequently during hot, dry, dust seasons.

Alternate solid fuel handling

Economic and environmental concerns have led to increasing steam generation from solid fuels derived from residential, commercial and industrial by-products and wastes. Key among these are municipal solid waste (MSW), wood and biomass as discussed in Chapters 29 and 30. The properties of these solid fuels require storage, handling and separation considerations different from those applied to coal.

MSW can either be burned with little pre-combustion processing (mass burn) or as a refuse-derived fuel (RDF). As-received refuse for mass-burn units is delivered to the tipping area and stored in an open concrete storage pit. The refuse pit is usually enclosed and kept under a slightly negative pressure to control odors and dust emissions. The tipping bay is designed to facilitate traffic flow based upon the frequency of deliveries and the size of the delivery trucks or trailers. The pit is usually equipped with a water spray system to suppress fires that may arise in part due to heat generated from decomposition of the refuse. An overhead crane is used to mix the raw MSW in the storage pit, to remove bulky items and to transfer material to the boiler feed charging hoppers. Large objects and potentially explosive containers are located and removed prior to combustion. (See Chapter 29.) A full capacity spare crane is recommended. Storage capacity is typically three to five days to accommodate weekends, holidays and other periods when refuse delivery may not be available. Longer term storage of refuse is not normally recommended.

MSW may be processed to yield a higher and more uniform Btu, lower ash RDF. The degree of processing required is determined by economics and by the fuel properties necessary for efficient boiler operation. MSW is usually delivered to an enclosed receiving floor. Front-end loaders can be used to spread the refuse, remove oversized and potentially dangerous items and feed the MSW to the RDF processing system as needed. RDF processing includes an integrated system of conveying, size reduction, separation, ferrous and non-ferrous metal recovery, sizing and other equipment discussed in depth in Chapter 29. MSW may be processed into RDF at the power plant site or at a remote location. The selection is based upon a number of economic factors, but operation of the RDF processing system at the boiler site typically will enhance availability to support uninterrupted steam generation.

Wood, forestry and agricultural wastes generally consist of bark, sawdust, saw mill shavings, lumber rejects, raw tree trunks and prunings, and straw. Material is generally shipped by truck to the steam generator site near the source. Material can be dumped directly on the storage pile or an unloading facility can be used. The unloading and handling

equipment must be designed to handle very abrasive material under extremely dusty conditions. Wood products can be stored in large outdoor piles or inside bins or silos. This fuel is not typically stored in piles for more than six months or in silos or bins for more than three to five days. Wood is typically screened to remove oversized material for further size reduction. Oversized material is reduced by a shredding machine, or hog, and either returned to storage or sent directly to the combustor. Mechanical belt conveyors are the most popular method of transporting the fuel on site, although pneumatic systems can be effective with a finely ground, clean fuel such as sawdust. Tramp iron is usually removed by a magnetic separator. This material is fibrous and very stringy, so careful evaluation must go into the design and selection of the fuel handling and storage system. While most modern wood-fired boilers can burn materials with a moisture

content of up to 65% as-received (see Chapter 30), pre-drying may be required. Mechanical hydraulic presses or hot gas drying, or both, are used.

Economics

The selection of the fuel source, degree of cleaning, and transportation system are closely tied to providing the lowest plant fuel cost. The selections must not be made in isolation, but in concert with evaluating the impact of the specific fuel on the boiler and bypass system operation, and the environment. For example, use of a new less expensive fuel may result in significant deterioration in boiler performance and availability due to more severe slagging and fouling tendencies of the flyash. (See Chapter 21.) The relative contributions of coal cleaning, transportation and base fuel price vary widely.

Coal storage and handling facilities at a utility power plant.

Chapter 13

Coal Pulverization

The development and growth of coal pulverization closely parallels the development of pulverized coal-firing technology. Early systems used ball-and-tube mills to grind coal and holding bins to temporarily store the coal before firing. Evolution of the technology to eliminate the bins and direct fire the coal pneumatically transported from the pulverizers required more responsive and reliable grinding equipment. Vertical air-swept pulverizers met this need.

The first vertical air-swept pulverizer by The Babcock & Wilcox Company (B&W) was designated the type E pulverizer, introduced in 1937. Today, B&W offers a broad line of proven B&W Roll Wheel™ pulverizers (see Fig. 1) to meet utility needs, and ball-and-race mills designated EL pulverizers (see Fig. 5) to meet lower load utility and industrial requirements. Both use rolling elements on rotating tables to finely grind the coal which is swept from the mill by air for pneumatic transport directly to the burners.

Reliable coal pulverizer performance is essential for sustained full load operation of modern pulverized coal-fired electric generating stations. Also, an effective pulverizer must be capable of handling a wide variety of coals and accommodating load swings. The B&W Roll Wheel pulverizer, through conservative design, reserve capacity and long grinding element life, has set the standard for high availability, reliability and low maintenance, contributing to stable boiler performance.

A key difference between much of the boiler system and the pulverizer is that the pulverizer is sized and operated as a mass flow machine while the boiler is a thermal driven machine. Therefore, the heating value of the fuel plays a key role in integrating these two components.

Vertical air-swept pulverizers

Principles of operation

The elements of a rolling action grinding mechanism are shown in Fig. 2. The roller passes over a layer of granular material, compressing it against a moving table. The movement of the roller causes motion between particles, while the roller pressure creates compressive loads between particles. Motion under applied pressure within the particle layer causes at-

trition (particle breakup by friction) which is the dominant size reduction mechanism. The compressed granular layer has a cushioning influence which reduces grinding effectiveness but also reduces the rate of roller wear dramatically. When working surfaces in a grinding zone are close together, near the dimensions of single product particles, wear is increased by three body contact (roller, particle and table). Wear rates can be as much as 100 times those found

Fig. 1 B&W Roll Wheel™ pulverizer.

Fig. 2 Roller mill grinding mechanism.

in normal pulverizer field experience. Wear from the three body contact has also been observed in operating mills when significant amounts of quartz bearing rock are present in sizes equal to or greater than the grinding layer thickness.

As grinding proceeds, fine particles are removed from the process to prevent excessive grinding, power consumption and wear. Fig. 3 presents a simplified B&W Roll Wheel pulverizer, showing the essential elements of a vertical air-swept design. A table is turned from below and elements, in this case called *roll wheels*, rotate against the table. Raw coal is fed into the mill from above and passes between the rollers and the rotating table. Each passage of the particles under the rollers reduces the size of the coal. The combined effects of centrifugal force and displacement of the coal layer by the rollers spills partly ground coal off the outside edge of the table. An upward flow of air fluidizes and entrains this coal.

The point where air is introduced is often called the throat, air port ring, or nozzle ring. Rising air flow, mixed with the coal particles, creates a fluidized particle bed just above the throat. The air velocity is low enough so that it entrains only the smaller particles and percolates with them through the bed. This selective entrainment is the initial stage of size separation or classification. The preheated air stream also dries the coal to facilitate pulverization and enhance the combustion process.

Vertical pulverizers are effective drying devices. Coals with moisture content up to 40% have been successfully handled in vertical mills. Higher moisture coals could be pulverized, but the very high primary air temperature needed would require special structural materials and would increase the chance of pulverizer fires. A practical moisture limit is 40%, by weight, requiring air temperatures up to 750F (399C).

As the air-solids mixture flows upward, the flow area increases and velocity decreases, allowing gravity to return the larger particles to the grinding zone for the second stage of size separation. The final stage of size separation is provided by the classifier located at the top of the pulverizer. This device is a centrifugal separator. The coal-air mixture flows through openings angled to impart spin and induce centrifugal force. The larger particles impact the perimeter,

come out of suspension and fall back into the grinding zone. The finer particles remain suspended in the air mixture and exit to the fuel conduits.

Pulverizer control

There are two input streams into an air-swept pulverizer, air and coal. Both must be controlled for satisfactory operation. Many older methods of coal flow control are still used successfully. Either volumetric or gravimetric belt feeders are the currently preferred method of coal flow regulation. Accurate measurement of coal flow has allowed parallel control of air and coal (Fig. 4).

Pulverizer design requirements

Many different pulverizer designs have been applied to coal firing. Successful designs have met certain fundamental goals and requirements:

1. optimum fineness for design coals over the entire pulverizer operating range,
2. rapid response to load changes,
3. stable and safe operation over the entire load range,
4. continuous service over long operating periods,
5. acceptable maintenance requirements, particularly grinding elements, over the pulverizer life,
6. ability to handle variations in coal properties,
7. ease of maintenance (minimum number of moving parts and adequate access), and
8. minimum building volume.

Fig. 3 Pulverizer coal recirculation.

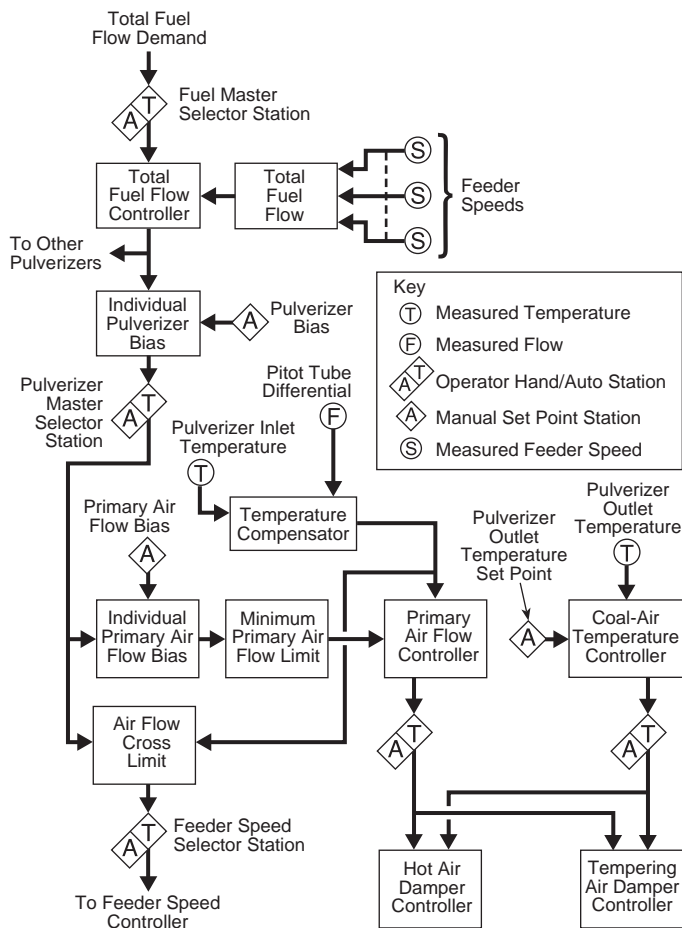

Fig. 4 Schematic of parallel cross limited pulverizer control system.

Pulverizer designs

Mill development efforts by B&W were, for many years, based on variations of ball-and-race (ball-and-race) grinding elements. In the 1930s, B&W introduced the type E pulverizer. During the early 1950s, a redesign was installed and tested at a textile plant in Lancaster, South Carolina. This design, which uses two vertical axis horizontal rings, was designated E (Lancaster) or EL (Fig. 5). The lower ring rotates while the upper ring is stationary and is spring loaded to create grinding pressure. A set of balls is placed between the rings. The force from the upper ring pushes the balls against the coal layer on the lower ring.

Type E and EL mills have size designations which indicate approximately the centerline diameter of the grinding track. Type E mills have been built as large as the E-70 with a capacity of 12.5 t/h (11.4 t_m/h). Type EL mills have been built as large as the EL-76 with a nominal capacity of 20 t/h (18 t_m/h), and with modern enhancements, a maximum capacity of 23 t/h (21 t_m/h) is possible. Approximately 1600 E and EL mills have been installed, with more than 1000 still in service. The major wear parts of E and EL pulverizers are the two rings and the balls which are made of abrasion resistant alloys and are easily replaced.

B&W introduced the roll wheel style coal pulverizer to the North American market in the 1970s and installed more than 1100 units during the next three decades. B&W has continuously advanced the design,

developing a unique product with enhanced performance and reduced operating costs. Having completed the license agreement, B&W retains all of the original technology as well as all of the design advancements and has changed the name to the B&W Roll Wheel™ pulverizer. A current configuration is shown in Fig. 1. B&W continues to fully support the full fleet of units with state of the art replacement parts and service.

The B&W Roll Wheel pulverizer is an air-swept, roller type vertical pulverizer; however, it differs in significant ways from other roller mills. The rollers (roll wheels) of the B&W mill are supported and loaded by a unique system which loads the three rollers simultaneously. The common loading system allows independent radial movement of each roller. This, in turn, allows continuous realignment with the grinding track as rollers wear. The rollers can also accommodate large foreign objects such as tramp iron or rocks which inadvertently enter the grinding zone. The B&W mill can maintain design performance with as much as 40% of the roll wheel tires' weight lost due to wear.

Roll wheel mills operate at speeds which produce centrifugal force at the grinding track centerline of about 0.8 times the force of gravity. This very low speed contributes to low vibration levels and the ability to handle large foreign objects.

This mill also introduced a gear drive module to coal pulverizer design, where the self-contained gear box is separate from the pulverizer housing structure. This feature is now popular with most mill designers in the United States (U.S.). When the gear drive module needs repair or preventive overhaul, the pulverizer is only disabled for the brief time it takes to remove the drive and install a spare unit. This allows thorough and economic gear drive maintenance, independent of production demands.

Fig. 5 B&W EL ball-and-race pulverizer.

The major replaceable wear parts of B&W pulverizers include the tires and ring segments plus minor items such as wear guide plates, ceramic linings, and parts for the throat or air port ring. Wear life of all parts in contact with the coal is dependent upon the coal abrasiveness, and ranges from less than 10,000 to more than 100,000 hours.

The B&W mill size designations are also based upon the grinding track centerline diameter, in inches. Units have been furnished ranging from the B&W-56™ to the B&W-118™ designs with capacities ranging from 15 to 115 t/h (13 to 105 tm/h) respectively.

Table 1 lists important features and characteristics of B&W Roll Wheel and EL mills for comparison.

Horizontal air-swept pulverizers

High speed pulverizers

One high speed design which has been used in the U.S. serves the same applications as the vertical types. This machine operates at about 600 rpm and grinds by both impact and attrition. Coal and heated air enter at the impact section for initial size reduction then pass between moving and stationary parts for final size reduction (Fig. 6). At the final stage, an exhaust fan draws the air and coal through the mill for drying and transport. There is no classifier and the design relies upon the action of the rotor and stator to achieve size control in a single pass of the coal. The coal passes through quickly so there is little storage

in the mill. This pulverizer is limited to coals with moisture content of 20% or less because of the short residence time for drying.

Beater mills are used outside North America (Fig. 7). These are similar in some respects to the attrition mills described above. These mills are used for grinding and drying the fossil fuels referred to as brown coals. These are very low grade lignite type coals with high ash and moisture contents and low heating values. Moisture content of brown coal often exceeds 50% and combined ash and moisture contents may exceed 60%.

Beater mills grind by impact and attrition with very rapid drying. They achieve drying despite short residence time by replacing primary air with extremely high temperature gas extracted from the upper furnace at temperatures about 1900F (1038C). Flue gas from a cooler location such as the air heater outlet may be mixed with the hot gas for mill outlet temperature control. Coal is mixed with the gas stream ahead of the mill for initial drying to reduce the inlet temperature. The final stage is the fan section which maintains a negative pressure in the mill at all times. Beater mills operate at variable speed to control grinding performance at varying coal feed rates. One and two shaft machines are used, trading simplicity in the former for more flexibility in the latter. Because of the low coal quality, beater mills must handle huge amounts of coal and are made in very large sizes. There are very few coal deposits in North America which would require this grinding/drying technology. However, significant deposits in Germany, Eastern Europe, Turkey

Table 1
Characteristics of B&W EL and B&W Roll Wheel™ Pulverizers

	Type EL Ball-and-Race	Type B&W Roll-and-Race
Size range	EL-17 to EL-76	B&W-56 to B&W-118
Capacity, t/h (t _m /h)	1.5 to 23 (1.4 to 21)	17 to 115 (15 to 104)
Motor size, hp (kW)	25 to 350 (18 to 260)	200 to 1500 (149 to 1120)
Speed	Medium	Slow
Table, rpm	231 to 90	32 to 21
Operates under	Pressure	Pressure
Classifier	Internal, centrifugal	Internal, centrifugal
Classification adjustment	Internal	Internal (standard) External (special)
Optional dynamic classifier	Internal, dual stage, variable speed	Internal, dual stage, variable speed
Drying limit	40% H ₂ O or 700F (371C) maximum Primary air temperature	40% H ₂ O or 750F (399C) maximum Primary air temperature
Moisture load correction	None up to temperature limit	Load correction above 4% surface moisture
Maximum exit temperature limit	250F (121C)	210F (99C)
Effect of wear on performance	None if fill-in balls added	Power increase up to 15% at fully worn condition
Air-coal control system	Mill level with table feeders, parallel control with belt feeders	Parallel coal and air flow control
Air/coal weight ratio	1.75:1 at full load	1.75:1 at full load
Internal inventory	Medium, 2 to 3 min of output	High, 5 to 6 min of output
Load response	> 10%/min	> 10%/min
Specific power, kWh/t (kWh/t _m)	Low, 14 (15) including primary air fan	Low, 14 (15) including primary air fan
Noise level	Above 90 dBA	Above 90 dBA, 85 dBA attenuated
Vibration	Moderate	Low

Note: Capacities are those for bituminous coal with a 50 HGI and 70% fineness passing through 200 mesh (74 microns). Specific power is that at full load.

Fig. 6 Horizontal high-speed pulverizer.

and Australia make brown coal a very important fuel for power generation throughout these regions.

Low speed pulverizers

The oldest pulverizer design still in frequent use is the ball-and-tube mill. This is a horizontal cylinder, partly filled with small diameter balls (Fig. 8). The cylinder is lined with wear resistant material contoured to enhance the action of the tumbling balls. The balls

Fig. 7 Single-shaft beater mill.

fill 25 to 30% of the cylinder volume. The rotational speed is 80% of that at which centrifugal force would overcome gravity and cause the balls to cling to the shell wall. Grinding is caused by the tumbling action which traps coal particles between balls as they impact.

Ball-and-tube mills may be either single or double ended. In the former, air and coal enter through one end and exit the opposite. Double ended mills are fed coal and air at each end and ground-dried coal is extracted from each end. In both types, classifiers are external to the mill and oversize material is injected back to the mill with the raw feed. Ball-and-tube mills do not develop the fluidized bed which is characteristic of vertical mills and the poor mixing of air and coal limits the drying capability. When coals with moisture above 20% must be ground in ball-and-tube mills, auxiliary equipment, usually crusher dryers, must be used.

Ball-and-tube mills have largely been supplanted by vertical air-swept pulverizers for new boilers. They typically require larger building volume and higher specific power consumption than the vertical air-swept pulverizers. They are also more difficult to control and have higher metal wear rates. They are, however, well suited for grinding extremely abrasive, low moisture, and difficult materials such as petroleum coke. Their long coal residence time makes them effective for fine grinding.

Application engineering

The arrangement of coal-fired system components must be determined according to economic factors as well as the attributes of the coal. The performance in terms of product fineness, mill outlet temperature, and

Fig. 8 Typical pressurized ball-and-tube coal pulverizing system.

air-coal ratio must all be determined as part of overall combustion system design.

Pulverizer systems

Pulverizers are part of larger systems, normally classified as either direct-fired or storage. In direct firing, coal leaving each mill goes directly to the combustion process. The air, evaporated moisture, and the thermal energy which entered the mill, along with the ground coal, all become part of the combustion process. Storage systems separate the ground coal from the air or gas, evaporated moisture and the thermal energy prior to the combustion process. Stored ground coal is then injected with new transport air or gas to the combustion process. Bin storage systems are seldom used in steam generation today, but are still used with special technologies such as coal gasification and blast furnace coal injection. More than 99% of the B&W Roll Wheel pulverizers in service in the U.S. are used in direct-fired systems.

The essential elements of a direct-fired system are:

1. a raw coal feeder that regulates the coal flow from a silo or bunker to the pulverizer,
2. a heat source that preheats the primary air for coal drying,
3. a pulverizer (primary air) fan that is typically located ahead of the mill (pressurized mill) as a blower, or after the mill (suction mill) as an exhaustor,
4. a pulverizer, configured as either a pressurized or suction unit,
5. piping that directs the coal and primary air from the pulverizer to the burners,
6. burners which mix the coal and the balance of combustion air, and
7. controls and regulating devices.

These components can be arranged in several ways based on project economics. With pressurized pulverizers, the choice must be made between hot primary air fans with a dedicated fan for each mill, or cold fans located ahead of a dedicated air heater and a hot air supply system with branches to the individual mills. Hot fan systems have a lower capital cost because a dedicated primary air heater is not required. Cold fan systems have lower operating costs which, on larger systems, may offset the higher initial cost. Figs. 9 and 10 show these systems.

The terminology for air-swept pulverizers refers to the air introduced for drying and transport as primary air. Control of primary air is of vital importance to proper pulverizer system operation. Primary air must be controlled for flow rate and pulverizer outlet temperature. This control can be achieved by three inter-related dampers. Hot and cold air dampers regulate air temperature to the mill and these dampers are often linked so that as one opens, the other closes. The third damper independently controls air volume. On cold fan systems, modern controls allow flow and temperature control with just the hot and cold air dampers, eliminating the need for the independent flow control damper, thus reducing cost with no loss of controllability.

Because direct-fired pulverizers are closely linked to the firing system, engineering must coordinate the design performance of the mills and burners. A set of curves can be used to relate important operating characteristics of volume flow, velocities at critical locations, and system pressure losses through the load range of the boiler. The curves consider the number of mills in service and the output range of the individual mills. An example set of curves is shown in Fig. 11. Study of these curves provides information on many aspects

Fig. 9 Direct-fired, hot fan system for pulverized coal.

Fig. 10 Direct-fired, cold fan, fuel-air system for pulverized coal.

of pulverizer and system operation. The lower curve, labeled A, shows boiler steam flow versus coal output per pulverizer. The individual lines show the number of mills in operation. In this example, a full boiler load of 3.6×10^6 lb/h (454 kg/s) steam flow can be reached with five mills in service at about 89,000 lb/h (11.2 kg/s) each. The maximum load also can be reached with four mills at about 111,000 lb/h (14.0 kg/s) each. The maximum steam flow with three mills is just over 3.0×10^6 lb/h (378 kg/s). The minimum load line shown is determined by Curve C. The indicated 36,000 lb/h (4.54 kg/s) is a very good turndown ratio, but the practical minimum may be higher based on ignition stability or the onset of mechanical vibration.

Curve B shows primary air flow at mill exit conditions. Maximum flow is 55,800 ft³/min (26.34 m³/s) for a B&W-89TMN mill, corresponding to 124,000 lb/h (15.6 kg/s) coal flow. The minimum equipment design flow is approximately 65% of this or 36,300 ft³/min

(17.13 m³/s). However, the exact minimum flow may need adjustment to permit stable burner operation. This is illustrated by 39,000 ft³/min (18.41 m³/s) minimum shown in Fig. 11, curve B, and the 3000 ft/min (15.2 m/s) minimum in curve D.

Curve C is the air/fuel ratio expressed in ft³ of air per lb of coal. This ratio is critical to stable ignition at low loads and is influenced by coal rank and fineness. For this example, the maximum air to fuel ratio is 65 ft³ air per pound fuel, typical of bituminous coal. Dividing the minimum air flow by this ratio establishes the minimum pulverizer load.

Curve D shows primary air velocity in the burner pipes versus pulverizer coal flow. This curve is plotted by dividing air volume at mill exit conditions by the total flow area of the pipes connecting the mill to the burners. The minimum velocity allowed is 3000 ft/min (15.2 m/s), at which the pulverized coal can be kept entrained in the primary air stream. The mini-

Fig. 11 B&W-89TMN pulverizer-burner coordination curves.

mum, or saltation, velocity is particularly important in long horizontal spans of pipe. This velocity limit is influenced by air density and viscosity, particle loading and particle size. For the relatively narrow range of density, viscosity and particle size distribution in burner pipes, the minimum velocity limit is typically adjusted only for particle loading (see Fig. 12).

An important pulverizer performance requirement is particle size leaving the mill. There is a mixture of particle sizes with any pulverizer because of the statistical distribution of particle sizes produced by the pulverizing process. The most frequently referenced size fraction for coal combustion is that portion smaller than a 200 U.S. standard sieve opening (mesh), or 74 microns. The portion passing this sieve size has been used as a gauge of pulverizer capacity as well as for assuring good combustion and good carbon burnout. The required particle size (fineness) is determined by the combination of coal combustion characteristics and the combustion chamber.

For bituminous coals burned in water-cooled enclosures, a fineness of 70% passing through 200 mesh (74 microns) or better is traditionally required. The nominal capacity rating of pulverizers in the U.S. is also based on 70% fineness. This value is suitable for good combustion efficiency with conventional combustion systems, but may not be sufficient for low nitrogen oxides (NO_x) systems which delay combustion. Coarse particles, those larger than 100 mesh (150 microns), are primary contributors to unburned carbon loss. With traditional stationary classifiers it may be necessary to maintain fineness above 70% passing 200 mesh for acceptable unburned carbon loss. With modern rotating classifiers, the slope of the particle distribution curve is changed such that very low coarse particle delivery and acceptable unburned carbon losses can be achieved with fineness at or below 70%.

Outlet temperature

Coal with low volatile content may require higher air-coal temperatures to assure stable combustion, especially at lower burner inputs or low furnace loads. The typical pulverizer exit temperature is 150F (66C). Higher temperatures, up to 210F (99C) for coal, may be used if needed. Higher temperatures require care in the selection of internal lubricants and soft seal materials. In addition, high outlet temperatures require high inlet temperatures which increase the risk of pulverizer fires. Some pulverizer applications, notably bin storage systems, will require high outlet temperatures to assure complete drying and prevent han-

Fig. 12 Correction curve for minimum velocity.

dling problems with fine coal. Usually, 180F (82C) is adequate to assure drying of coal having raw coal moisture up to 10%. For direct firing, the outlet temperature requirements are determined by volatile content and the need for stable combustion. Table 2 lists mill outlet temperatures for various coal types.

Effects of coal properties

Grindability When determining pulverizer size, the most important physical coal characteristic to consider is *grindability*. This characteristic is indicative of the ease with which coal can be ground. Higher grindabilities indicate coals which are easier to pulverize. The test procedure to determine the commonly used Hardgrove Grindability Index (HGI) is described in The American Society for Testing and Materials (ASTM) D 409. The operative principle with this procedure is the application of a fixed, predetermined amount of grinding effort or work on a prepared and sized sample. The apparatus shown in Fig. 13 is used to determine grindability. By rotating exactly 60 revolutions, this miniature pulverizer does a fixed amount of work on each sample. The amount of new, fine material produced is a measure of the ease of grinding. The neutral value of grindability used by B&W is HGI = 50, i.e., at HGI = 50, the capacity correction factor is 1.0. The index is open ended with no upper limit on the HGI scale.

Grindability is not strictly a matter of hardness. Some materials, fibrous in nature, are not hard but are very difficult to grind. Sticky or plastic materials can also defy grinding.

The procedure described in ASTM D 409 was originally developed as a purely empirical method but provides a valid capacity calculation for vertical pulverizers when grinding bituminous coal. When lower rank coals are tested in the Hardgrove apparatus, the correlation between laboratory tests and field operating equipment is often quite poor. There is a strong but unpredictable effect of sample moisture on test re-

Fig. 13 Hardgrove grindability testing machine.

Table 2
Typical Pulverizer Outlet Temperature

Fuel Type	Volatile Content, %*	Exit Temperature F (C)**
Lignite	All values	120 to 140 (49 to 60)
Subbituminous	All values	130 to 150 (54 to 66)
High volatile bituminous	Above 31	140 to 175 (60 to 79)
Medium and low volatile bituminous	14 to 31	160 to 200 (71 to 93)
Anthracite and coal waste	0 to 14	200 to 210 (93 to 99)
Petroleum coke	0 to 8	200 to 250 (93 to 121)

* Volatile content is on a dry, mineral-matter-free basis.

** The capacity of pulverizer is adversely affected for exit temperatures below 125F (52C) when grinding high moisture lignites.

sults, illustrated in Fig. 14. For high ash content coals, the possibility of mineral accumulation in the pulverizer, which hinders the grinding process, is not accounted for in the HGI procedure. A more accurate index of grindability for low rank coals is determined in a laboratory sized roll wheel pulverizer. This equipment has all the features of a field installation and can simulate field conditions. The capacity of the mill is about 800 lb/h (0.10 kg/s) and a coal capacity test requires a 3000 lb (1361 kg) sample. Fig. 15 is an arrangement diagram of this test apparatus. Results are interpreted as apparent grindability and the values are valid for capacity calculations.

Wear properties Wear in coal pulverizers results from the combined effects of abrasion and erosion. The mechanism which dominates in the wear of a particular machine component depends upon the designed function of the component and on the properties of the coal being ground. Abrasiveness and erosiveness are the important properties to be considered when evaluating the influence of a candidate coal on expected maintenance cost. Unfortunately, these two important properties are inherently difficult to measure, especially with a material as variable as coal.

Abrasiveness Abrasion is the removal of material by friction due to relative motion of two surfaces in contact. A coal's ability to remove metal is primarily related to the quantity and size distribution of quartz and pyrite found in the as-received coal, especially for particles larger than 100 mesh (150 microns). While standard and accepted procedures are available to determine the quantity of these two minerals in a sample (ASTM D 2492 and ASTM D 2799 for pyrite and quartz respectively), procedures to establish quartz and pyrite particle sizes are not widely accepted.

Unfortunately, direct small-scale laboratory abrasiveness testing is not satisfactory for correlation to field wear conditions because of operating differences between small laboratory equipment and power plant pulverizers. However, satisfactory abrasiveness measurements have been made using the laboratory sized roll wheel pulverizer with 4000 lb (1814 kg) samples. Although expensive, wear life testing with this procedure can typically predict field performance with an error of 10% or less. While other abrasiveness

tests such as Yancy-Geer Price apparatus are used to provide some insight into relative wear rates, they are of very limited value in predicting actual field wear rates.

Erosiveness Erosion is not the same as abrasion. It can be defined as the progressive removal of material from a target on which a fluid borne stream of solids impinges. For a given combination of particles and target material, wear rate increases with increasing ve-

Fig. 14 Hardgrove Grindability Index versus fuel moisture.

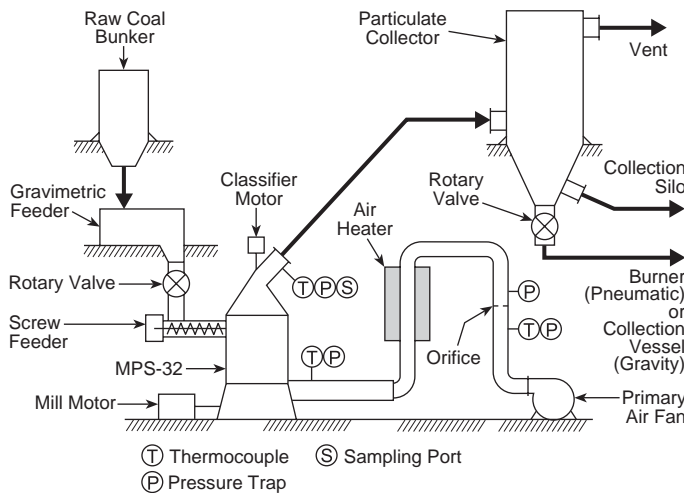

Fig. 15 B&W's test apparatus for low rank coals.

locity, particle size, and the solids content of the stream. For ductile target materials, the wear rate increases for an impingement angle from parallel up to approximately 45 deg, at which point wear begins to decline.¹ For brittle materials, the rate of erosion increases up to the angle of approximately 70 deg, where rebounding material interferes with the impinging stream and measurement becomes erratic.

Moisture Moisture content in the fuel is a key design parameter. Coal moisture is highly variable and depends more on coal type than on the amount of water introduced after mining. Coals used in the U.S. range from inherent moisture levels of 2% for Appalachian bituminous to near 40% for lignites. Brown coals may range up to 70%. Moisture in coal is determined according to the procedures in ASTM D 3302. For pulverizer capacity corrections and primary air system design, the total moisture must be separated into air dry moisture (air dry loss) and residual moisture (moisture remaining after air drying). For capacity correction, since the air dry moisture is evaporated from the coal sample before performing the HGI grindability test, an additional correction factor for air dry moisture must be included. For the primary air system design, residual moisture requires just enough heat to raise it from raw coal temperature to mill outlet temperature. The air dry moisture will be evaporated in the pulverizer, so it requires much more heat.

Pulverizer size selection

The ultimate task in pulverizer application is the selection of the size and number of mills for the proposed project. The total boiler heat input and coal flow requirements are established from the combustion calculations (see Chapter 10) and the specified boiler steam flow requirements. The coal flow rate is then divided by the capacity correction factor to establish the equivalent required pulverizer capacity. The correction factor not only includes the fineness and grindability factors shown in Fig. 16, but also the appropriate fuel moisture correction.

The number of pulverizers is then evaluated by dividing the equivalent required capacity by the unit pulverizer rated capacity based upon 70% passing

through a 200 mesh (74 microns) screen and a grindability of 50. The unit pulverizer rated capacity is based upon pulverizer size, type and manufacturer. The tradeoff between fewer larger mills and more smaller mills is based upon balancing total capital cost with the proposed operating requirements such as boiler turndown. Frequently an extra pulverizer is specified to permit the boiler to operate at full load while one mill is out of service for maintenance.

Pulverizer selection and sizing are complicated by the frequent need to consider various coal sources and emission requirements. If the coal that determines the pulverizer size is greatly different from the intended primary use coal, the result may be oversized mills and limits on turndown on the primary coal. In such a case, it may be necessary to consider eliminating this coal, or accepting a load reduction when burning it.

Performance testing

Acceptance testing will usually be guided by the procedures in The American Society of Mechanical Engineers (ASME) Performance Test Code, PTC 4.2 which references other applicable codes and standards. Testing may also be done as part of an overall boiler test, or simply to learn whether maintenance or adjustments are needed.

Fineness testing

The method of fineness sampling is well described in PTC 4.2 and ASTM D 197. While this procedure has inherent weaknesses, it is the basis for measuring one of the fundamental performance parameters to verify pulverizer capacity. Periodically, alternative sampling procedures or new hardware are proposed and they may be more accurate or easier to use than the ASTM method. However, the ASTM probe is the accepted standard on which capacity correction factors for fineness are based. Any potential improvement in absolute accuracy does not justify the abandonment of decades of data based on the ASTM method, nor the cost to establish a new database.

When tests are run to determine the condition of the pulverizer system or to evaluate a proposed new coal, comparative values between successive tests may be adequate. In such cases, alternatives, such as the ISO probe, may serve well if they provide acceptable repeatability and are not sensitive to variables such as velocity or temperature. Panel board instruments, if they can be read with sufficient precision, will serve as well as calibrated instruments for periodic testing.

Evaluating test results

The evaluation approach depends on the purpose of the tests. If the parties have agreed upon test protocols as prescribed by PTC 4.2, results evaluation is simply a calculation process. When results indicate that the performance requirements have not been met but that the shortfall is slight, reference to the ASTM standards, D 409 and D 197, may show that the shortfall could lie within the limits of laboratory analysis repeatability. The protocols should provide for resolution of small deviations in the test results.

Most testing is to evaluate the equipment or its systems. It is a mistake to try to read excessive precision into test results. It is more important to track relative performance to indicate the need for corrective action or the frequency of retesting. It is useful to develop checklists or troubleshooting guides to note what each abnormality indicates. For example, acceptable fineness but excessive pressure differential probably indicates a need to adjust the pulverizer load springs. Acceptable fine fraction fineness but poor coarse fraction fineness indicates erosion damage and internal short circuiting through the classifier. Also, it is common to discover that recalibration of primary measuring devices is needed on a regular schedule.

When equipment tests are first undertaken, it is important to collect all data which could possibly prove useful. As test experience grows, extraneous data can be removed. It is usually only a short time before standard data sheets evolve and testing becomes a routine task for an individual plant.

Operations

The main costs of coal pulverizer operation are capital, power consumption, and maintenance. The capital cost is usually an annual levelized charge including capital, taxes, and several other factors. Power and maintenance are often expressed as costs per ton of coal ground, and are influenced by plant operating practices.

Power consumption

When comparing pulverizer designs, it is common to combine primary air fan and pulverizer power consumption. The power consumption for B&W Roll

Fig. 16 Capacity correction factor.

Wheel or EL pulverizers and their respective fans is about 14 kWh/t (15 kWh/t_m) with coal at 50 HGI and 70% fineness, operating at rated output and with new grinding parts. These conditions seldom exist for any length of time during operation. Most modern installations include extra capacity for future coal variation. For most mills, there will be either a decline in capacity or an increase in power consumed as wear progresses. Therefore, because of the combined effect of pulverizer oversizing and wear, a realistic power value might be 20 kWh/t (22 kWh/t_m) for a well sized mill on a base loaded boiler or 22 kWh/t (24 kWh/t_m) on a load following unit.

There are various ways of calculating the cost of auxiliary power. The lowest cost which can be calculated is the cost of coal used to generate the power. This is a heat rate cost and, for a hypothetical boiler using coal with a 13,000 Btu/lb (30,238 kJ/kg) heating value and a thermal heat rate of 10,000 Btu/kWh (34.1% efficiency), 22 kWh/t (24 kWh/t_m) is about 0.85% of the fuel energy input to the boiler. As heating value declines, more power is spent grinding and moving material which does not produce thermal input, so the 22 kWh/t (24 kWh/t_m) becomes a higher percentage of thermal input.

Power can be expected to increase as the grinding parts wear. The depth of the grinding track may play a part in the power increase as well. There is little information to show whether power increases uniformly with time or if it takes place mostly at the end of wear life.

Maintenance

Costs for material and labor depend on wear life which varies with the abrasiveness of the coal. Wear life on B&W Roll Wheel mills grinding U.S. coals ranges from less than 10,000 to more than 100,000 hours, and normally between 25,000 and 60,000 hours. Therefore, average annual maintenance costs can vary widely. Costs will also vary by mill size, where part costs are proportionately higher for smaller mills. For a given set of assumptions, the B&W-67™ mill maintenance will cost about 60% of the power costs cited above at a wear life of 25,000 hours and as little as 20% at 60,000 hours. Respective values for B&W-89 are 40% and 10%. For a very rough estimate, maintenance costs will be about one half the power costs for small mills and about one third for larger mills.

Maintenance and power costs are also influenced by operating practices. For example, experienced operators may notice that an increase in pulverizer pressure differential or pulverizer motor power indicates a need for spring readjustment. There may be cost effective decisions between maintenance and operations regarding rebuild frequency to minimize the costly power increases near the end of wear life.

Ceramics The use of ceramic tiles for erosion resistance has reduced repair costs. Erosion resistance of ceramic is at least eight times greater than an equivalent thickness of carbon steel. Ceramic lined panels are used in classifier cones, in the housing above the throat, and in the discharge turret in B&W Roll Wheel mills. Ceramic lining is used extensively in burner pipe elbows and for wear shields on roller brackets. When ceramic

tiles are used, they must be carefully fitted to avoid undercutting and loss of the lining. Ceramic tiles are not suitable for all forms of erosion protection. High angles of impingement are destructive to brittle materials.

Record keeping Records are useful for pulverizer maintenance. Critical dimensions as recommended by the manufacturer should be measured and recorded during internal inspections. Suspicious wear data should be recorded and given special attention at the next inspection. When lubricants are drained, the amount should be noted and recorded and a sample obtained for analysis. Many owners are now including periodic gearbox vibration measurements in their data collection and record keeping. Such data may provide early warning of bearing or gear failure.

Fires and explosions

It must always be remembered that a coal pulverizer grinds fuel to a form suitable for good combustion. Combustion can and does occur at unplanned locations with costly results. Pulverizer fires are serious and should be treated with preplanned emergency procedures. The surprising speed with which a fire can develop requires prompt action.

Pulverizer fires can develop in the high temperature areas of mills or in the coal rich low temperature areas. Usually, there should be no coal in the areas upstream of the throat – the high temperature areas. Excessive spillage, because of insufficient air flow or throat wear, can cause coal accumulation in the plenum or windbox of the pulverizer. If this coal is not rejected promptly to the pyrite removal system, it can be ignited by the high temperature primary air. Coal will also enter this area when a mill is tripped or shut down quickly. Coal in the windbox may burn out without damage and, indeed, this form of fire may go undiscovered. Fires in the cooler, fuel rich zones may develop more slowly, but these fires are fed by enormous amounts of coal and can quickly destroy the internal pulverizer parts.

The most common fire indicator is mill outlet temperature. Temperature indicators are slow in response because they are sheltered by erosion protection, but they are inherently reliable and their indications should be taken seriously.

Control room operators can gain useful information about potential hazards by following consistent operating practices, especially on multiple mill installations. If, for example, all mills are at the same coal feed rate, and if primary air control is in the automatic mode, all mills should have the same air/coal ratio. Under these conditions, a significant temperature difference from inlet to outlet in one mill may indicate a fire and should be investigated immediately. Of course, there are other possible causes of inlet temperature differences such as faulty feeder calibration, faulty air flow calibration, or coal moisture variation between the respective mills. The significant point is that there is important information to be drawn from careful observation of the vital signs of pulverizer system performance. Use of all vital signs as leading indicators of potential hazards is important to safe operations.

Severe fire damage has also been caused by feed-

ing burning coal from silos or bunkers. All pulverizer manufacturers prohibit this practice. Silo fires must be dealt with separately by emptying the fire through special diverter chutes or by extinguishing agents applied to the coal surface.

In mill trips, the sudden loss of air flow allows the collapse of the fluid bed above the throat. The coal then falls into the windbox and contacts the hot metal surfaces. Low rank coals can begin smoldering within a few minutes at temperatures of 450F (232C) or more, and, upon agitation, dust clouds can be created leading to explosions. The agitation may be from mechanical action of the pyrite plows upon restart, or from the start of primary air flow before restart. The danger of explosion is minimized by removing the coal under rigidly controlled conditions. It is first necessary to assure personnel safety by evacuating all workers from places which could be affected by an explosion if the enclosures of the mill, ducts or burner pipes are breached. The mill is isolated from all air flow and an inert internal atmosphere is created by injecting inert gas or vapor. Brief operation of the mill, while isolated, rejects the coal to the pyrite removal system. The inert atmosphere prevents any smoldering coal from igniting the dust cloud raised internally by mill operation.

When a mill explosion occurs it is nearly always during changes in operating status, such as during startup and shutdown.² During startup, the air-coal mixture in the mill passes from extremely fuel lean to fuel rich. There is a transitional mixture which is ideal for a dust explosion if a sufficiently strong ignition source exists. One recurring source of ignition is smoldering fires which develop in the residual coal left in the hot zone of a mill following a trip. The coal removal procedure just described was devised to avoid or safely remove this ignition source.

Undiscovered fires can cause dust explosions during otherwise normal shutdowns. These are not common, but experience has led many operators to actuate audible and visible alarms before routine starts and stops. This is a recommended safety precaution for all coal pulverizer operators.

Controls and interlocks

The most widely followed standard for design and application of coal pulverizer systems is the National Fire Protection Association Standard, currently NFPA-85. This sets the minimum standards listed below for safety interlocks to be used with coal pulverizers:

1. failure of primary air flow trips the pulverizer system,
2. failure of the pulverizer trips the coal feeder and primary air flow,
3. closing of all burner pipe valves trips the pulverizer, the feeder, and the primary air flow, and
4. primary air flow below the manufacturer's minimum trips the pulverizer.

Other interlocks not mandated by NFPA but required by B&W are:

1. loss of the lube oil pump, or low oil pressure, trips the pulverizer (B&W Roll Wheel mill only), and
2. flame safety systems trip the pulverizer if minimum flame detector indications are not met.

Additional indications of malfunctions which may require manually tripping a mill include:

1. excessively high or rapidly rising mill exit temperature probably indicates a fire,
2. inability to maintain an exit temperature of at least 125F (52C) may lead to loss of grinding capacity,
3. loss of seal air pressure or flow will eventually lead to bearing failure, and
4. high lube oil temperature indicates a loss of cooling water flow which may lead to gear drive damage.

Items 2, 3 and 4 above are not safety related. They are examples of the designers' choices to avoid unnecessary mill trips and the resultant special safety procedures required to restart tripped mills as well as to protect the equipment from damage.

Special safety systems

The procedure for removing coal after a pulverizer trip requires a separate control system. This system must bypass the control logic which prevents operation of the pulverizer drive motor without adequate primary air flow. To prevent misuse of this bypass feature, the coal removal logic (referred to as inert and clear logic) is enabled by actuation of the mill trip logic. A typical schematic logic diagram is shown in Fig. 17.

Another special system has been developed to deal with a phenomenon which has been observed in ducts after trips. A fine layer of dust is often seen in the clean

air portion of the primary air system. This is thought to be due to a turbulent dust cloud which persists after collapse of the fluidized bed of coal above the throat. An array of water fog nozzles under the throat will intercept this cloud if actuated with the mill trip signal. Hardware for tangential wash nozzles to enhance the coal removal action of the pyrite plows during the inert and clear cycle can be installed adjacent to the fogging nozzles. The wash nozzles are actuated manually at the appropriate time in the cycle.

Advanced designs

Rotating classifiers

As noted under *Application engineering*, product fineness is under review after being generally standardized at 70% passing through 200 mesh (74 microns) for direct firing of bituminous coal. Advanced low NO_x combustion systems benefit incrementally from higher 200 mesh fineness, but very high 100 mesh fineness can sharply reduce unburned carbon losses. Modern independently driven rotating classifiers can provide up to 95% passing 200 mesh fineness but at a significant reduction in coal flow capacity. Alternately, they can provide excellent 100 mesh fineness at 70% or less though 200 mesh, with little or no capacity reduction. While main shaft driven rotating classifiers were part of the earliest E mill de-

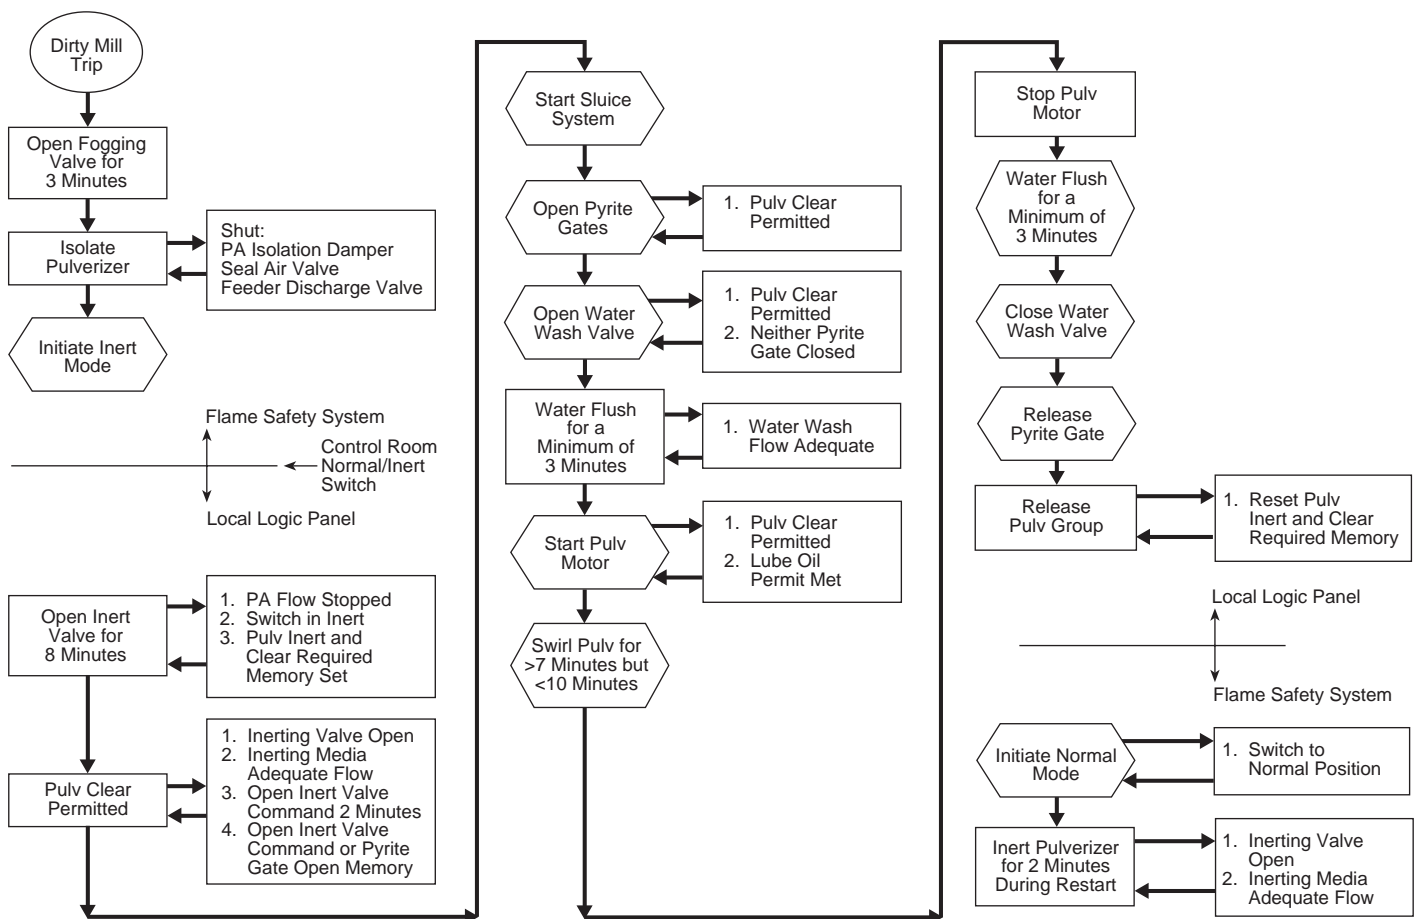

Fig. 17 Typical safety system logic diagram.

sign, independently driven variable speed classifiers were developed in the 1970s, and the two stage design shown in the B&W Roll Wheel mill in Fig. 18 was developed in the 1990s. A similar dynamically staged variable speed (DSVS®) classifier for EL pulverizers, is shown in Fig. 19. The improved particle distribution achieved with the DSVS classifier is shown in Fig. 20.

Rotating throats

Rotating throat rings were introduced for B&W Roll Wheel mills in the 1980s, initially to reduce erosive wear. The rotating throat designs have been further enhanced to provide better air distribution and lower air resistance, as well as better reliability and easier installation.

Variable spring loading

Also for the B&W Roll Wheel mills, a variable on-line spring load adjusting system is available. With the traditional spring loading system, the applied grinding force is a compromise between efficient high load operation, and smooth operation at low loads, including start and stop. With the Auto Spring™ system, the spring load can be increased for optimum high load performance, then reduced for stable low load operation as well as grind out and startup. The typical spring load control will vary pressure with coal flow, but it can also vary loading to accommodate wide variations in coal grindability, as shown in Fig. 21.

Fine grinding

Vertical roller mills have a practical limit of about 95% passing through 200 mesh (74 microns) for product fineness. As the product becomes finer, the recirculated material in the grinding chamber also becomes finer and the compressed layer becomes more fluid and

Fig. 18 DSVS® rotating classifier for B&W Roll Wheel™ pulverizer.

Fig. 19 DSVS® rotating classifier for EL mill.

less stable. For very fine grinding other machines are needed. One of these is the ball-and-tube mill, offering the long residence time needed for an extremely fine product. In addition, ball-and-tube mills are built in the large sizes needed for direct firing.

The high capacity of ball-and-tube mills may not be needed to meet fine grinding applications. One potential application of fine grinding is to provide fuel for coal-fired lighters to reduce oil consumption for startup and low load flame stabilization. Another application is firing very fine coal in smaller furnaces, originally intended for oil or natural gas and not suit-

Fig. 20 Particle size distribution.

Fig. 21 B&W Roll Wheel™ pulverizer variable spring force versus coal flow.

able for traditional coal firing. Smaller capacity mills could be used for this application.

Mills for fine grinding have been used to grind pigments, food and pharmaceuticals. These are small mills, generally 5 t/h (4.5 t_m/h) or less. Grinding principles include fluid energy, stirred ball, and high speed attrition. Fluid energy mills cause solids bearing fluid streams to impinge; particle impacts cause the size reduction. Stirred ball mills, usually wet grinders, use

a charge of small balls in a cylindrical vessel which are agitated by a rotor, grinding the solids flowing through the charge.

High speed attrition mills grind by the combination of first stage impact and final stage attrition. It is these mills which have begun to attract some attention for preparation of oil or natural gas replacement fuel. The mill's rotor is a series of disks, each with impact bars, and each forming the driver for a grinding stage. The grinding stages are separated by diaphragms and coal must move inward against centrifugal force to pass from one stage to the next. Coal captured in each stage is said to provide an effective wearing surface to protect the mill shell from rapid wear. These mills are made in capacities up to about 5 t/h (4.5 t_m/h) and may be once-through or be equipped with external centrifugal classifiers for size control. Manufacturers of these mills refer to the product as micronized coal. When the term was adopted in the early 1980s, micronized coal referred to coal which was 100% finer than a 325 mesh (44 microns). The output of vertical high speed attrition mills is about 98% passing through 200 mesh (74 microns), 86% passing through 325 mesh (44 microns). However, this coal is reported to be fine enough to be easily ignited without the need for preheated primary or combustion air. These mills are high in power consumption and motor power is said to be sufficient to provide the necessary energy for drying most coals. The economic attractiveness of finely ground coal as a stabilizing and startup fuel depends on oil and natural gas prices.

Coal pulverizers at a modern utility power station.

Chapter 14

Burners and Combustion Systems for Pulverized Coal

Advanced low NO_x (nitrogen oxides) pulverized coal (PC) combustion systems, widely in use today in utility and industrial boilers, provide dramatic reductions in NO_x emissions in a safe, efficient manner. These systems have been retrofitted to many existing units and are reducing NO_x emissions to levels which in some cases rival the most modern units. The challenges are considerable, given that the older units were not built with any thought of adding low NO_x systems in the future. Low NO_x combustion systems can reduce NO_x emissions by up to 80% from uncontrolled levels, with minimal impact otherwise on boiler operation; and they do so while regularly exceeding 99% efficiency

in fuel utilization. These advanced low NO_x systems, depicted in Fig. 1, start with fuel preparation that consistently provides the necessary coal fineness while providing uniform fuel flow to the multiple burners. Low NO_x burners form the centerpiece of the system, and are designed and arranged to safely initiate combustion and control the process to minimize NO_x . An overfire air (OFA) system supplies the remaining air to complete combustion while minimizing emissions of NO_x and unburned combustibles. Distributed control systems (DCS) manage all aspects of fuel preparation, air flow measurement and distribution, flame safety, and also monitor emissions. Cutting edge diagnostic

Fig. 1 Advanced low NO_x pulverized coal-fired combustion system.

and control techniques, using neural networks and chaos theory, assist operators in maintaining performance at peak levels. Like automobiles, the fundamentals go back more than 100 years, but the modern product is dramatically more reliable, more efficient, and lower in emissions.

The greatest use of coal worldwide is for the energy source in electric power generation. Coal remains the dominant fuel for electrical generation in the United States (U.S.) and in many other countries as well. This is attributable to both the abundance and relatively low cost of this fossil fuel. It can be burned in a number of ways depending upon the characteristics of the coal and the particular boiler application. Cyclone, stoker, and fluidized-bed firing methods are used for a variety of applications as discussed in Chapters 15 through 17. However, pulverized coal (PC) firing – burning coal as a fine powder suspension in an open furnace – is the most prevalent method in use today. PC firing has made possible the large, efficient utility boilers used as the foundation for power generation in many utilities worldwide.

Pulverized coal firing differs from the other coal combustion technologies primarily through the much smaller particle size used and the resulting high combustion rates. The combustion rate of coal as a solid fuel is, to a large extent, controlled by the total particle surface area. By pulverizing coal to a nominal 50 micron diameter or smaller (see Chapter 13), the coal can be completely burned in approximately one to two seconds. This approaches the rate for oil and gas. In contrast, the other technologies discussed in subsequent chapters use crushed coal of a larger size and require substantially longer combustion zone residence times (up to 60 seconds or longer).

Pulverized coal was first used in the 1800s as a cost effective fuel for cement kilns.¹ The ash content enhanced the properties of the cement and the low cost resulted in the rapid displacement of oil and gas as a fuel. However, early pulverizing equipment was not very reliable and, as a result, an indirect bin system was developed to temporarily store the pulverized coal prior to combustion, providing a buffer between pulverization and combustion steps. Use in the steel industry followed closely. In this application, the importance of coal drying, particle size control and uniform coal feed were recognized.

Success for boiler PC firing applications required modification of the boiler furnace geometry to effectively use the PC technology. In the early 1900s, fireboxes and crowded tube banks had to be expanded to accommodate PC firing. By the late 1920s, the first water-cooled furnaces were used with pulverized coal-fired systems. Burner design progressed, providing improved flame stability, better mixing, and higher combustion efficiency. Coupled with improvements in pulverizer design and reliability, improved PC burners permitted the use of direct firing with coal transported directly from the pulverizer to the burner. (See Fig. 2.)

The exponential increase in the U.S. electric power generation and the increase in boiler size from 100 MW to 1300 MW could not have been achieved economically without the development and refinement of

Fig. 2 Early pulverized coal-fired radiant boiler.

pulverized coal firing. Today, nearly all types of coal from anthracite to lignite can be burned through pulverized firing. Combustion efficiencies of most coals approach those of oil and gas. Current research is focusing on further reduction in emissions of nitrogen oxides (NO_x) for environmental protection without sacrificing boiler performance or availability. (See also Chapter 34.)

Combustion

The manner in which a coal particle burns depends on how it was pulverized, its inherent characteristics, and conditions in the furnace. Pulverization obviously produces fine coal particles, but is also accompanied by introduction of heated primary air (PA) to the coal to facilitate grinding and drying, and for transport of the coal from the pulverizer. The quantity and temperature of PA varies significantly with the type of pulverizer, grinding rate, and coal properties. Hot PA causes some of the moisture in the coal to evaporate and raises the temperature of the coal from ambient to nominally 150F (66C). In a direct fired system, the pulverized coal is immediately transported to the burners by the moisture laden PA. Secondary air is introduced through a burner to the PA/PC mixture, in a controlled manner to induce air-fuel mixing in the furnace. As a coal particle enters the furnace (see Fig. 3), its surface temperature increases due to radiative and convective heat transfer from furnace gases and other burning particles. As particle temperature in-

Fig. 3 Coal particle combustion.

creases, the remaining moisture is vaporized and volatile matter is released. This volatile matter, which ignites and burns almost immediately, further raises the temperature of the char particle, which is primarily composed of carbon and mineral matter. The char particle is then consumed at high temperature, leaving the ash content and a small amount of unburned carbon. The volatile matter, fixed carbon (char precursor), moisture and ash content of the fuel are identified on a percentage basis as part of the proximate analysis discussed in Chapter 9.

Volatile matter content

Volatile matter is critical for maintaining flame stability and accelerating char burnout. Coals with minimal volatile matter, such as anthracites and low volatile bituminous, are more difficult to ignite and require specially designed combustion systems. The amount of volatile matter evolved from a coal particle depends on coal composition, the temperature to which it is exposed, and the time of this exposure. The American Society for Testing and Materials (ASTM) Method D 3175 stipulates a temperature of $950 \pm 20^\circ\text{C}$ for seven minutes for volatile matter content determination.² Raising the temperature would increase volatile yield with other factors held constant. The heat contribution from volatile matter, as a percentage of total coal heating value, can be less than 10% for anthracites, reaches 40% for high volatile bituminous and subbituminous coals, and can exceed 50% for lignite. Coals with higher volatile matter content also benefit from more effective NO_x control by combustion methods, as discussed later. Ignition is influenced by the quality and the quantity of volatile matter. Volatile matter from bituminous and higher rank coals is rich in hydrocarbons and high in heating value. Volatile matter from lower rank coals includes larger quantities of carbon monoxide and moisture (from thermal decomposition) and consequently has a lower heating value. Volatile matter from higher rank coals can provide twice the heating value per unit weight as that from low grade coals.

Char particles

The rate of char particle combustion depends on several factors including composition, particle size, porosity, thermal environment, and oxygen partial

pressure. Char reactions often begin as the coal particle is heated and devolatilizes, but they continue long after devolatilization is complete. Devolatilization is mostly completed after 0.1 seconds, but char-based reactions continue for one to two seconds. The char particle retains a fraction of the hydrocarbons. Char reactivity lessens with increasing coal rank due to accompanying changes in composition and structure of the coal. Younger coals benefit from higher inherent reactivity and from a structure which more closely resembles fibrous plant matter than rock. Many coals go through plastic deformation and swell by 10 to 15% when heated. These changes can significantly impact the porosity and reactivity of the coal particle. Char reactivity drops during the combustion process, which further extends the time for char burnout.

Char oxidation requires oxygen to reach the carbon in the particle and the carbon surface area is primarily within the particle interior structure. Char combustion generally begins at relatively low particle temperatures. Reaction rates are primarily dependent upon local temperature as well as oxygen diffusion and char reactivity. Small char particles, with 10 to 20 micron diameters, benefit from high surface to mass ratios and heat up rapidly, while coarse particles heat more slowly. Rapid heat transfer to and combustion of smaller particles lead to higher particle temperatures. Reaction rates increase exponentially with temperature, and oxygen (O_2) for diffusion into the particle becomes the controlling parameter. Particle diameter and density change in the process. At higher particle temperatures, char reactions are so fast that oxygen is consumed before it can penetrate the particle surface. The particle shrinks as the outer portions are consumed, and transport of oxygen from the surroundings to the particle is the factor governing combustion rate.

For larger particles, the solid mass is reduced as carbon monoxide (CO) and carbon dioxide (CO_2) form, but particle volume is maintained. Coarse particles, more than 100 micron diameter, burn out slowly as a result of their lower surface to mass ratios. Longer burn-out times cause these larger char particles to continue reacting downstream where the flame temperature and oxygen concentration have moderated. A portion of the carbon may not be oxidized depending on the residence time and combustion environment. This unburned carbon amounts to an efficiency loss for the boiler.

Effect of moisture content

The moisture content of the coal also influences combustion behavior. Direct pulverized coal-fired systems convey the moisture evaporated during pulverization to the burners. This moisture plus that remaining in the coal particles present a burden to coal ignition. The water must be vaporized and superheated during the early stages of the combustion process. Further energy is absorbed at elevated temperatures as the water molecules dissociate.

Moisture content increases as rank decreases as discussed in Chapter 9. 15% moisture is common in high volatile bituminous coals, 30% is seen in subbituminous, and more than 40% is common in some lig-

nites. Moisture contents in excess of 40% exceed the ignition capability of conventional PC-fired systems. Alternate systems are then required to boost drying during fuel preparation and/or divert a portion of the evaporated moisture from the burners. Char burnout is impaired by moisture which depresses the flame temperature. This is largely compensated for by the generally higher inherent reactivities and porosities of the higher moisture coals.

Effect of mineral matter content

The mineral matter, or resulting ash, of the coal is inert and dilutes the coal's heating value. Consequently, more fuel by weight is required as ash content increases in order to reach the furnace net heat input. Mineral matter content averages about 10% for U.S. coals but can exceed 30% in some U.S. and a number of international coals.

The ash absorbs heat and interferes with radiative heat transfer to coal particles, inhibiting the combustion process noticeably with high ash coals. The forms of mineral matter determine the slagging tendencies of the ash. These impact combustion by influencing the furnace size and burner arrangement and the resulting flame temperatures and residence time. The additional effects of ash on overall boiler design are discussed in Chapter 21.

Pulverized coal combustion system

Effect of coal type

A variety of laboratory tests and correlations (Table 1) have been developed to predict combustion performance of coal and other PC-fired hydrocarbons such as coke. The tests provide basic information on coal properties and combustion behavior using small samples of coal. Coal heating value, proximate and ultimate analyses are fundamental requirements and essential for performance calculations and emission predictions. Other tests are performed to better characterize combustion behavior, particularly for unfam-

iliar coals. Correlations predict key aspects of combustion such as ignitability and char reactivity. The correlations are often functions of proximate and ultimate analyses as these are nearly universally available. They relate experience to coal properties and assist designers in formulating an appropriate combustion system for the coals in question.

Conventional PC Pulverized coal firing is adaptable to most types of coal. Its versatility has made it the most widely used method of coal firing for power generation worldwide. Most PC-fired systems have the burners located in the lower portion of the furnace. Wall-fired systems usually have the burners positioned on either one wall or on two walls in an opposed arrangement as shown in Fig. 4. The other common arrangement positions the burners in the corners of the lower furnace, and is referred to as corner or tangentially-fired. Primary air typically at 130 to 200F (54 to 93C) conveys pulverized coal directly to the burners at a rate set by the combustion controls based on steam generation requirements. Secondary air is supplied by the forced draft fans and is typically preheated to about 600F (316C). All or most of the secondary air is supplied to the windboxes enclosing the burners. A portion of the secondary air may be diverted from the burners to overfire air (OFA) ports (discussed later) in order to control the formation of NO_x. The secondary air supplied to the burners is mixed with the pulverized coal in the throat of the burner. This permits the coal to ignite and burn.

The combustion process continues as the gases and unburned fuel move away from the burner and up

Table 1 Key Tests and Correlations to Evaluate Coal	
Test	Information
Proximate analysis	Combustibles: volatile matter, char Inerts: moisture, ash
Ultimate analysis	Major elements: carbon, hydrogen, sulfur, nitrogen, oxygen
Drop tube furnace tests	Ignition and char burnout behavior
Thermogravimetric analysis	Ignition, evaporation and char burnout behavior
Free swelling index	Char reactivity
Petrographic examination	Char reactivity
Correlation	Information
Dulong's heating value	Estimated heating value of coal
Ignition factor (B&W)	Ignitability of coal
(Volatile matter x coal oxygen) dry, ash-free	Char reactivity prediction

the furnace shaft. Final burnout of the char depends on the coal properties, particle fineness, excess air, air-fuel mixing, and thermal environment. The products of combustion proceed out of the furnace after being cooled sufficiently and enter the convection pass. Properly controlled furnace exit gas temperature is critical for achieving the required steam conditions and efficiency, and to limit slagging and fouling on downstream tube surfaces.

Low volatile coals While the majority of bituminous, subbituminous, and lignite PC-fired units are arranged in the manner described above, alternate designs are required to accommodate other coals. Coals with low volatile matter content, notably anthracites, are difficult to ignite. Their volatile matter provides insufficient ignition energy for stable combustion with a conventionally configured system. In addition, their advanced coalification (see Chapter 9) has reduced char reactivity, resulting in elevated char ignition and burnout temperatures. These factors require hotter furnaces to sustain combustion. A downshot firing system (see Fig. 5) accomplishes this in combination with an enlarged, refractory-lined lower furnace. The downshot arrangement causes the flame to travel down and then turn upward to leave the lower furnace. The char reactions, which build in intensity some distance down from the burners, return their heat near the burners as the gases turn upward to exit the lower furnace. This heat supplies energy to ignite the fuel introduced at the burners. The refractory lining in the furnace inhibits heat transfer and

elevates gas temperatures to sustain combustion. The enlarged lower furnace also provides increased residence time to accommodate the slower burning char. In addition, very high coal fineness is used to accelerate char reactions and reduce unburned carbon loss. Indirect firing systems can provide hotter, fuel-rich mixtures to the burners to further improve ignition performance with anthracites. Economics and NO_x emission regulations have limited downshot fired units in the U.S., although they are applied internationally where low volatile coals are a major fuel source.

High moisture coals The other main category of non-conventional PC-fired units is that used for lignites with very high moisture content. Moisture content in these coals typically ranges from 50 to 70% by weight, which is well beyond the level that air-swept pulverizers can adequately dry. (See Chapter 13.) Instead, hot gases, removed from the upper portion of the furnace, are used in combination with beater mills to dry and prepare the fuel. These hot gases, near 1832F (1000C), are more suitable for coal drying than preheated air, with a practical upper limit of 752F (400C). Furthermore, the low oxygen content of the flue gas provides a relatively inert atmosphere in the grinding equipment, lessening the threat of fire or explosion as the hot gas mixes with these reactive coals. The fuel is conveyed from the mills to the burners located on the walls, and combustion proceeds as secondary air mixes with the fuel in the furnace. Units of this design are prevalent in parts of Europe and Australia where high moisture brown coals are used.

Combustion system and boiler integration

The most fundamental factors that determine the boiler design are the steam production requirements and the coal to be fired. The thermal cycle defines the heat absorption requirements of the boiler which supplies the rated steam flow at design temperature and pressure. Gas-side parameters, based on the design coal, are used to estimate boiler efficiency. Heat input requirements from the coal can then be determined, setting the coal firing rate at maximum load. The number and size of pulverizers are then selected. Frequently, the pulverizer selection is based on meeting maximum requirements with one mill out of operation. This permits maintenance on one pulverizer without limiting boiler load.

The size and configuration of the furnace are designed to accommodate the combustion characteristics and the slagging tendencies of the coal ash as discussed in Chapter 21. NO_x emission control factors are also incorporated into the layouts of modern combustion systems. Furnace volume must provide sufficient residence time to complete combustion. Heat input per plan area is a key parameter to gauge thermal loading, and has to be moderated with high or severe slagging coals. Peak flame temperatures can exceed 3000F (1649C) in the burner zone, well in excess of ash fusion temperatures. Molten ash accumulations are controlled by providing a furnace of appropriate size, and by inclusion of sootblowers. Furnace width strongly influences the burner arrangement, furnace depth is critical to gas-side mixing and OFA system per-

Fig. 5 Downshot-fired unit with refractory-lined furnace for low volatile coals and primary air exchange (PAX) burners.

formance, and height is elemental for setting vertical burner spacing and for residence time. Increasing the height of the burner zone reduces thermal loading and tends to reduce NO_x formation. However, taller burner zones tend to reduce upper furnace residence time and pose problems for completing combustion for a given furnace volume. The best overall furnace design takes into consideration many cross-related factors and is strongly influenced by experience.

The number of burners and the heat input per burner are selected to minimize flame impingement on the furnace walls. Multiple burners at moderate inputs, in an opposed-fired arrangement, are favored to provide uniform heat distribution across the furnace and to inhibit localized slagging. The burner design is based on fuel parameters and NO_x emission control requirements in order to provide complete combustion and minimum pollutant emissions. An OFA system may be included to further reduce NO_x , depending on emission limits and coal sulfur content. High sulfur coals pose corrosion risks to common furnace tube materials under fuel-rich conditions. OFA can still be safely employed in such cases by use of alloy weld overlay or similar measures to protect tubes in the burner zone.

Theoretical and excess air quantities are determined for the required coal input rate from combustion air calculations as discussed in Chapter 10. Fans, ductwork, air heaters, windboxes, and burners are sized to satisfy flow, pressure loss, air preheat and velocity requirements for the unit. OFA ports are designed to satisfy jet penetration and dispersion criteria with acceptable pressure drop.

Burner integration

Burners are the central element of effective combustion system designs which include fuel preparation, air-fuel distribution, furnace design and combustion control. Burners can be categorized as pre-mix and throat-mix types. Pre-mix burners combine secondary air and fuel upstream of the combustion chamber. Throat-mix burners, including essentially all PC-fired burners, introduce secondary air to the fuel in the burner throat at the entrance to the furnace (Fig. 6). The secondary air is supplied in a manner to induce air-fuel mixing and thereby sustain ignition and produce a stable flame. The mixing rate of air and fuel directly affects flame stability, flame shape, and emissions.

Fuel preparation influences Pulverizers are designed to grind a specific quantity of coal, with given grinding characteristics, to a prescribed level of fineness (see Chapter 13). The pulverizer type and operating conditions determine the quantity and fineness of pulverized coal supplied to the burner, as well as the required quantity of primary air. The number of burner lines per pulverizer varies with the furnace size and design philosophy, with four to eight as the most common range for medium and large utility boilers. In practice this results in burner maximum coal rates typically in the range of 10,000 to 30,000 lb/h (1.26 to 3.79 kg/s). Given the normal range of coal heating values, this translates into maximum burner heat inputs of 100 to 300 million Btu/hr (29 to 88 MW_t). In contrast, small utility and industrial boilers have PC-fired burn-

Fig. 6 Circular register pulverized coal burner with water-cooled throat.

ers with maximum inputs commonly in the 50 to 100 million Btu/hr (15 to 29 MW_t) range, and may have only 2 or 3 burners per pulverizer. Pulverizers can typically operate at grinding rates down to 25 to 40% of maximum capacity, depending on the design, coal variability, and control system. Burners are expected to operate with stable flames over the normal turn-down range of the associated pulverizer. This can usually be accomplished with good coal, but can be problematic with difficult to ignite coals.

Primary air is supplied to the pulverizer to facilitate coal drying, for circulation within the mill, for classification of coal particles, and for transport of the coal through the coal pipes to the burners. Primary air temperature to the mill depends on the air preheat capability, moisture content in the coal, primary air to coal ratio in the mill, and the required mill outlet temperature. Mill inlet temperatures may drop below 300F (149C) for dry coals, and reach 700F (371C) with lower rank coals. Resulting mill outlet temperatures, approximately the fuel temperature supplied to the burners, range from 130F (54C) with low rank coals to 200F (93C) with high rank coals. Primary air leaving the mill is saturated with moisture with low rank coals, posing an ignition burden. Pulverizers typically require 40 to 70% of their full load primary air requirements at their minimum output level. In addition, the PA/PC mixture traveling to the burners must be transported at a minimum of 3,000 ft/min (15 m/s). This velocity serves to prevent the coal particles from dropping out of suspension in horizontal runs of coal pipe. Minimum primary air flow is the greater of the minimum PA flow required for the pulverizer or the minimum required to satisfy coal pipe velocity limits.

Stoichiometry refers to the ratio of air supplied to

the calculated theoretical air requirement. The primary stoichiometry, from the primary air, can vary by a factor of three depending on the coal and pulverizer conditions. Primary stoichiometry directly influences combustion conditions in the root of the burner flame, with strong impacts on NO_x formation as discussed later. Further, for a given burner stoichiometry, increasing PA reduces the available secondary air (SA). The SA/PA ratio is also seen to vary greatly with coal and pulverizer conditions. See Table 2. Higher SA/PA ratios provide greater aerodynamic control of air-fuel mixing and improved burner performance. Low SA/PA ratios can result in flame instability. In summary, fuel preparation issues dramatically vary the condition of the fuel stream supplied to the burner, and greatly influence the burner performance.

The quantity of coal supplied to the pulverizer is regulated by a coal feeder (see Chapter 12). Systems lacking accurate PA or coal measurement and control, as is commonly the case with ball tube mills, restrain optimization of combustion equipment and cause operational inconsistencies.

Primary air and pulverized coal exit a pulverizer and travel through coal pipes to the associated burners. The distribution of the PA/PC mixture among coal pipes is dependent on air and solids flow patterns at the pulverizer exit, and by flow resistance in the individual coal pipes. Restrictors or orifices in the coal piping from the pulverizer to its burners serve to more evenly distribute coal among several burners. As burner nozzle velocity increases, the ignition point gradually moves farther from the burner. Excessive burner nozzle velocity can result in blowoff of the flame, a potentially hazardous condition where coal ignition and flame stability are lost. High burner nozzle velocities also result in accelerated erosion of burner hardware.

Secondary air supply Forced draft (FD) fan(s) supply the secondary air (SA) for combustion. Total air to the boiler is basically the sum of primary air and secondary air. The FD fans must supply secondary air in sufficient quantity to achieve the intended excess air at the boiler outlet. Modern PC-fired boilers typi-

cally operate with 15 to 20% excess air at full load, and with higher excess air as load is reduced. Excess air, that is air beyond theoretical requirements, is necessary to assure complete combustion in practical systems given imperfections in air-fuel balance and unpredictable variations in coal quality. The FD fans also supply the motive force to pump secondary air through the various downstream equipment. In pressurized systems, the FD fans provide the pressure to overcome system resistance from the fans, through the boiler and all backend equipment. In balanced draft systems, the FD fans supply sufficient pressure for the SA to enter the furnace, then are augmented by Induced Draft (ID) fans which draw gases through the boiler and backend equipment.

Dampers and variable speed motor drives at the FD fans are used to regulate air flow. Steam coil or glycol heaters boost air temperature from the FD fans. Tubular or regenerative air heaters (Chapter 20) transfer heat from flue gas leaving the boiler and raise air temperature to about 600F (316C). In some systems, a portion of this preheated air is diverted to hot PA fans to boost pressure for use in the pulverizers. Other systems use cold PA fans and separate or tri-sector air heaters to supply PA for the pulverizers. The secondary air flow is measured downstream of the air heaters, then ducted to the windbox(es) which enclose the burners. The windbox may be partitioned or function as an open plenum, as discussed later. An overfire air system, if used, will extract a portion of the secondary air for the OFA ports.

Distribution of SA among burners in a windbox occurs by several means and to varying degrees of uniformity. The physical size of the windbox and the burner arrangement result in variations in SA pressure and velocity within the windbox which lead to SA maldistribution. The air flow resistance of the burners acts to improve distribution among burners to some extent. The burners may be equipped with adjustable dampers or registers which provide a means to further balance SA distribution. Modern burners are equipped with air flow measurement equipment to facilitate adjustments for uniform SA distribution.

Burner functions

Flame stability A burner introduces the primary air and pulverized coal to the secondary air in a manner that establishes a stable flame. This involves producing a flame front close to the burner over a range of operating conditions. Igniters are used to sustain combustion when flames would otherwise be unstable. Igniters are always required to initiate combustion as coal is first introduced to the burner, and during a normal burner shutdown. The burner normally sustains a stable flame by using heat from coal combustion to ignite the incoming pulverized coal. A flame safety system, included with modern burners, electronically scans the flame to verify stability and triggers corrective action if the flame becomes unstable.

Air-fuel mixing The burner initiates the mixing process of secondary air with the PA/PC mixture. However, overall air-fuel mixing is a combination of several factors. An air staging OFA system, if so equipped,

Table 2
Pulverizer Impact on Burners (Unstaged)

	Pulverizer Type				
	Vertical Spindle	Attrita	Ball Tube		
Pulverizer capacity, %	100	100	100	100	100
PA/PC (pulverizer), lb/lb	1.8	1.8	1.8	1.5	1.2
Coal heating value, Btu/lb	12,000	8000	6000	12,000	12,000
Coal theoretical air, lb/10 ⁴ Btu	7.5	7.5	7.5	7.5	7.5
Theoretical lb air/lb coal, lb/lb	9.0	6.0	4.5	9.0	9.0
Stoichiometry to burner nozzle	0.20	0.30	0.40	0.17	0.13
Total burner stoichiometry	1.15	1.15	1.15	1.15	1.15
SA/PA ratio	4.8	2.8	1.9	5.8	7.6

supplies the remaining secondary air to the process. Flue gas recirculation (FGR) to the furnace hopper or tempering ports, if so equipped for steam temperature control, adds additional flow and mixing dynamics to the furnace. Furnace mixing results from the expansion of high-temperature combustion products and flow energies of PA, SA, OFA and FGR systems; and from resulting flow conditions within the specific size and structure of the furnace enclosure.

The amount of air-fuel mixing produced by the burner is critical to combustion performance, and varies considerably with burner type. The simplest burners inject the fuel and air in parallel or concentric streams without the benefit of other burner-induced mixing. Entrainment of adjacent flow streams occurs as the jets develop and due to jet expansion from combustion. Corner-fired furnaces operate in this manner, as do some roof-fired designs. Combustion performance greatly depends on mixing subsequently generated in the furnace. Mixing effectiveness decreases with boiler load as air-fuel flow rates drop. This can result in poor combustion performance at reduced boiler loads.

Wall-fired burners may incorporate a variety of air-fuel mixing techniques. Burner mixing can be induced by using the primary air/pulverized coal (PA/PC) stream, by using the secondary air, or by a combination of the two. Looking first at the PA/PC side, the most frequently used burner mixing devices are deflectors, bluff bodies, and swirl generators. Deflectors are frequently installed near the exit of the burner nozzle to cause the PA/PC stream to disperse into the secondary air. These deflectors, or impellers, also reduce axial momentum of the fuel jet, reducing flame length. Impellers may also induce radially-pitched swirl of the fuel jet to further accelerate mixing. Bluff bodies are sometimes used in or adjacent to the burner nozzle exit. Flow locally accelerates around the upstream side of the bluff body and recirculates on the downstream side. The recirculation promotes mixing. The bluff body can also be used to increase residence time for a portion of the fuel near the burner, thereby improving flame stability. The PA/PC may also be divided and injected as multiple streams in order to increase the surface area of the fuel jets and increase the rate of combustion.

Secondary air swirl is the most common way to induce air-fuel mixing in circular throat burners. Swirl generators are used upstream of the burner throat to impart rotating motion to the secondary air. This air leaves the burner throat with tangential, radial and axial velocity components. Radial and axial pressure gradients form in the flow field downstream of the throat, with the lowest pressure being near the center of the throat.³ As swirl is increased, the pressure gradients increase. This causes the flow to reverse and travel along the axis of the flame toward the low pressure zone. A recirculating flow pattern is then generated near the burner. Deflectors and bluff bodies are also used to induce localized mixing from the secondary air. Modern low NO_x burners frequently subdivide the secondary air into two or more streams. Swirl may be imposed at different rates for these SA streams, to

satisfy flame stabilizing functions while limiting the overall air mixing rate.

Burner mixing intensity is directly related to burner throat velocity. This is a key design parameter and varies considerably from burner type to burner type. Higher throat velocities promote furnace mixing at the expense of burner pressure drop. Higher mixing rates tend to reduce unburned combustibles at the expense of higher NO_x emissions. Throat velocity decreases with decreasing burner firing rate. Optimal air-fuel mixing is achieved at reduced boiler loads by operating with fewer burners in service and by operating those burners at higher firing rates.

Emission control Modern PC-fired burners play a major role in controlling emissions of NO_x (NO and NO₂), in addition to carbon monoxide (CO) and unburned carbon. Unburned combustibles have traditionally been a criterion for efficient burner operation. Combustion efficiency depends on numerous other factors, including coal reactivity and fineness, burner design, OFA design, furnace design, excess air, and operating conditions. Unburned combustibles are minimized by rapid thorough mixing of air and fuel in the furnace. NO_x emissions from PC are minimized in the opposite manner, by gradually combining air and fuel. Many techniques which serve to lower NO_x tend to raise unburned combustibles and vice versa. The practical application of these techniques to combustion system design in order to effectively control emissions is considered in detail below.

Performance requirements

Pulverized coal-fired equipment should meet the following performance conditions:

1. The coal and air feed rates must comply with the load demand over a predetermined operating range. The burners have to operate in a reliable manner with stable flames. For modern applications with high volatile bituminous or subbituminous coal, flames should be stable without the use of igniters from about 30 to 100% boiler load. The minimum load depends on the coal, burner design, and pulverizer load; operation below this load is performed in combination with igniters in service.
2. Boiler emissions of NO_x, CO, and unburned carbon comply with design expectations for the particular application. The actual limits vary considerably due to regulations, the coal and combustion conditions, the use of downstream equipment to further reduce emissions, and ash disposal requirements.
3. The burner should not require continual adjustment to maintain performance. This fundamentally requires consistency in the fuel preparation system and SA systems supplying fuel and air to the burners. The unit should be designed to avoid the formation of localized slag deposits that may interfere with burner performance or damage the boiler.
4. Only minor maintenance should be necessary during scheduled outages. To avoid high temperature damage, alloy steel should be used for burner parts exposed to furnace radiative heat transfer. The burner structure needs to accommodate differen-

tial expansion and maintain integrity at high temperature. Burner parts subject to PC erosion should be protected with wear resistant ceramic materials.

5. Safety must be paramount under all operating conditions. Automated flame safety and combustion control systems are recommended, and often required.

Conventional PC burners

Prior to NO_x emission regulations introduced in 1971 in the U.S., the primary focus of combustion system development was to permit the design of compact, cost effective boilers. As a result, the burner systems developed focused on maximizing heat input per unit volume to enable smaller furnace volumes using rapid mixing burners which generated very high flame temperatures. An unintended side effect was the production of high levels of NO_x . Burners used on such boilers include the conventional circular burner, the cell burner, and the S-type burner. Most of these have been replaced with low NO_x burners in the U.S., but an examination of their designs is useful as it forms a foundation for the more advanced designs which followed.

Conventional circular burner

The circular burner (Fig. 6) was one of the earliest forms of swirl-stabilized PC-fired burners. Due to its success, this burner was used for more than six decades firing a variety of coals in many boiler sizes. The burner is composed of a central nozzle to which PA/PC is supplied. The nozzle is equipped with an impeller at the tip to rapidly disperse the coal into the secondary air. Secondary air is admitted to the burner through a register. The register consists of interlinked doors arranged in a circular pattern between two plates. The doors are closed to cooling position when the burner is out of service, are partially open for lightoff and are more fully open for normal operation.

The registers influence SA swirl as well as quantity. Opening the register doors allows more air into the burner, but reduces swirl, and vice versa. Moderate swirl produces a well shaped flame plume. Excessive swirl can cause the flame to flatten against the firing wall and cause localized slagging. Inadequate swirl results in flame instability. Register adjustments to modify flame shape can result in improper SA supply to the burner in multi-burner applications. High combustion efficiency depends on uniform air-fuel distribution.

The circular burner can fire natural gas, oil or pulverized coal. Simultaneous firing of more than one fuel is not recommended due to the potential for over-firing the burners and the resulting combustion problems. Variations of the circular burner are in operation at inputs from 50 to 300×10^6 Btu/h (15 to 88 MW_t).

Cell burner

The cell burner combines two or three circular burners into a vertically stacked assembly that operates as a single unit (Fig. 7). In the 1960s and 1970s, the cell burner was applied to numerous utility boilers which had compact burner zones. While highly efficient, the cell burners produced high levels of NO_x emissions and tended to be mechanically unreliable.

S-type burner

The S-type burner was developed in the early 1980s as a functional and mechanical upgrade for the circular burner. The S-type burner separates the functional attributes of the circular burner for improved SA control in a mechanically superior configuration. (See Fig. 8.) The burner nozzle is generally the same as that in the circular burner. However, secondary air flow and swirl are separately controlled. Secondary air quantity is controlled by a sliding disk as it moves closer to or farther from the burner barrel. Secondary air swirl is provided by adjustable spin vanes positioned in the burner barrel. An air-measuring pitot tube grid is installed in the barrel ahead of the spin vanes. This provides a local indication of relative secondary air flow to facilitate sliding disk adjustments to balance SA among burners. Swirl control for flame shaping is controlled separately by spin vanes. The S-type burner provides higher combustion efficiency and mechanical reliability than the circular unit and requires no pressure part replacement.

Low NO_x combustion systems

NO_x formation

NO_x is an unintended byproduct from the combustion of fossil fuels and its emissions are regulated in the U.S. and many other parts of the world. While a number of options are available to control and reduce NO_x emissions from boilers, as discussed in Chapter 34, the most cost effective means usually involves the use of low NO_x combustion technology, either alone or in combination with other techniques. The effectiveness of the pulverized coal NO_x control technology depends primarily upon the fuel characteristics and the combustion system design. For pulverized coal wall-fired units, NO_x emissions from older conventional combustion systems discussed above typically range from 0.8 to

Fig. 7 Conventional two-nozzle cell burner.

Fig. 8 S-type burner and components.

1.6 lb/10⁶ Btu (984 to 1968 mg/Nm³; see Note below). Low NO_x PC combustion systems are capable of reducing NO_x down to 0.15 to 0.5 lb/10⁶ Btu (185 to 615 mg/Nm³).

NO_x control by combustion

Approximately 75% of the NO_x formed during conventional PC firing is fuel NO_x; the remainder is primarily thermal NO_x. Consequently, the most effective combustion countermeasures are those limiting fuel NO_x formation. Fuel NO_x is formed by oxidation of fuel-bound nitrogen during devolatilization and char burnout. Coal typically contains 0.5 to 2.0% nitrogen bound in its organic matter. High oxygen availability and high flame temperatures during devolatilization encourage the conversion of volatile-released nitrogen to NO_x. Nitrogen retained in the char has a lower conversion efficiency to NO_x, primarily due to lower oxygen availability during char burnout. Reactive coals with high volatile matter and low fixed carbon/volatile matter (FC/VM) ratios tend to be the most amenable to NO_x control by combustion modification. Coals with higher FC/VM and nitrogen content tend to produce higher NO_x emissions.

The most effective means of reducing fuel-based NO_x formation is to reduce oxygen (air) availability during the critical step of devolatilization. Additional air must then be added later in the process to complete char reactions and maintain high combustion efficiency.

Oxygen availability can be reduced during devolatilization in two ways. One method is to design the burner(s) to supply all of the combustion air, but

in a manner which limits the rate of air introduction to the flame. Only a fraction of the air is permitted to mix with the coal during devolatilization. The remaining air is then mixed downstream in the flame to complete combustion. Burners employing this technique (low NO_x burners) can reduce NO_x emissions by 30 to 60% relative to uncontrolled levels. However, overall air-fuel mixing is reduced to some extent and the flame envelope is larger compared to rapid mixing conventional burners. Reducing the rate of air-fuel mixing also tends to increase the quantity of unburned combustibles from the process. This strong tendency can be counteracted by careful control of burner aerodynamics and overall combustion system design. In some cases, improvements in the fuel preparation/delivery system and increased coal fineness are required to limit unburned combustibles to acceptable levels.

A second method of reducing oxygen availability during the early phase of combustion is to remove a portion of the combustion air from the burners and introduce it elsewhere in the furnace. This method is referred to as air staging. Air staging systems are frequently used in combination with low NO_x burners to multiply the NO_x reduction effect. PC combustion systems typically operate with 15 to 20% excess air at maximum firing rate. (See Chapter 10.) In some staging situations, reducing the air flow by 10% at the burners is sufficient for a given level of NO_x emissions control. This permits the burners to continue to operate in an excess air condition. Reducing the air flow to less than stoichiometric (theoretically required for complete combustion air flow) conditions can further reduce NO_x emissions. This deeper staging minimizes NO_x formation, but inevitably results in more unburned or partially burned fuel leaving the burner zone. The remaining theoretical air and excess air must then be

Note: The International Energy Agency conversion has been adopted for NO_x emission rates: 1230 mg/Nm³ equals 1 lb/10⁶ Btu for dry flue gas, 6% O₂, 350 Nm³/GJ for coal.

supplied through air staging ports (NO_x ports or OFA ports). This can amount to 25% or more of the total air supplied to the boiler. The introduction of large quantities of staging air to the unburned fuel subsequently causes NO_x reformation to occur. The rate of introduction and mixing of OFA in the furnace are critical to minimizing NO_x reformation in deeply staged systems.

The application of an OFA system can increase unburned combustibles, slagging in the combustion zone and furnace, and the risks of furnace tube corrosion. These risks increase with coals having high sulfur content and/or high slagging characteristics, and with less reactive coals. While technologies exist to address these risks, the use of OFA may be limited or avoided with such coals for economic reasons in favor of alternate NO_x reduction methods.

Another method of reducing NO_x emissions is referred to as reburning or fuel staging. This control technique destroys NO_x after it has formed. Fuel staging involves introducing the fuel into the furnace in steps. Typically, the bulk of the fuel is burned in the furnace at near stoichiometric conditions. The balance of the fuel, with a limited amount of air, is then injected to create a reducing zone part way through the combustion process. The reducing conditions form hydrocarbon radicals which strip the oxygen from previously formed NO_x , thereby reducing overall NO_x emissions. The balance of the air necessary to complete the combustion is then added. Some fuel-staged systems involve separate burners or fuel injectors followed by NO_x ports which supply the remaining combustion air. The reburn fuel can be coal, but this calls for special measures to limit unburned combustibles from the process. Lighter fossil fuels, especially natural gas, generate more hydrocarbon radicals and can improve emissions reduction, but their cost or avail-

ability can deter usage. Fuel staged systems have generally not proven to be as cost-effective as other NO_x reduction techniques with PC-firing. However, some advanced low NO_x burners embody fuel staging while supplying all the fuel to the burners. A portion of the fuel is introduced in a manner to generate hydrocarbon radicals; these are mixed into the flame later to reduce previously formed NO_x . These burners can achieve NO_x reductions of 50 to 70% from baseline uncontrolled levels.

Dual register burner

The Babcock & Wilcox Company (B&W) began experimenting with techniques to reduce NO_x from PC-fired burners in the 1950s. A slot burner, which incorporated controlled air-fuel mixing, was first developed.⁴ The air introduced through the burner throat mixed rapidly in the flame while air diverted to the external slots mixed gradually. While effective, the design with slots external to the burner throat was difficult to apply to furnaces. In 1972, B&W developed the dual register burner (DRB) for firing pulverized coal. The DRB (Fig. 9) provided two air zones, each controlled by a separate register, around an axially positioned coal nozzle. A portion of the secondary air was admitted through the inner air zone and highly swirled to aid ignition and flame stability. The remainder passed through the outer air zone with moderate swirl and was gradually mixed downstream in the flame. The burner nozzle was equipped with a venturi to disperse the primary air-coal mixture. The mixture was then injected into the throat without deflection. The results were a stable flame with a fuel-rich core and gradually completed mixing downstream. The first unit retrofit was completed in 1973 and achieved 50% NO_x reduction relative to prior circular burners.

Fig. 9 Dual register burner (DRB) and compartmented windbox.

This retrofit required no modifications to boiler pressure parts, fans, or pulverizers, and NO_x ports were not used. The U.S. government granted a patent to B&W for the DRB in January 1974. Numerous variations have been used by B&W since its introduction.

The DRB was generally used in combination with enlarged furnace combustion zones to reduce thermal NO_x and with a compartmented windbox to better control air distribution (Fig. 9). This design has the burners coupled with each pulverizer situated in an individual windbox compartment. Secondary air was metered and controlled separately for each compartment. This approach corrected some of the SA flow imbalances among burners that were prevalent in open windbox designs.

The DRB typically reduced NO_x 40 to 60% from uncontrolled levels. This efficiency enabled its use on new boilers without NO_x ports or other air diversion systems. Utility boiler NO_x emissions with the DRB ranged from 0.27 to 0.70 lb/10⁶ Btu (332 to 861 mg/Nm³).

DRB-XCL® burner

The Dual Register XCL burner is a second generation low NO_x burner which incorporates fuel staging technology along with the air staging technology found in the original DRB. The DRB-XCL® is physically arranged as shown in Fig. 10, and draws heavily on the proven mechanical design of the S-type burner. Air flow to the burner is regulated by a sliding disk.

An impact/suction pitot tube grid is located in the burner barrel to provide a local indication of secondary air flow. With this information, the secondary air can be more uniformly distributed among all burners by adjusting the sliding disks or other means. Balanced air and fuel distribution among all burners is critical to combustion efficiency, particularly with low NO_x systems. Downstream of the pitot tube grid are the inner and outer air zones. Adjustable vanes in the inner zone impart sufficient swirl to stabilize ignition at the burner nozzle tip. The outer zone, the main SA path, is equipped with two stages of vanes. The upstream set is fixed and improves peripheral air distribution within the burner. The downstream set is adjustable and provides proper mixing of this secondary air into the flame. The burner nozzle is equipped with hardware to accomplish the necessary fuel mixing. This may include a conical diffuser and flame stabilizing ring or an impeller. These combine to improve flame stability while controlling NO_x and flame length. The DRB-XCL burner reduces NO_x 50 to 70%⁵ from uncontrolled levels without using NO_x ports. This added level of NO_x reduction is possible by the fuel staging effects generated in the near-flame field.

A plug-in version of the DRB-XCL enables its use in many retrofit applications without requiring pressure part modifications, and has demonstrated reduced unburned combustibles.⁶ The burner can be equipped for firing natural gas and/or fuel oil when multi-fuel capability is desired.

Fig. 10 DRB-XCL® low NO_x burner for pulverized coal firing.

DRB-4Z® burner

B&W's third generation low NO_x burner, the DRB-4Z® burner, incorporates even more advanced emission control technology in a well proven mechanical configuration. The patented DRB-4Z design combines primary zone stoichiometry control with fuel staging and air staging technology to achieve very low NO_x emissions along with improved combustion efficiency. Conceptual development, using Computational Fluid Dynamics (computer modeling), indicated the benefits of an additional air zone separating the coal nozzle from the principal air zones of the burner.⁷ These concepts were proven through extensive testing⁸ during the development of the burner in B&W's Clean Environment Development Facility.⁹

This additional air zone, the *transition zone*, acts as a buffer between the high temperature, fuel-rich flame core and the secondary air streams (see Fig. 11). The flow field produced by the transition zone draws gases from the outer portions of the flame inward toward the flame core. NO_x formed in the oxygen-rich outer flame region is reduced back to other nitrogenous species in the process. A further advantage of the transition zone is the ability to alter primary zone stoichiometry.

Table 2 indicates the variations in primary stoichiometry which are inherent to different coals and pulverizer designs. Inadequate primary zone stoichiometry inhibits combustion during the critical stage of devolatilization. Air supplied by the transition zone can compensate for this without flooding the flame core with secondary air from the main air zones. SA swirled through the inner air zone serves to anchor and stabilize the flame. SA admitted through the outer air zone is staged to gradually mix into the flame. NO_x

reductions of up to 80% from uncontrolled levels are possible with the DRB-4Z. The burner is well-suited for use with an OFA system when the lowest NO_x emissions are required.^{10,11}

The physical arrangement of the DRB-4Z is depicted in Fig. 12. The mechanical construction was adapted from the proven integrity of the DRB-XCL, while incorporating the advanced aerodynamic features. The coal nozzle strongly resembles the predecessors and is interchangeable in some situations. The transition zone is supplied with SA by means of slots and a manually adjustable sliding sleeve. A sliding air damper is used to regulate SA to the main air zones. A linear actuator positions this damper in open windbox applications in order to automatically control the SA flow to the burner. A pitot tube grid is installed downstream of the damper to provide a local indication of SA flow. Manually adjustable vanes are located in the inner and outer air zones to enable optimization of swirl settings during burner commissioning. Fixed vanes are supplied to improve air flow distribution and reduce pressure drop through these air zones. The DRB-4Z plugs into wall openings from most existing burners to facilitate its use as a replacement upgrade. Improved aerodynamics provide better overall air-fuel mixing which results in significantly lower unburned combustibles than earlier low NO_x burner designs.

The shop-assembled construction of the DRB-4Z is illustrated in Fig. 13. The one-piece assembly simplifies and quickens installation. Front end components are fabricated from heavy, high quality stainless steel and mechanically stiffened in a manner which accommodates differential expansion at elevated temperature while maintaining product integrity. Permanent thermocouples are supplied to assure components are

Fig. 11 DRB-4Z® low NO_x combustion zones.

Fig. 12 DRB-4Z® low NO_x burner for pulverized coal applications.

kept within safe operating temperatures. The burner is also capable of low NO_x firing natural gas, or can be equipped to fire fuel oil as a primary fuel.

Low NO_x cell burner

The cell burners discussed earlier produced high NO_x emissions, but their unique arrangement (Fig. 7) made it difficult to fit low NO_x burners in the existing wall openings. The Low NO_x Cell burner (LNCB) was developed to replace two nozzle cell burners in a plug-in design. In essence, all the coal is supplied to one burner throat with a portion of the secondary air. The balance of the secondary air is supplied to the other burner throat, which serves as an integral NO_x port for each burner location. NO_x levels can be reduced by 50% with the LNCB while maintaining high combustion efficiency. Advanced second and third generation low NO_x burners are designed for plug-in use in cell burners and now provide lower NO_x alternatives to the LNCB.

Air staged systems

Air staging involves removing a portion of the air from the burners to reduce oxygen availability early in the combustion process, and reintroducing it later in the combustion process. Often the physical arrangement dictates replacing the staged air through ports located above the combustion zone, hence the name overfire air (OFA) is commonly applied to such systems. The layout of a combustion system and furnace, however, may necessitate supplying staged air

at the same elevation or below the burner zone, such that OFA is something of a misnomer. OFA is used here in its generic sense to refer to any air staged system. The ports through which the OFA is injected are called OFA ports or NO_x ports.

B&W pioneered the development and application of NO_x ports and air staging as a NO_x emission control technique. This work, which began in the 1950s, was initially directed at NO_x reduction for oil- and gas-fired boilers in California. R.M. Hardgrove of B&W filed a patent for a *Method for Burning Fuel* on June

Fig. 13 Fully assembled DRB-4Z® burner ready for shipment.

18, 1959, disclosing key aspects of air-staging influences on NO_x emissions. The patent was granted in 1962, and NO_x ports have been used ever since by B&W. Today, the NO_x reduction effectiveness of OFA systems is attested to by their widespread use in coal, oil and gas units, including wall-fired, corner-fired and Cyclone designs.

The degree of NO_x reduction achieved by air staging depends on numerous factors, including fuel properties, burner design and associated NO_x emissions, furnace design, operating conditions, and the OFA system design. Key design issues are the quantity of OFA and the arrangement and NO_x port design. NO_x reduction is a function of the percent combustion air removed from the burners for use as OFA. Consider a typical PC-fired situation for a unit operating at 20% excess air at full load, that is, with 120% theoretical air (Fig. 14).

1. A low NO_x burner (LNB) would produce a NO_x emission level noted as a_1 for this example.
2. Adding a moderate amount of air staging, in this case 15 percentage points of air, would still leave the combustion zone under oxidizing conditions (above 100% theoretical air). Burner zone stoichiometry (BZS) is 1.05 in this case. NO_x emissions are reduced to level b_1 . Removing this 15 percentage points of secondary air from an existing combustion system would reduce burner mixing effectiveness to some degree, impairing flame stability, and may add to slagging tendencies in the burner zone.
3. Increasing the air staging to 30 percentage points drops the combustion zone to reducing conditions (less than 100% theoretical air). BZS is now 0.90, and the greater air staging reduced NO_x emissions to point c_1 . Notice that some NO_x reformation occurred from the introduction of the OFA such that the exit NO_x c_2 was somewhat higher than c_1 . Removing 30 percentage points of SA from an existing combustion system requires new or revised burners to produce sufficient mixing with lesser SA. A BZS of 0.90 means only 90% of theoretical air is supplied to the burners, so at least 10% of the fuel remains unburned leaving the burner zone. This raises risk of increased unburned combustibles even after addition of OFA. Reducing conditions in the burner zone also raise risks of furnace tube corrosion with high sulfur coals, and can be problematic for slagging.
4. Increasing air staging to 40 percentage points drops BZS to 0.80, meaning at least 20 percent of the fuel is unburned leaving the combustion zone. Actual constraints inherent to the process cause considerably more than 20% of the fuel to leave the burner zone unburned. NO_x leaving the burner zone dropped to point d_1 . In this example, the rapid addition of 40 percentage points of OFA to the significant amount of unburned fuel resulted in major NO_x reformation. Consequently the exit NO_x d_2 actually exceeded the lesser staged case c_2 . However, NO_x reformation could be lessened by gradually reintroducing the OFA, and limiting O_2 concentrations and combustion rates in the latter stages of combustion. This results in the lowest level of exit NO_x noted as d_3 .

OFA with wall-fired systems The description above illustrates the advantages of air staging for NO_x reduction, but also reveals potential problems which may result. Application of OFA to an existing wall-fired system reduces burner-induced mixing, which tends to impair flame stability and slows the combustion process. This occurs due to lower burner throat velocities and lower secondary air to primary air ratio. Resulting reductions in burner SA momentum and mixing energy can best be compensated for by raising burner throat velocity. Deep staged OFA systems therefore necessitate the use of new, smaller burners for good combustion performance. Greater amounts of swirl, for at least a portion of the SA, further assist in flame stabilization. The burner arrangement and/or swirl orientation may need to be altered to present a more uniform flow field to the OFA system. Advanced low NO_x burners with improved SA control measures can compensate for these issues with air staged systems, and have demonstrated equal or less furnace slagging tendencies compared to some unstaged conventional designs.

After properly dealing with the wall-fired burners, the design of the air staging system can proceed. The major functional issue concerns proper distribution of the OFA within the furnace, in a manner which minimizes NO_x reformation, CO, and unburned char. Minimizing unburned combustibles calls for rapid mixing of OFA, while minimizing NO_x calls for gradual mixing. The OFA port jets have to travel cross flow to the furnace gases and deliver air in time for combustion reactions to be completed in the furnace. This favors fewer ports with high mass flow and velocity. But OFA must also be adequately dispersed to cover the entire cross-section of the furnace. This tends to favor a large number of smaller ports. Ports located closer to the burners provide more time for mixing and lessen unburned combustibles, while locating ports further away tends to maximize NO_x reduction. Effective implementation of OFA systems requires the combination of experience, computer modeling, and on-line adjustability. Computer modeling (see Chapter 6) pro-

Fig. 14 The effects of OFA design on NO_x emissions.

vides a means to evaluate the mixing effectiveness of alternate OFA system designs, with regard to port size, quantity, placement, and design.¹² High grid resolutions near the burners and OFA ports enable more accurate assessment of reactions and flow fields, but require larger model size and computational resources. Validation of model predictions to field experience is essential. Ultimately, supply of equipment with on-line adjustability provides the means to tune the OFA system to the actual conditions and minimize emissions in the field.

The Dual Zone NO_x port (Fig. 15) provides the means to vary on-line the jet penetration versus dispersion characteristics of OFA supplied through this port. A sliding sleeve damper with linear actuator provides the means to regulate OFA to each port. This enables varying OFA among the various ports to improve distribution, and to vary OFA versus load for NO_x control. A relative indication of air flow is provided locally at each port by a pitot grid installed inside the port. The inner zone of the Dual Zone port is comprised of a core pipe with a manually adjustable sliding disk to adjust air flow. The core pipe produces a high velocity air jet for penetration across the furnace. The outer zone of the port is equipped with spin vanes. Increasing the swirl of this air causes more localized mixing by entraining furnace gases in the recirculation. The vanes can be manually adjusted to vary swirl over a wide range. The combination of these adjustments has a strong effect on mixing rates and emissions. Dual Zone ports, or other types, can be enclosed in windboxes in a manner similar to the burners. In some situations, it is more economical to supply individual air ducts to each port. Performance and repeatability benefit from the inclusion of equipment to

measure and regulate air flow to the OFA system distinctly from flow to the burners.

Maximum NO_x reduction with air staging requires operation at low burner zone stoichiometries, e.g. 0.85 or less. NO_x reformation becomes a problem if all the associated OFA is rapidly reintroduced to the furnace. To avoid this, it is beneficial to employ two levels of OFA. The level closest to the burner zone supplies a lesser portion of the OFA to bring the BZS close to 1.00. This is followed by the second level of OFA which supplies the balance of secondary air. This arrangement reduces peak O₂ levels and moderates combustion rates in the upper furnace to control NO_x, while providing the mixing necessary to limit unburned combustibles.

Most OFA systems draw hot SA from the ducts or plenums which supply air to the burners. Use of pre-heated air supplied from the FD fans through the air heaters helps maintain boiler efficiency, but limits the available static pressure for the OFA system. The location, quantity, size and design of the OFA ports have to be compatible with static pressure constraints. Booster fans can be used to raise static pressure, but can become massive to accommodate the quantities and temperature of OFA involved with many utility boiler applications. Complications with locating such fans, along with their expense and operating costs, detract from their use. Most often the FD fans are suitable as motive sources for proper system design.

OFA with corner-fired systems Overfire air has proven to be very effective in corner-fired boilers and is the dominant method of NO_x control with modern systems.¹³ It is useful to first consider the functionality of the corner-fired combustion system before considering the application of overfire air with such

Fig. 15 Dual Zone NO_x port.

equipment. In a corner-fired system, coal and air are introduced into the furnace at distinct elevations through windbox assemblies located in the corners (for four corner furnaces) and at protrusions midway along the front and rear walls (for eight corner furnaces). The windbox nozzles direct the coal and air streams at slight angles off of the diagonals and tangent to an imaginary firing circle in the center of the furnace as shown in Fig. 16. The combination of the firing angles and momentum of the fuel and air streams create a rotating or cyclonic fireball that fills the plan area of the furnace. In this firing system, the furnace acts like a large burner where each corner provides the ignition energy to the corner downstream and the swirling action of the fireball stabilizes the flames. For steam temperature control at lower loads, the fuel and air nozzles are designed to tilt up or down in unison to raise or lower the fireball and thus increase or decrease furnace exit gas temperatures.

Each windbox is divided along its height into alternating compartments of air and coal as shown in Fig. 17. Each pulverizer serves one complete coal elevation (i.e., all four or eight corners). The windboxes distribute secondary combustion air as fuel air and auxiliary air. Fuel air is the portion of the secondary air admitted to the furnace through the coal compartments and air annulus around each coal nozzle tip and is used to support combustion and stabilize flames. Auxiliary air is the balance of the secondary air which is admitted into the furnace through air nozzles located in the compartments above and below each coal elevation to complete the combustion. Primary air is the balance of air entering through the coal pipes and nozzles and serves in the same manner as in wall-fired burner arrangements. Secondary air is distributed in the windbox by a system of dampers located at the inlet of each compartment as shown. Fuel air dampers are controlled based on pulverizer feed rate whereas auxiliary air dampers are controlled based on windbox to furnace differential pressure. In conventional applications, all of the secondary air enters through the

Fig. 16 Plan view of corner-firing arrangement.

corner windbox assemblies. However, these corner-fired combustion systems embody air staging technology by virtue of the layered introduction of fuel and air. This lowers NO_x by slowing the mixing of air and fuel as they proceed into the flame vortex.

Application of overfire air to a corner-fired system involves diverting a portion of the auxiliary air to an overfire air zone located above the combustion zone. Depending on the required NO_x reduction, OFA can be introduced at the top of the windbox through two or more air compartments and/or through separate ports located some distance above the top coal elevation. Increasing the separation between the combustion zone and the OFA ports reduces NO_x emissions most effectively. Therefore, for a given quantity of OFA, separated OFA is generally twice as effective as windbox OFA for reducing NO_x . Also, since separated OFA ports require new openings in the upper furnace, they can be made larger than windbox overfire air for greater NO_x reduction, as windbox compartment sizes are limited by the existing windbox width and compartment heights.

Approved approach for retrofitting a separated OFA low NO_x system involves the addition of one level of four to ten ports depending on furnace type. For smaller four-corner furnaces, the ports are typically located on furnace corners since adequate coverage

Fig. 17 Corner-fired windbox assembly for coal firing (courtesy of R-V Industries, Inc.).

can be achieved as these furnaces have smaller, more square cross-sections than the larger eight-corner units. Also, ductwork for four-corner units is simpler when the ports are located on the corners. For larger eight-corner furnaces with center division walls, the ports may be located on the front and rear walls. They are arranged in an interlaced fashion from front to rear and offset in the direction of fireball rotation. This effectively reduces NO_x while providing more complete coverage of the furnace plan area and corners for better carbon burnout and CO control. In both furnace types, the ports are located several feet above the highest coal elevation to allow separation distance for effective NO_x control but low enough to allow ample furnace residence time for good carbon burnout after overfire air injection. The location and sizing of ports are also set to avoid or minimize buckstay modifications when possible. If necessary, computer modeling serves to optimize port arrangement and performance.

The typical B&W separated OFA port for corner firing shown in Fig. 18 uses an all welded (no refractory), deep throat, perpendicular opening to cool the air nozzles from the intense radiant heat in the OFA zone. The port normally has two air compartments with integral turning vanes and independent flow control dampers to maximize velocity and penetration over the load range. The air nozzles can be manually tilted and/or yawed on line for enhanced emissions control. A small pitot tube grid is located near the inlet of each nozzle for relative air flow indication and balancing.

Addition of an OFA system reduces secondary air flow to the main windbox. To compensate for this, the existing auxiliary air compartment and damper sizes are reduced using blocking plates and the auxiliary air nozzles are replaced with smaller ones. These modifications are required to maintain existing injection velocity, pressure drop and thus, damper controllability over the load range. Adding only OFA has proven to be the most cost effective and reliable combustion system modification for reducing NO_x emissions in corner-fired boilers.

Fig. 18 Corner-fired overfire air port (courtesy of R-V Industries, Inc.).

NO_x reduction for units with only windbox overfire air typically ranges from 20 to 30%. For additional NO_x reduction, separated OFA can be added to units with or without windbox overfire air. NO_x reduction with these arrangements typically ranges from 40 to 60%, depending on initial NO_x levels, boiler size, furnace type, heat release rate, separation distance and coal reactivity.

Typical of other air staged systems, NO_x reduction on corner-fired units may be accompanied by some increase in CO emissions and unburned carbon. However, with careful system design and field tuning, existing CO emissions can normally be maintained with reasonable unburned carbon (UBC) results.

Burners for difficult coals

A few coals have proven to be considerably more difficult to burn than others, including unreactive coals and reactive coals which would burn readily except for an overabundance of moisture and/or ash. B&W has developed burners specifically for use with these problem coals. The selection of burner type is based on an empirical ignition factor derived from full scale experience with difficult coals. This factor relates variations in fuel ratio (FC/VM), moisture content, ash content, and coal heating value to ignition behavior. Burner choices for these applications include conventional and low NO_x burners discussed above, the enhanced ignition (EI) burner, and the primary air exchange (PAX) burner.

Enhanced ignition burner

The enhanced ignition (EI) burner resembles the DRB-XCL burner. The nozzle is equipped with a conical diffuser which concentrates the coal particles into a fuel-rich ring near the walls of the fuel nozzle. However, the EI burner uses a larger coal nozzle tip to reduce the primary air and coal mixture velocity as it enters the furnace. In addition, the dimensions of the inner and outer air zones are adjusted relative to the DRB-XCL burner to produce greater recirculation of hot gases along the fuel jet. These hot gases accelerate ignition of the dense, low velocity fuel jet and significantly improve burner flame stability. The EI burner is well suited for firing high moisture (>35%) lignites and low volatile bituminous coal.

Primary air exchange burner

The primary air exchange (PAX) burner is designed to fire anthracite and similar coals. Some anthracites can be wall-fired conventionally with the PAX burner, while those lowest in volatile matter must be fired in a downshot arrangement (Fig. 5). The design of the air zones for the PAX burner is similar to that of the EI burner. However, in the case of downshot firing, air staging ports direct air away from the burner to better sequence air supply with the slower burning nature of these coals, thus elevating flame temperature.

The anthracite fineness is increased to 90% (or even higher) through 200 mesh to help accelerate ignition and to reduce unburned carbon. In addition, mill exit temperature is increased to the maximum for the pul-

verizer, often limited to 200F (93C) for mechanical reasons. Tests have shown the benefit of higher temperatures on ignition performance. The PAX burner raises the primary air and pulverized coal (PA/PC) temperature by a patented design which separates half of the primary air from the PA/PC mixture and vents it into the furnace. This primary air is replaced by secondary air near 700F (371C), significantly raising fuel temperature as it enters the furnace. In some situations, indirect firing systems are used for firing anthracite. Pulverized coal from the storage bin can be transferred to the burners with hot secondary air to provide a hot, dense fuel mixture. In either case, the PAX nozzle tip is sized for low velocity to further assist ignition. Even with these techniques, good combustion is dependent upon high furnace temperatures. Low load operation still requires igniters for flame stabilization.

Unburned combustibles

Unburned carbon (UBC) in solid form, as distinguished from partially oxidized carbon in gaseous form (CO), results to varying degrees from all pulverized coal systems. Unburned combustibles represent an efficiency loss to the process which can vary from 0.05% for lignite, to 0.5% for bituminous coal, and to 5.0% or higher for anthracite. These order of magnitude variations are largely a consequence of inherent differences in coal reactivity. Variations around these values can occur due to gradients in coal reactivity, variations in coal fineness, and variations in how oxygen is made available to the coal during the combustion process.

Fineness

Given a coal of lesser reactivity, one of the most effective techniques to lower UBC is to reduce the quantity of coarse coal particles from the pulverizers. Pulverizer power is dependent on the mean particle size, which is heavily influenced by the fine particles. Therefore, the most efficient means of reducing UBC is to selectively reduce the coarse particles without over-grinding the fine particles. Advanced pulverizer classifiers, especially dynamic versions, can essentially eliminate the large 50 mesh particles and sharply reduce the 100 mesh fraction, with little change to the dominant smaller 200 mesh size. Such fineness improvements have accomplished significant reductions in UBC with bituminous and higher rank coals.

Oxygen availability

The influence of oxygen availability on carbon burnout depends on each coal particle's history regarding O₂ concentration, and the corresponding temperature and time exposures. Global factors include the excess air level for the process, rate and uniformity of air-fuel mixing, and residence time. Increasing excess air increases overall oxygen availability and reduces UBC, but with some offset in boiler efficiency due to increased dry gas loss. Increasing excess air also raises NO_x, placing further constraint on this countermeasure. Air infiltration to a boiler tends to indirectly increase unburned combustibles. Balanced draft units

actually operate under a small vacuum which draws air into the boiler through cracks, tears, and miscellaneous openings in the structure. This air can enter the process once gases have cooled and it does not mix well, such that it provides little or no benefit to combustion. However it is measured as excess air by instruments located at the boiler outlet, which in turn cause reduction in air to the combustion equipment to maintain the target excess O₂. Inadequate excess air to the combustion equipment then causes UBC and CO to increase. Thus, minimizing air infiltration is important for controlling unburned combustibles.

Air/fuel imbalances

Air/fuel ratio and mixing rates are a consequence of many factors and vary considerably even within a given furnace. Fuel imbalance can occur because of variations in raw coal feed rate to the multiple pulverizers.

Another aspect of fuel imbalance concerns non-uniformities in coal distribution among the multiple burners on a furnace. Techniques for measuring burner line coal distribution have expanded, but retain a level of uncertainty and can be time consuming and expensive. This complicates implementing and verifying the effectiveness of corrective measures. Burner line restrictors are a proven method of improving coal pipe fuel distribution, but new techniques are under development to correct fuel distribution exiting the pulverizers. Air imbalances among burners can act to magnify air/fuel imbalances. Many modern burners are equipped with air measuring and adjustment hardware to correct this. Air-fuel mixing rates are directly influenced by interactions induced by the burners and OFA (if so equipped), and consequential flow patterns in the furnace. Adjustments which increase mixing rates will tend to reduce UBC while increasing NO_x.

Residence time

Furnace residence times combined with oxygen availability, thermal environment, and coal reactivity ultimately control unburned combustibles. Full load furnace residence times can vary from 1 to 3 seconds depending on burner location, furnace geometry, and operating conditions. Adding an OFA system to an existing furnace further reduces the residence time for final carbon burnout. Increased air-fuel mixing rates can help compensate for marginal residence time and reduce UBC and CO, but with some increase in NO_x.

Gaseous losses

CO emissions result from insufficient oxygen and/or temperature to complete combustion. Localized or global air deficiency and flame quenching are common causes for CO emissions in practical systems. Air/fuel balance is difficult to maintain over all combustion conditions. Combustion tuning, to some degree, involves compensating for errors. Fuel excesses from one burner are offset by air excesses on another. Changes in firing conditions, inevitable with different combinations of pulverizers/burners in service, cause shifts in air-fuel distribution with resultant increases in CO.

Advanced techniques

New diagnostic tools and control systems are providing improved means to reduce unburned combustibles while maintaining low NO_x emissions. Flame diagnostic equipment such as the Flame Doctor® system use non-linear analysis (chaos theory) to provide a means to better tune individual burners. Diagnostic instrumentation in the upper furnace or boiler outlet can more accurately assess excess air and emission levels, and identify localized areas with high emissions. Automated flow control devices on the burners and OFA ports enable adjustments with conventional or neural network control systems to dynamically minimize emissions.

Auxiliary equipment

Oil/gas firing equipment

In some cases, PC-fired furnaces are required to burn fuel oil or natural gas up to full load firing rates. These fuels can be used when the PC system is not available for use early in the life of the unit, due to an interruption in coal supply, or as a NO_x control strategy. Some operators avoid installing a spare pulverizer by firing oil or gas when a mill is out of service.

To fire oil, an atomizer is installed axially in the burner nozzle. Erosion protection for the atomizer is recommended. A source of air is needed when firing oil or gas to purge the nozzle and improve combustion. This air system must be sealed off prior to PC firing. Steam-assisted atomizers are recommended for best performance.

Gas elements of several designs can be used in PC-fired burners. These include designs with manifolds which supply multiple elements in the air zone, or single element designs mounted axially in the coal nozzle. Gas manifolds can be located inside or outside of the windbox. Installation in the windbox clears the burner front of considerable hardware but prevents on-line adjustment or repair of gas elements. External manifolds are more complex, but enable rotational adjustment or replacement of the gas injection spuds. On-line adjustability is very useful for optimizing emissions and to counteract any tendency toward burner rumble. A single axial high capacity gas element (HCGE) in the coal nozzle offers the most effective NO_x control in use with advanced low NO_x PC-fired burners. The HCGE (see Chapter 11) has to be inserted for operation and has to be retracted and supplied with seal air when out of service. Regardless of gas element type, the issue of compatibility with the combustion system has to be considered. Retrofit of gas or oil elements increases the forced draft fan load in many cases. Primary air is eliminated which results in higher quantities of secondary air compared to PC firing. As a result, fan flow and static margins need to be considered.

See Chapter 11 for more information on oil and gas firing equipment.

Igniters

An igniter is required to initiate combustion as pulverized coal is first introduced to the burner, as the burners are being normally shut down, and as otherwise required for flame stability. Additionally, the igniters may be used to warm the furnace and combustion air prior to starting the first pulverizer. In some cases they are used to synchronize the turbine prior to firing coal. Igniters typically use a High Energy Ignition spark system to ignite the fuel, which is usually natural gas or No. 2 fuel oil. Igniters on utility boilers and most large industrial boilers are operated with an input capacity of approximately 10% or more of the main PC-fired burner. Such igniters are categorized by NFPA (National Fire Protection Association) as Class I. The use of Class I igniters reduces the complexity of the flame detection system and permits operation of the igniters as desired under any boiler conditions. Modern boilers have automated controls to start, operate, purge, and shut down the igniters from the control room. (See also Chapter 11.)

Flame safety system

Modern PC-fired boilers are equipped with a flame safety system (FSS). The FSS uses one or more flame scanners at each burner to continuously monitor flame conditions electronically. The flame scanners are used to evaluate several characteristics of the igniter and/or main flames. The lack of satisfactory flame signals causes the FSS to automatically initiate actions to prevent hazardous operation of the burner and boiler. The specific actions taken by the FSS can vary with the boiler design, boiler load, fuel in service, and the status of the igniters in a burner group. The steps taken, and their sequence, are designed to prevent unburned fuel from entering the furnace and avoid large swings in the total furnace fuel-to-air ratio, thereby significantly reducing the risk of an explosion.

Safety and operation

Uncontrolled ignition of pulverized coal may result in an explosion which can severely harm personnel and destroy equipment. Explosions result from ignition of an accumulated combustible mixture within the furnace or associated boiler passes, ducts, and fans. The magnitude and intensity of the explosion depend on the quantity of accumulated combustibles and the air-fuel mixture at ignition. Explosions result from improper operation, design, or malfunction of the combustion system or controls. The National Fire Protection Association (NFPA) publishes codes to address these concerns. These have been consolidated into the NFPA 85 Boiler and Combustion Systems Hazards Code, which is periodically updated.¹⁴ This serves as an excellent source of information concerning design and equipment issues, operation and control of PC-fired equipment.

Another key source of information is the operating instructions. Operators of PC-fired equipment should

expect the instructions to provide specific information concerning the purpose, design, calibration and adjustment, startup, operation and shutdown of the various equipment. The instructions should also provide maintenance and troubleshooting information.

Other PC applications

Pulverized coal in metal and cement industries

The application of pulverized coal firing to copper and nickel-ore smelting and refining has been standard practice for many years. With the use of pulverized coal, high purity metal can be obtained because the furnace atmosphere and temperature can be easily controlled. Pulverized coal may be favored over other fuels for several reasons: it may be less expensive, it offers a high rate of smelting and refining, and it readily oxidizes sulfur.

Copper reverberatory furnaces for smelting and refining are fitted with waste heat boilers for steam generation. These boilers supply a substantial portion of power for auxiliary equipment and also provide the means for cooling the gases leaving the furnace.

In producing cement, the fuel cost is a major expense item. Except in locations where the cost favors oil or gas, pulverized coal is widely used in the industry. Direct firing, with a single pulverizer delivering coal to a single burner, is common practice in the majority of U.S. cement plants. The waste heat air from the clinker cooler, taken from the top of the kiln hood through a dust collector, usually serves as the preheated air for drying the coal in the pulverizer.

Pulverized coal is being applied effectively in the steel industry where it is injected into the blast furnace tuyères. The pulverized coal replaces a similar weight of higher priced coke. Theoretically, 40% of the coke could be replaced by pulverized coal.

Chapter 15

Cyclone™ Furnaces

The Babcock & Wilcox Company (B&W) developed the Cyclone™ furnace concept in the 1940s to burn coal grades that are not well suited for pulverized coal (PC) combustion. The ash from these coals has a low melting (fusion) temperature and would enter the superheaters of PC units in a molten state, creating severe slagging.

The Cyclone furnace was originally designed to take advantage of:

1. lower fuel preparation capital and operating costs (crushers only),
2. a smaller furnace, and
3. less flyash and convection pass fouling (15 to 30% of the fuel ash enters the convection pass instead of 80% for PC firing).

Cyclone furnace arrangement and basic operation

As shown in Fig. 1 and the facing page illustration, the Cyclone furnace consists of a horizontal cylindrical barrel 6 to 10 ft (1.8 to 3.0 m) in diameter, attached to the side of the boiler furnace. The Cyclone barrel is of water-cooled tangent tube construction. Inside the Cyclone barrel, short pin studs are welded to the outside surface of the tubes in a very dense pattern. A refractory lining material is installed in between the studs. This insulation maintains the Cyclone at a high enough temperature to permit adequate slag tapping from the bottom of the unit and significantly reduces the potential for corrosion.

Crushed coal and some air (primary and tertiary) enter the Cyclone through specially designed burners on the front of the Cyclone. In the main Cyclone barrel, a swirling motion is created by the tangential addition of the secondary air in the upper Cyclone barrel wall. A unique combustion pattern and circulating gas flow structure result (discussed below). The products of combustion eventually leave the Cyclone furnace through the re-entrant throat. A molten slag layer develops and coats the inside surface of the Cyclone barrel. The slag drains to the bottom of the Cyclone and is discharged through the slag tap.

Principles of operation

To understand the Cyclone concept, the basics of solid fuel combustion must first be considered, particularly as they relate to PC firing. During coal combus-

tion in a boiler furnace, the volatiles burn without difficulty; however, combustion of the fuel carbon char particles requires special measures that ensure a continuing supply of oxygen to unburned carbon particles. A thorough mixing of coal particles and air must occur with sufficient turbulence to remove combustion products and to provide fresh air at the particle surface.

PC firing achieves these requirements by reducing the coal to a very fine powder, nominally 70% of which passes through a 200 mesh (74 micron) screen. This powder then mixes with the turbulent combustion air. After this initial phase, the small particles are carried in the air stream with much less mixing. Without the

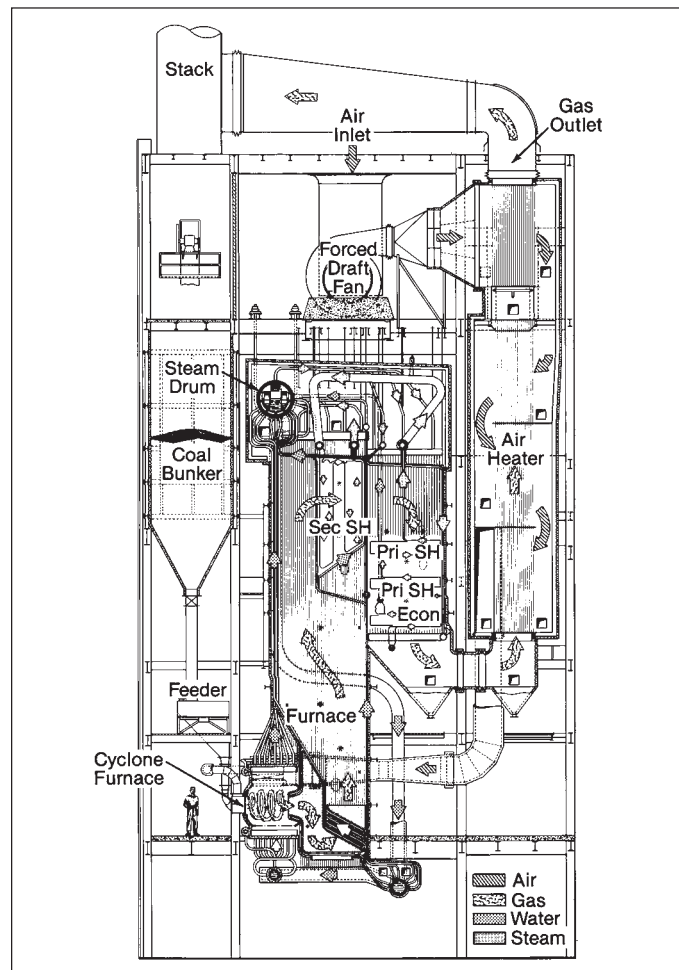

Fig. 1 Cyclone™ furnace boiler showing air, flue gas, water and steam flows.

continued rapid mixing action, the coal particulate combustion must be completed through diffusion of the oxygen and combustion products around the particle. The relatively large PC furnace provides sufficient residence time for oxygen to penetrate the combustion product's blanket around the particles as well as cooling of the ash to minimize convection pass fouling.

The Cyclone furnace, on the other hand, fires relatively large crushed coal particles of which approximately 95% pass through a 4 mesh screen (nominal 0.187 in. or 4.75 mm) and is dependent upon the fuel type being fired. Fuel of this size is too large to burn completely in suspension and would pass through the PC-fired boiler without burning all of the carbon. Therefore, the large particles must be retained in place with the air passing over the particle (air scrubbing) for complete combustion to occur. The Cyclone furnace accomplishes this by forming a molten sticky slag layer which captures and holds the heavier particles. While the large particles are trapped in the slag layer, the volatiles and fine coal particles (recommended at about 10+% passing 200 mesh) burn in suspension providing the intense radiant heat required for slag layer combustion. Ideally, all of the large coal particles become trapped in the molten slag where they complete carbon burnout, leaving behind ash to replenish the slag layer.

With most of the combustion occurring in the confines of the Cyclone furnace, the main boiler furnace can be relatively small compared to a pulverized coal furnace design.

Cyclone combustion

In the Cyclone, fuel is fired at high heat inputs and under very turbulent operating conditions to maximize combustion efficiency. Injecting the main combustion air tangentially at high velocities creates a swirling motion which throws the large coal particles against the Cyclone inside surface, where they are trapped in the slag layer and burn to completion. The hot gases then exit through the Cyclone core and depart through the re-entrant throat into the main boiler furnace.

Air distribution

The cyclonic gas flow does not follow a simple corkscrew path from entry to exit. (See Fig. 2.) The main combustion air (*secondary air*) enters the Cyclone furnace tangentially at high velocity and passes along the Cyclone periphery, also known as the *recirculation zone*. In this zone, the air-gas flow along the chamber is away from the exit opening and toward the burner, pulled along by the vortex vacuum created near the burner end of the Cyclone. Closer to the center of the Cyclone, the general gas flow is toward the exit (re-entrant throat). Eventually, the hot combustion gases flow from the recirculation zone to the Cyclone core, known as the *vortex*. Once in the vortex, the gases and particulate are immediately pulled out of the Cyclone and into the main furnace. The fuel residence time in the recirculation zone is affected directly by the velocity of the secondary air and inversely by the size of the re-entrant throat opening.

The balance of the combustion air is admitted as primary and sometimes tertiary air as discussed be-

low. The air injection locations are identified in Fig. 2 and later in Fig. 5.

The *primary* air enters the burner tangentially in the same rotational direction as the secondary air, carrying the coal into the Cyclone. This primary air controls the coal distribution within the main Cyclone chamber. For optimized operation, the primary air is typically minimized to avoid throwing the raw coal too deep or near the vortex, but must not be set so low as to create a fuel buildup near or in the burner. Adequate velocity must be maintained to allow for proper coal distribution into the cyclone.

The *tertiary* air enters the center of the burner along the Cyclone axis, directly into the Cyclone vortex. It helps keep the cyclone burner door cool and controls the vortex vacuum which consequently determines the position of the main combustion zone, the primary source of radiant heat. As a negative effect, too high an amount of tertiary air reduces the vortex vacuum at the burner, allowing the main combustion zone to move deeper into the Cyclone toward the re-entrant throat and main boiler furnace.

Heat rates

Within the Cyclone, the fuel burns at a heat release rate of 450,000 to 800,000 Btu/h ft³ (4.66 to 8.28 MW_t/m³), developing gas temperatures of more than 3000F (1649C). Heat absorption rates by the water-cooled walls are relatively low as the unit has a relatively small surface protected by a refractory coating – 40,000 to 80,000 Btu/h ft³ (414 to 828 kW/m³). The high heat release and low heat absorption rates combine to ensure the very high temperatures needed to complete the combustion and maintain the slag layer in a molten state. The high temperature and high heat release rate characteristics of Cyclone firing also provide the conditions to produce very high uncontrolled nitrogen oxides (NO_x) emission levels. The Cyclone furnace traps and burns only as much coal as it can handle. The excess passes into the main furnace and boiler back-end as unburned carbon carryover. During overfiring, long term corrosion and/or erosion with associated tube deterioration could occur in the Cyclone and/or lower furnace regions. In addition, overfiring may cause problems in the main furnace,

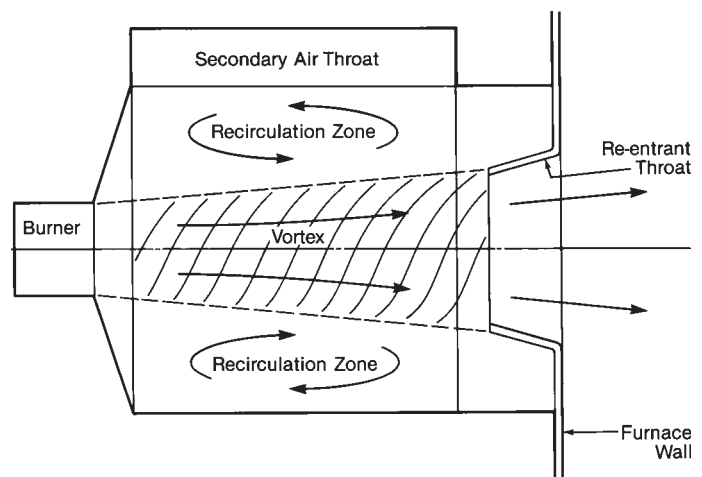

Fig. 2 Cyclone furnace gas recirculation pattern.

convection pass, economizer, and other downstream equipment components.

Slag layer

The intense radiant heat and high temperatures melt the ash into a liquid slag coating which covers the entire Cyclone interior surface except for the area immediately in front of the secondary air opening. The unit's refractory lining further assists this molten condition by limiting heat absorption to the water-cooled walls. The slag coating is kept hot and fluid by combustion and flows constantly from the Cyclone into the main furnace, where it drains through a floor tap opening into a water-filled tank. The slag layer must be constantly replenished by the ash from incoming coal. For this reason, bituminous coals fired in Cyclones need a minimum of 6% ash (dry basis); subbituminous coals must contain at least 4% ash (dry basis).

Optimal combustion conditions are generally achieved when excess air is maintained at about 10 to 13% at the Cyclone. Cyclone operating temperatures tend to decline at higher excess air levels. In addition, the adiabatic flame temperatures within the Cyclone will actually be higher at near theoretical air operating conditions.

A primary indicator of Cyclone combustion temperature is the slag temperature at the slag tap. Slag temperature is a function of radiant heat input to the Cyclone. The degree of radiant heat input indicates the portion of the combustion occurring within the Cyclone. Relative slag temperatures can be monitored with an optical or ultraviolet pyrometer from the furnace side ports or by sighting through an inactive Cyclone on opposed wall-fired units. Although the traditional method of aiming a pyrometer through the Cyclone front observation port has not proven to be as effective, new techniques are being investigated using existing scanners and/or other equipment viewing from the Cyclone front to help evaluate performance.

Under ideal combustion conditions, the Cyclone can capture approximately 70 to 75% of the original fuel ash as slag and drain it to the furnace for disposal in the slag tank. (See Fig. 3.) Smaller boilers can retain more of the ash by capturing additional quantities on the walls and screen tubes. Other details of the Cyclone furnace and boiler arrangements are discussed under *Design features*.

Suitable fuels

The Cyclone furnace can handle a wide range of coals from low volatile bituminous to lignite, depending on the fuel preparation and delivery system. Cyclones have also successfully co-fired solid waste fuels such as wood chips, sawdust, bark, coal chars, refuse-derived fuel (RDF), petroleum coke, paper and sewage sludge, and tire-derived fuel (TDF). Fuel oils or gases (natural gas, coke oven gas, and others) can be burned in Cyclone furnaces as the primary, contingency or startup fuel.

On a continuous basis, the Cyclone must fire either a solid fuel or a liquid/gaseous fuel. Long term firing of oil or gas should only be pursued in a bare tube

Fig. 3 Comparison of ash distribution from a large Cyclone furnace unit and typical pulverized coal unit.

Cyclone because these fuels can destroy the refractory lining. The resulting loose slag and/or refractory debris would severely erode the tubing, leading to eventual pressure part failure. Cyclones switching from coal to oil or gas for an extended period should have all refractory within the cyclone removed, the slag tap direction reversed and all air ducts cleaned. The pin studding can remain, although a study should be performed to evaluate the change in magnitude on heat absorption profiles. When switching back to coal, the refractory must be reinstalled and the slag tap must be set in the correct direction.

Fuel criteria

Coals and co-fired fuels (solid or otherwise) must be evaluated against several criteria. Volatiles must be higher than 15% on a dry basis to ensure stable combustion within the Cyclone. The ash content must be at least 6% for bituminous coals or 4% for subbituminous coals, but should not exceed about 25% on a dry basis. Higher ash content fuels require special considerations. With low ash coals, the proper slag coating can not be developed, nor can it be maintained. Thin, low viscosity slag coatings do not protect the refractory. To compensate for this condition, the slag can be thickened by increasing excess air and reducing the Cyclone combustion temperature if other operating conditions permit.

The moisture content for standard bituminous coal firing Cyclones should not exceed approximately 20%. Higher moisture content requires better crushing and higher secondary air temperatures to dry the fuel for

proper combustion. For subbituminous coals with moisture contents typically in the 25 to 30% region, other Cyclone modifications including reduced sized, tight gap re-entrant throats and segmented secondary air velocity dampers are required to maintain good Cyclone operating conditions. Improved coal fineness operation is also imperative to achieve good Cyclone combustion when firing subbituminous coals. Particularly high moisture fuels may require the pre-dry system used on lignite-fired Cyclone-equipped boilers.

Operating experience demonstrates that coal ash has a tendency to concentrate iron, initiate slag tapping problems, and/or result in a corrosive iron sulfide attack on the refractory and Cyclone furnace. This can be evaluated by comparing the total amount of sulfur to the iron/calcium and iron/magnesium ratios. (See Fig. 4.) Frozen iron puddles found on the Cyclone or furnace floor during outages provide an indication of the magnitude of the potential problems.

Slag viscosity factor – T_{250} value The most important evaluation consideration for Cyclone coals is the slag viscosity characteristic or T_{250} value. This ultimately separates coals into categories suitable and unsuitable for Cyclone operation. The T_{250} value denotes the temperature at which the coal slag has a viscosity of 250 poise. At this viscosity the slag flows on a horizontal surface. A slag with a higher viscosity would fail to flow steadily from the Cyclone and main furnace and would be too stiff to trap the unburned coal particles for proper combustion. The currently recommended maximum T_{250} value for all Cyclone bituminous coals is 2450F (1343C). With the advent of increasing low sulfur subbituminous coal use in the 1990s, B&W established a T_{250} limit of 2300F (1260C) for subbituminous coals fired in standard Cyclones. This value compensates for the effect of increased coal moisture on Cyclone combustion temperatures.

The preferred method of establishing the T_{250} value is by experimental measurements on actual fuel ash samples. However, due to the large database accumulated from past testing, the T_{250} value can also be estimated based upon calculations using the coal mineral ash analysis. (See Chapter 10.)

Fig. 4 Coal suitability for Cyclone furnaces based on tendency to form iron and iron sulfide.

For some coals and/or other solid fuels, the T_{250} value of the slag can be lowered by altering its ash base to acid (B/A) constituent ratio (discussed in Chapter 21) through the addition of a fluxing agent (e.g. limestone, dolomite, etc.). Although B&W does not generally recommend this approach, sometimes it is the only alternative to improve operation. Fluxing system design considerations must incorporate the capability to accurately, uniformly, and continuously distribute the flux material with the fuel stream.

If a Cyclone unit must burn high fusion temperature fuel, the best approach is to adjust the T_{250} value by blending in a different coal or solid fuel; however, this usually represents higher fuel handling costs. Both fuel blending and fluxing create concerns with maintaining acceptable consistency.

Co-fired fuels must be evaluated on an individual basis with emphasis placed on the resulting ash content as a percentage of the total heat input.

The general characteristics of coals suitable for Cyclone furnace firing are summarized in Table 1.

Cyclone coal burner types

In the United States (U.S.), Cyclone furnaces have been equipped with three primary coal burner types – scroll, vortex and radial (two sub-types), as shown in Fig. 5. All types inject coal from the front end of the Cyclone and impart a swirl to the crushed coal in the same rotation as the secondary (main) combustion air. To protect the burner coal inlet from excessive erosion, all utilize a protective wear liner known as the *wear blocks*. The material used for these blocks is normally comprised of metal, ceramic, or a combination of the two. Finally, the burners are normally kept cool with the addition of a water-cooled jacket on the burner door and the burner scroll. The main purpose of the cooling jacket is personnel protection along with reducing the operating temperatures of the burner itself. Since untreated water is normally used for the cooling media, corrosion and pluggage can be encountered with time. Although not normally recommended, this water cooling capability has been removed by some

Table 1
Summary of Cyclone Furnace Coal Suitability

Ash	Bituminous — minimum	> 6% dry basis
	Subbituminous — minimum	> 4% dry basis
	Maximum	< 25% dry basis
Moisture	Bin firing system (Bit.)	< 20% as-fired
	Direct firing system (Subb.)	< 30% as-fired
	Pre-dry firing system	< 42% as-fired
Volatile		> 15% dry basis
T_{250}	Bituminous	< 2450F (1343C)
	Subbituminous	< 2300F (1260C)
Coal type		Bituminous Subbituminous Lignite
Coal ash iron/sulfur tendencies		See Fig. 4

operators. If this is done, the burner material should be upgraded and insulation should be applied over the burner to provide personnel protection.

The *scroll* burner, which was used in the first Cyclones, combines the primary air and coal at the feeder outlet and injects the mixture into the Cyclone in a cone shaped distribution pattern. Tertiary air, admitted at the center of the burner, controls the position of the main flame within the Cyclone. However, this

injection pattern resulted in a high concentration of recirculating coal particles around the burner outlet, leading to heavy burner wear-block erosion. The premixing of primary air and coal required the addition of a rotary seal to protect the feeder from backflow of hot combustion air. Later scroll burner applications eliminated the rotary valve by using a higher head of coal at the feeder inlet to prevent hot air backflow into the feeder and coal bunker.

The *vortex* burner eliminated the rotary seal by feeding coal and primary air to the burner separately. The primary air entered the Cyclone burner tangentially as with the scroll design, but the coal is gravity fed (along with feeder seal air) into the backside of the burner. Although this configuration eliminated the tertiary air, adjusting feeder seal air has the same effect on the Cyclone vortex zone. The vortex burner produced a similar cone shaped injection pattern as the scroll model. Advanced ceramic wear blocks and a new burner door/coal inlet design have significantly reduced erosion problems encountered with earlier designs.

The development of the *radial* burner eliminated the severe wear-block erosion. Like the vortex burner, the radial version does not combine coal and primary air until both enter the burner chamber. However, on a radial burner the coal is introduced tangentially in the same rotation as the primary air. The coal particles form a long rope (concentrated stream of coal) as they are swept across the burner wear blocks and enter the Cyclone. This approach greatly reduces the concentration of coal recirculating around the burner, effectively reducing wear-block erosion. Similar to the scroll burner, tertiary air is admitted using the same axial entry location.

A newer *thin door* radial burner version with the option to eliminate tertiary air (and/or redirect how it is introduced) has been offered since the late 1990s. The benefits of this design are the potential to minimize and/or eliminate tertiary air without adversely affecting performance, an improved range of view within the cyclone, and an overall smaller, easier to open door.

The radial burner remains the modern standard for coal-fired Cyclones. The scroll burner is utilized on modern lignite-fired Cyclone units because the pre-dry system requires mixing of the primary air and coal during coal preparation, prior to the burner inlet. (See later discussion.) As the scroll, vortex and radial type burners have slightly different coal inlet locations, switching from one burner to another requires a change in the coal handling system.

Design features

Boiler furnace

Commercial Cyclone furnaces have been built in sizes ranging from 6 to 10 ft (1.8 to 3 m) in diameter, with standard maximum heat inputs ranging from 150 to 425×10^6 Btu/h (44 to 124.6 MW_t), respectively. Higher Cyclone heat inputs under peaking conditions are feasible with the existing equipment, but at the cost of various operational concerns (such as higher

unburned carbon in the flyash, higher particulate loadings, increased maintenance, etc.). New larger diameter, higher capacity Cyclone designs are feasible and could be incorporated if the additional capital costs associated with such an overall retrofit can be justified versus the associated increased boiler/turbine output.

As illustrated in Fig. 6, the Cyclone furnace has been used on three general boiler arrangements – single wall firing with screen, open furnace single wall firing, and opposed wall firing. Full boiler drawings are provided in Figs. 1, 7 and 8, respectively. Boiler and Cyclone furnace arrangements have ranged from one 6 ft (1.8 m) Cyclone on a single wall unit to twenty-three 10 ft (3 m) Cyclones on an 1150 MW opposed wall unit. In all cases, the main furnace is relatively small to maintain furnace temperature over the furnace floor slag taps and to promote slag flow on the furnace walls. The lower furnace chamber also contains a protective refractory lining held in place by thousands of pin studs which are welded to the tubes. Generally, the Cyclone boiler can be operated continuously down to about 50% of total capacity. Below this point the slag freezes on the furnace floor and plugs the floor taps. Many units have been equipped with larger floor slag taps to improve slag removal.

Coal preparation

The Cyclone equipped boilers feature three fuel delivery systems – bin, direct-fired, and direct-fired with pre-drying configurations. (See Fig. 9.) The bin system, the simplest, least expensive and most common, uses a pair of large crushers in a central location to prepare the coal for overhead storage bunkers (bins). Because the Cyclone-required crushed coal has a relatively large particle size, the storage hazards as compared with pulverized coal systems are lessened, but not eliminated. Adequate venting to remove freshly released combustible gases from the crushed coal systems must still be maintained along with all associated dust control systems. Safety requirements are imperative for low rank, high volatile coals. With the

Fig. 6 Selected firing arrangements for Cyclone furnaces.

bin system, a short crusher outage does not interrupt boiler operations. An existing bin system can be upgraded to fire high moisture coals by converting the coal piping into a simple pre-dry system (see Fig. 9).

The direct-fired system uses a smaller separate crusher, sometimes called a coal conditioner, between the coal feeder and burner on each individual Cyclone furnace. These crushers are swept by hot air which removes moisture from the freshly crushed coal. This produces an advantage by improving crusher performance and fuel ignition when firing coals with a moisture content up to 30%. The direct-fired system has also been used where the existing plant layout could not accommodate the bin system.

The direct-fired with pre-dry system represents the Cyclone fuel preparation system for firing lignite and other high moisture coals. In addition to the hot air-swept individual crushers, this system can also include crusher classifiers and mechanical cyclone moisture separators. The classifiers increase the coal fineness which results in more moisture extraction and better

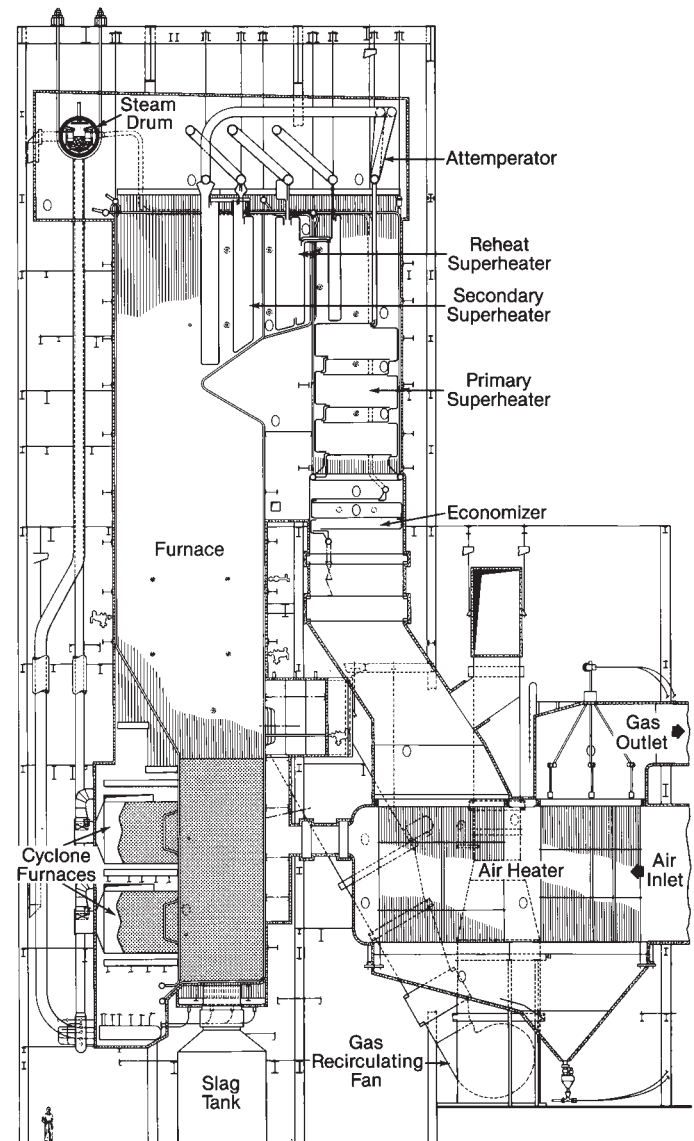

Fig. 7 Radiant boiler with Cyclone furnaces (one wall) and bin system for coal preparation and feeding.

combustion. The mechanical cyclone separators remove the moisture and fines from the coal-air mixture and vent the mixture directly to the boiler furnace through the gas recirculation plenum area. The exclusion of moisture from the main coal increases Cyclone combustion temperatures and subsequently enhances slag tapping. With moisture separators, this system, designed for lignites with moisture higher than 36%, handles poor Cyclone quality, low sulfur coals as easily as standard bin system Cyclones fire high grade bituminous coal.

The preferred coal size distribution for various coal grades is shown in Fig. 10. With high moisture, high ash

fusion or other difficult-firing coals, every attempt should be made to produce the highest percentage of coal fines.

Coal feeders

A number of different feeders have been used with Cyclones since their inception. Early units had small table type feeders, followed by drag types, then volumetric belt types and now gravimetric belt types, some of which have been upgraded with microprocessor controls. With the introduction of each model, the control and continuity of the coal flow improved.

The preferred feeder type today is the gravimetric (weighing) type with a microprocessor control upgrade.

Fig. 8 Universal Pressure (UP®) boiler with opposed-wall Cyclone furnaces and bin system for coal preparation and feeding.

Fig. 9 Bin, direct-fired, and pre-drying bypass systems for coal preparation and feeding to a Cyclone furnace.

Accurate fuel-air control is needed to optimize Cyclone performance, requiring a modern gravimetric feeder.

Slag handling equipment

Cyclone boilers feature a batch removal system for disposing of slag after it is discharged from the main furnace. (See Fig. 11.) The molten slag continuously flows through the furnace floor tap and into a tank beneath the floor where it is quenched and solidified in a water bath. At intervals, the accumulated slag is broken down by a clinker grinder and removed in batches. However, combustible gases can build up at the top of the tank. Similarly, a plugged or partially closed furnace floor tap can result in carbon monoxide accumulation. Both potentially hazardous situa-

Fig. 10 Crushed coal sizing requirements for Cyclone furnaces.

tions could be generally reduced by installing and properly maintaining a flue gas vent line on top of the slag tank. The main purpose of the slag tank vent line is to maintain a positive flow of hot furnace gases through the floor tap, which reduces the potential of the tap from plugging, especially at low boiler loads. The vent typically either runs from the top of the tank to the boiler economizer or to an aspirator which utilizes windbox air to vent the flow into the furnace.

Oil and gas burners

Although coal is the primary Cyclone fuel, oil and gas have been used as startup, auxiliary and main fuels using the combustion system shown in Fig. 12.

Originally, the oil burner could either be a simple transverse pipe across the secondary air inlet or a single oil gun through the coal burner door. The transverse pipe burner, or *roof burner*, has a single row of radial holes directed into the Cyclone tangent. This simple design has proven to be an excellent combustor. Many Cyclones are equipped with this burner and are typically capable of obtaining full Cyclone rated capacity. However, injecting the oil directly into the Cyclone furnace recirculation zone resulted in an extremely high heat release rate and Cyclone tubes would experience long term thermal damage. The oil roof burner continues to be used as an emergency Cyclone furnace deslagger for units firing coals with high T_{250} values. It is also used to deslag a Cyclone prior to a boiler outage. When coal flow to the Cyclone is interrupted, a heat input of up to about one half of the Cyclone rating is recommended for continuous load carrying purposes.

The alternate design uses an oil burner located at the Cyclone centerline firing directly into the Cyclone furnace vortex.

If continuous, long-term oil-only firing at full Cyclone rated capacity is required, splitting the heat input 50/50 between the roof burner and the center fired burner should be considered.

The Cyclone gas burners (capable of firing natural

Fig. 11 Batch removal slag handling system for Cyclone furnace boiler.

gas, coke oven gas, or other gaseous fuels) are located in the secondary air throat, injecting gas normally through three flat nozzles. Although this also injects fuel directly into the recirculation zone, the lower radiant heating of natural gas produces a lower heat absorption rate within the Cyclone furnace. Therefore, long term thermal damage has not been observed with a gas burner. Natural gas assists in deslagging plugged Cyclones, but its low radiant heat transfer rate to the Cyclone does not heat slag deposits as well as oil firing.

Cyclone units firing coal may switch to oil or gas for a short period without serious damage. However, for long term gas and oil operation, the Cyclone should be stripped of all slag and refractory to prevent erosive scrubbing of the tubes as previously discussed.

Waste burning

Due to their high heat release rate, the Cyclone furnaces have always been suited for firing a number of waste fuels with coal. A nominal blend ratio tested has been in the range of 5 to 20% heat input from the co-fired waste, with a less than 10% level typically being considered acceptable. However, waste or refuse fuel should first be thoroughly tested on the prospective Cyclone equipped boiler to determine these limits.

Refuse-derived fuel (RDF) RDF consists of the lighter, more easily burned materials from municipal waste. The ideal point of injection is the secondary air throat to maximize fuel particle time in the Cyclone. A scaled-up insulated version of the gas burner nozzle provides the best injector. However, the resistance welded flat studs found in original Cyclones may not withstand the associated particulate erosion, and increased furnace slagging are potential negative consequences.

Tire-derived fuel (TDF) Along with stokers and wet slagging PC units, Cyclones have been viewed as one of the best proposed methods for disposing of scrap automobile tires. Tire rubber provides an excellent low sulfur fuel, but the material's elasticity prevents it

from being crushed or pulverized like coal. It generally appears that a 0.5 to 1.0 in. (13 to 25 mm) sizing is close to optimum. Smaller grinds can be provided by the waste rubber industry, but the cost greatly exceeds that of coal. The TDF should fire easily when mixed with the coal. Although the steel content from bead and radial ply tires does not affect the iron sulfide factor noticeably, the bead wiring may be difficult to melt.

Petroleum coke A number of Cyclone operators have successfully blended petroleum coke with their coal. However, the lack of volatiles in petroleum coke can delay fuel burnout, increasing furnace exit gas temperature and resulting in superheater slagging.

Wood chips Wood chips, sawdust, bark and other similar solid waste products have long been co-fired in Cyclones. Moisture content and sizing of the prospective waste fuel helps determine the optimum blend ratios.

Various sludges Paper mill and sewage sludge materials have been successfully co-fired with coal and/or natural gas in new Cyclone-fired boilers. The Cyclones are designed to utilize a secant firing technique for the sludge material while the coal and/or natural gas are introduced according to standard arrangements. Secant firing introduces the fuel through dedicated openings in the Cyclone that are located directly beneath the secondary air inlet. This approach maximizes the retention time and temperature within the Cyclone itself to allow for successful operating characteristics at higher than typical waste material heat inputs (greater than 50% heat input on sludge). As with any Cyclone-fired application, fuel acceptability criteria must be closely followed to optimize operation (fuel T_{250} value, fuel fineness, minimal fuel moisture, etc.).

Combustion controls

The fuel/air ratio at each Cyclone remains the critical item in the combustion control system. When the Cyclone total air flow becomes too low or too high, operating problems can develop. The balancing of the fuel/air ratio is relatively easy to accomplish and monitor on smaller boilers with only one to five Cyclones. On these units, individual ducts supply the total combustion air flow to each Cyclone furnace. On larger

Fig. 12 Arrangement of gas and oil burners in Cyclone furnace.

units, multiple Cyclones are housed within common windboxes for the supply of secondary air. This arrangement inherently makes it more difficult to accurately monitor air to individual Cyclone furnaces. As a result, larger Cyclone equipped boilers have typically been operated at higher excess air levels than smaller units. Modern measurement and control techniques are improving the accuracy of air flow measurement. Although new devices are being designed with more repeatable measurements, it is still advisable to field-verify the equipment by performing air calibrations after installation. When retrofitted with accurate gravimetric coal feeders for each Cyclone, such devices permit tighter individual Cyclone furnace control.

With the advent of the Cyclone air staging technology to help reduce NO_x emission levels, the importance of maximizing the accuracy of the fuel/air flow measurements and controllability has increased. Improving this accuracy not only enhances the NO_x reduction capability of the system, but also maintains the required characteristics for acceptable Cyclone operation.

Operation

Igniters

Cyclones can be equipped with either No. 2 oil or natural gas igniters, with oil igniters being the more common option. On coal-fired Cyclones, both igniters are located at or near the Cyclone front in the secondary air throat outlet. The oil igniter is installed external to the Cyclone and is a retractable design to prevent overheating of the igniter and related problems with the oil atomizer. The gas igniter is a fixed design and installed inside the secondary air duct immediately ahead of the exit into the Cyclone. Original Cyclones were equipped with either a 10×10^6 Btu/h (3 MW_t) or 17×10^6 Btu/h (5 MW_t) oil igniter that employed mechanical atomization, or a 17×10^6 Btu/h (5 MW_t) stationary gas igniter. Both fuel igniter designs made use of high voltage ignition.

Demand for increased oil igniter heat release and decreased opacity, especially during cold start operations, led to the development of a larger, air atomized oil igniter with high energy spark ignition system. This new igniter, the CFS model, is capable of an input rating of 25×10^6 Btu/h (7.3 MW_t) under specific conditions. These higher input oil igniters require a slightly larger tube opening than was supplied on original Cyclones and would require some tube modifications if installed on these older units.

Minor design changes and field testing of the standard stationary gas igniter led to a revised igniter capacity on natural gas to approximately 30×10^6 Btu/h (8.8 MW_t), thereby providing similar capacity on either gas- or oil-fired Cyclone igniters.

Cyclones firing only oil and natural gas as the main fuels have additional igniter options with respect to location. The retractable CFS oil and/or gas igniter can be located axially down the center of the retired coal burner or through the modified burner door.

For further information on oil and gas igniters, refer to the igniter section in Chapter 11.

Sectional secondary air control dampers

Cyclone furnaces can be equipped with sectional dampers (2 or 3 blade sections) across the width of the secondary air inlet. This arrangement provides an additional level of control for the Cyclone furnace combustion. Biasing these dampers permits adjustment to the Cyclone combustion pattern and increases fuel retention time. The effectiveness of this additional control technique is greater when difficult to burn fuels are being fired (e.g., high moisture/low sulfur coal, higher ash fusion fuels, etc.).

Low load operations

Typically, Cyclone furnaces firing a good Cyclone bituminous coal can not operate below half load without the slag freezing. In addition, the main boiler furnace floor typically stops tapping slag below half load. When firing subbituminous type coals, this minimum low load level is higher due to the more difficult nature of firing that fuel in Cyclone boilers. In either case, the slag taps tend to plug solid. An individual Cyclone can continue to operate and should eventually start retapping. However, a boiler with a solidly plugged floor tap must be shut down for manual slag removal.

Power requirements

Cyclone furnace boilers have significantly different power requirements than do pulverized coal units. Fuel preparation power consumption for Cyclone boilers is very low because the coal is only crushed, not pulverized, and the primary air fan is not used. However, the forced draft fan power usage is substantially higher due to the relatively high Cyclone windbox to furnace pressure drop [typically 25 to 45 in. wg (6.2 to 11.2 kPa)]. This is illustrated in Fig. 13. The difference between Cyclone and PC firing is dependent upon the fuel type and heating value. PC firing has an advantage for high heat content and high grindability bituminous coal firing applications. Cyclone firing has an advantage for low heat content and lower rank fuels such as subbituminous, lignite and brown coals which are also harder to pulverize. In the case of the high heat content bituminous coals, the lower operating costs of PC firing must be balanced against the lower capital costs of Cyclone-based firing systems.

Maintenance

Corrosion and erosion within the Cyclone are the two most critical maintenance items. The Cyclone's wet slagging environment produces a potentially corrosive iron sulfide attack on the pressure part tubing.

Erosion is also a problem in an area opposite the secondary air throat where a protective slag coating can not form. The coal particles wear away the edges of the protective flat studding and can cut a channel between the studs and potentially damage the tubes.

Tubing – pin studs and refractory

In areas coated by molten slag, the tubes are protected by a refractory layer held in place by pin studs (Fig. 14). In addition to retaining the refractory, the

Fig. 13 Auxiliary power requirements for typical high-capacity, pressure-fired Cyclone furnace and pulverized coal units.

pin studs cool the refractory surface in contact with the corrosive slag and retard the corrosive chemical action. The pin studs protect the refractory and the refractory in turn protects the pin studs. Over time, experience has demonstrated that tighter, or denser, pin stud spacing improves refractory performance. The denser pin stud patterns have provided very good performance in their ability to protect refractory and resist corrosion (Figs. 15a and b).

Tubing – flat studs

An advanced design has been developed and installed by B&W to reduce maintenance (Fig. 16). The newer flat staggered stud design, using a hand applied fillet weld, offers the following advantages:

1. more precise stud manufacturing and closer spacing,
2. minimum potential for channeling and accelerated wear between studs,
3. excellent heat transfer which reduces metal temperature and erosion rates, and
4. thicker stud sizes to extend life.

Metallization

To enhance tube life, the plasma arc flame spraying of alloy metals onto the tube surface has been used. Despite a number of experiments with different metallization powders, the results generally remain inconclusive. Some applications using expensive coatings

resulted in a nickel sulfide attack which consumed the coating in the same manner as iron sulfide corrodes studs and tube surfaces. Furthermore, the pin studing does not lend itself to consistent spray applications. Some coatings prohibit installing replacement pin studs unless the coating and any interacting tube surface have been removed.

Refractory

Field experience has demonstrated that corrosive slag in any form should be kept away from the tubes by a refractory coating. Experience on operating units has proven that the most durable refractories are ram-type high density formulations. The specific refractory selection may be contingent upon the specific plant fuel.

Key overall issues to achieve the best potential chance for increased refractory life include:

1. Ensure proper maintenance/application of studs (along with maximizing stud density).
2. Choose the proper refractory for the application (proven positive experience).
3. Use refractory that has not exceeded its shelf life.
4. Follow proper refractory installation and curing procedures.
5. Follow good Cyclone startup/operation procedures.

Any one of these items done incorrectly can cause early loss of refractory.

Coal crusher

Cyclone coal crushers have generally remained unchanged over the years. With the increased use of difficult to fire subbituminous low sulfur coals and the need to crush the fuel as fine as possible, a change in maintenance practice is recommended. Cages should be adjusted and mills should be reversed more frequently than with standard Cyclone furnace coals. In addition, the hammers should be discarded at their half life to maintain adequate striking mass. To improve fineness to a greater degree, fine grind cages can be installed. This normally reduces the original capacity of the crushers and requires a motor upgrade and/or additional installed crusher capacity to restore system capacity.

Fig. 15b Modern *super dense* pin stud pattern after five years without maintenance.

Additional advancements

Additional retrofit design features continue to be developed to improve the performance and reduce maintenance costs of Cyclone boilers. These features, based on site-specific needs, include:

1. contoured flat studs designed for the tubes that make up the Cyclone slag tap,
2. improved seal welding design,
3. tighter gapped and extra reduced size re-entrant throats,
4. continued wear block development,
5. stainless steel cooling water jackets for burners, and
6. improved radial and vortex burner design elements.

Air pollution control

Flyash

To meet modern particulate emission standards, a Cyclone equipped boiler precipitator must be about the same size as that for a pulverized coal unit. Fabric filters have also been applied. However, the produc-

tion of more slag and less flyash can offer a significant disposal benefit. Furnace slag is much easier to dispose of than flyash in most cases. The constituent minerals are tightly bound in Cyclone slag, minimizing any leachate problems if landfilled. Cyclone slag physical properties have led to its reuse as road bed fill, shingles in the building industry, and sandblasting material (among other applications).

Sulfur dioxide (SO₂) reduction

As with other combustion systems, SO₂ emissions from Cyclone units are a function of the sulfur content in the fuel. One frequently used method for reducing SO₂ emissions is to switch to lower sulfur coal. Changing fuels typically requires a complete review of the impacts on boiler operation (e.g. slagging, fouling, sootblower capability, main and reheat steam temperatures, economizer outlet gas temperature, flyash collection, etc.). In the case of Cyclone furnace boilers, additional care is required in such a change because Cyclone furnaces are more sensitive to the ash composition, ash quantity, heating value and especially moisture in the fuel. If high moisture subbituminous or lignite fuels are to be substituted for low moisture bituminous coal, installing the direct-fired pre-dry system could be considered to optimize performance. This system has been successfully used for lignite coal-fired Cyclone furnaces.

Provided that the fuel selected meets the T₂₅₀ value discussed earlier, a standard Cyclone equipped boiler can potentially be modified to handle low sulfur, high moisture subbituminous or lignite coals through a series of hardware and operational changes. Key changes focus on improving and maintaining overall coal fineness, maximizing Cyclone furnace temperatures as high as possible, continuing an aggressive maintenance program, and making provisions for rapid deslagging. The actions required are unit specific and are usually established following an engineering study and test fuel burn.

Coal washing systems may be installed to remove pyritic sulfur. Although washing raises the T₂₅₀ value and makes the coal more difficult to burn, SO₂ emissions will be reduced.

Nitrogen oxides (NO_x) reduction

Historically, Cyclone equipped boilers have produced relatively high uncontrolled levels of NO_x emissions, ranging from 0.70 to 2.6 lb of NO_x as NO₂ per million Btu (approximately 1050 to 3900 mg/Nm³ corrected to 3% O₂). Based on ever increasing needs to reduce NO_x emission levels, various commercially available Cyclone equipped boiler NO_x reduction techniques are available and include, but are not limited to:

1. fuel switching from a bituminous to a subbituminous type coal,
2. air staging,
3. reburning,
4. selective catalytic reduction (SCR) technology, and
5. selective non-catalytic reduction (SNCR) technology.

Switching from a standard Cyclone bituminous coal to a subbituminous coal has shown that a nominal 10 to 25% NO_x reduction can be observed. These reduction levels are due to two factors:

1. reduced thermal NO_x component with the high moisture content of the fuel (lower Cyclone peak operating temperatures), and
2. lower fuel NO_x component due to the inherent constituents in the coal (lower fixed carbon to volatile ratio, lower nitrogen component, etc.).

The most widely used Cyclone boiler NO_x control technique is air staging. The basic theory of air staging is to reduce the fuel NO_x component within the burner zone by reducing oxygen availability. Additionally, numerical modeling activities have shown that due to the unique combustion characteristics of Cyclone equipped boilers, some reburning chemical reactions also help to reduce the overall NO_x emissions during air staging operation. This reburning phenomenon helps to explain the high percentage NO_x reduction that has been identified on numerous staged-air applications on Cyclone-fired units (up to 80% reduction).

Cyclone air staging employs multiple combustion zones within the furnace region (see Fig. 17), defined as the main combustion zone (Cyclone region) and the burnout zone (OFA ports to the furnace exit). The main combustion zone is designed to operate at nominal substoichiometric conditions. Operating at higher Cyclone stoichiometries is feasible, but at a cost of minimizing the overall NO_x reduction capabilities; actual operating Cyclone stoichiometries would be optimized during startup to provide the required NO_x reduction while maintaining optimum boiler operation. The balance of the required combustion air is introduced through overfire air (OFA) ports in the burnout zone. A satisfactory residence time within the burnout zone is required for complete combustion.

Experience indicates good NO_x reduction without major negative operational impacts while air staging on Cyclone units. However, there are potential negative issues that must be addressed. Reducing atmospheres accelerate corrosion, which can lead to significant maintenance problems. Corrosion and iron formation concerns are possible while operating under reducing/oxidizing conditions. Utilizing lower sulfur/iron fuels, such as lignite or low sulfur subbituminous

coals, will help reduce, but not eliminate, corrosion and iron formation concerns. Additional operational issues may include higher unburned carbon levels, increased boiler flyash, increased boiler slagging/fouling, steam temperature reductions, and higher opacity levels.

Low NO_x Cyclone reburn technology has been specifically developed to reduce NO_x emissions levels from Cyclone equipped boilers (up to 70% reduction) while permitting successful Cyclone furnace operation. In this system, the Cyclone furnace can be operated under fully oxidizing conditions, but at a reduced load – typically 70 to 85% of full load air and fuel flow. The balance of the fuel is injected directly into the main boiler furnace with minimum air for fuel transport to create a reburning zone. In this zone, the reburn fuel creates an oxygen deficient or reducing zone where the NO_x created in the Cyclone furnace is reduced or decomposed into molecular nitrogen through a series of complex interactions with free hydrocarbon radicals. Overfire air ports located above the reburn zone permit injection of the balance of the air to produce a final stoichiometry of 1.15 to 1.20 and complete the fuel combustion. The use of coal, oil, or gas as the reburn fuel depends upon an economic evaluation balancing the higher capital cost of a coal based system against the fuel cost differential for other fuels.

Post-combustion technologies have also been successfully applied to Cyclone boilers and offer varying degrees of NO_x control capability (see Chapter 34).

Applications

The Cyclone boilers gained wide acceptance due to their ability to burn a substantial reserve of coals deemed unsuitable for pulverized coal firing. Also, the unique inherent combustion characteristics of Cyclone furnaces have proven to be an effective means to safely fire a variety of waste materials. New Cyclone boiler applications co-firing sludge materials have been and continue to be developed.

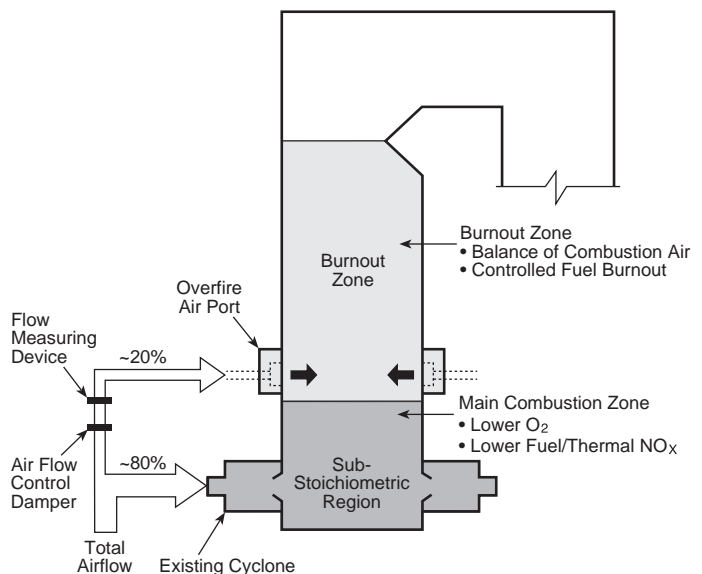

Fig. 17 Cyclone-equipped boiler air staging NO_x control system.

B&W Cyclone™ furnace.

Chapter 16

Stokers

Many technologies have evolved to convert a wide variety of fuels to alternate forms of energy. One important technology is the mechanical stoker. All stokers are designed to feed fuel onto a grate where it burns with undergrate air (UGA) passing up through it, and overfire air (OFA) passing over it. The grate is located within the lower furnace and is designed to remove the ash residue after combustion. Evolving from the hand-fired boiler era, mechanical stoker/grate system designs are available to burn a wide range of fuels for industrial, small utility and cogeneration applications. In addition to burning all forms of coal, other fuels burned include sludge, wood waste and biomass (e.g., wood, bark, straw, bagasse, rice hulls, peach pits, almond shells, orchard prunings, coffee grounds), as well as residential, agricultural, industrial and commercial refuse. Modern mechanical stoker firing systems are composed of:

1. a *stoker* or fuel feeding system,
2. a stationary or moving *grate* assembly to support the burning mass of fuel and admit undergrate air to the fuel,
3. an OFA system to complete combustion and limit atmospheric pollutant emissions, and
4. an ash or residual discharge system.

These components are then integrated into the overall furnace design to optimize combustion and heat recovery while minimizing unburned fuel, atmospheric emissions and cost.

Despite the functional differences stated above, it is not uncommon to hear or see the term stoker referring to not only the feeding device but also the entire system, including the grate and air system. The feeding device can also be referred to as a *feeder*, *distributor* or *spout*, as well as a stoker.

A successful installation requires selecting the correct type and size of stoker for the fuel being used and for the load conditions and capacity being served. There are two general types of systems: *underfeed* and *overfeed*. Underfeed stokers supply both the fuel and air from under the grate while overfeed stokers supply fuel from above the grate and air from below the grate. Overfeed stokers are further divided into two

types: *mass feed* and *spreader*. In the mass feed stoker, fuel is continuously fed to one end of the grate surface and travels horizontally across the grate as it burns. The residual ash is discharged from the opposite end. Combustion air is introduced from below the grate and moves up through the burning bed of fuel. In the spreader stoker, combustion air is again introduced primarily from below the grate but the fuel is thrown or spread uniformly across the grate area. The finer fraction of the fuel burns in suspension as it is lifted by the upward moving flue gas flow. The remaining heavier fraction of the fuel lands and burns on the grate surface with any residual ash removed from the discharge end of the grate.

There is little demand in today's market for the underfeed and small mass overfeed coal-fired units because of cost and environmental considerations. This market has been replaced with shop assembled oil- and gas-fired units and to some extent, by overfeed spreader stoker systems.

The stoker/grate systems are provided in many mechanical configurations depending upon the manufacturer. Table 1 summarizes several variations of basic stoker designs by type, fuel, heat release rate and approximate largest capacity available. Grate heat release rate is the fuel input divided by the *active* or *effective* area of the grate upon which fuel burning is intended to occur.

For a given boiler steam capacity, the typical fuel burning rates in Table 1 generally determine the plan area of the grate and furnace in which it is installed. Practical considerations limit stoker size and, consequently, the maximum steam generation rates. For coal firing, this maximum steam generation rate is about 390,000 lb/h (49.1 kg/s); for wood or biomass firing it is about 900,000 lb/h (113.4 kg/s).

Almost any coal can be burned on some type of stoker. Many other solid fuels such as refuse and biomass can be burned alone on a grate or in combination with another fuel such as pulverized coal, oil or natural gas.

The spreader stoker, in combination with the various grate types, is most commonly used for a steaming capacity range from 75,000 to 900,000 lb/h (9.5 to 113.4 kg/s). It responds rapidly to changes in steam

Table 1
Stoker/Grate System Overview

Stoker Type	Grate Type	Fuel	Typical Release Rate* 1000 Btu/h ft ² (MW _t /m ²)		Steam Capacity 1000 lb/h (kg/s)	
Underfeed:						
Single retort	—	Coal	425	(1.34)	25	(3.15)

* Specific fuel characteristics and firing arrangements may allow higher heat release rates.

** Municipal solid waste

*** Refuse-derived fuel

demand, has good turndown capability and can use a wide variety of fuels. It is not, however, suitable for low volatile fuels such as anthracite and petroleum coke because of carbon burnout problems.

Underfeed stokers

There are two general types of underfeed stokers: the horizontal feed side ash discharge type shown in Fig. 1 and the gravity fed rear ash discharge type shown in Fig. 2.

In the side ash discharge type, coal is fed from a hopper to a central trough, called a *retort*, by a screw or ram pusher. Air is admitted through the tuyères or air nozzles as shown. In the larger units, a ram assisted by pusher blocks or a sliding retort bottom (fuel distributors) moves the fuel upward and into the retort. As the coal moves upward and over the retort edges and spreads out over the active grate area, it is exposed to air and radiant heat. Drying occurs and distillation of volatiles begins. As the coal moves to the sides and/or rear, the distillation is completed, leaving coke which is burned out near the edges or end of the grate. High pressure OFA is used to produce high turbulence and reduce smoke.

Burning coal in this fashion increases the probability of *clinkering* (producing large agglomerates of ash slag) or *matting* (layers of ash slag). To reduce this tendency, alternate fixed and moving grate sections are applied to the underfeed stoker design to agitate the fuel. Coal characteristics are critical to underfeed stoker performance. Table 2 outlines coal specifications for stationary and moving grates, although underfeed stokers have burned coals outside of these guidelines. To burn these coals, some deviation from the normal maximum grate release rate may be required. A reduction in the percentage of fines helps to keep the feed bed porous and extends the range of coals with a higher coking index.

With suitable coal, single and double retort units are generally limited to 25,000 to 30,000 lb/h (3.2 to 3.8 kg/s) steam flow. Typical grate release rates are 425,000 Btu/h ft² (1.34 MW_t/m²) with water-cooled walls and 300,000 Btu/h ft² (0.95 MW_t/m²) with refractory walls. Capacities up to 500,000 lb/h (63 kg/s) steam are possible with multiple retort rear ash discharge units similar to that shown in Fig. 2. Grate release rates up to 600,000 Btu/h ft² (1.89 MW_t/m²) are practical with a 20 to 25 deg (0.35 to 0.44 rad) grate inclination from the horizontal.

Fig. 1 Single-retort underfeed stoker with horizontal feed, side ash discharge.

Fig. 2 Multiple-retort, gravity-fed underfeed stoker with rear ash discharge.

Mass feed stokers

Two types of mass feed stokers are used for coal firing: the water-cooled vibrating grate and the moving (chain and traveling) grate stokers. Another mass feed stoker system used for municipal refuse is discussed in Chapter 29.

Mass feed stokers are characterized by the gravity feed of fuel onto a stoker via an adjustable gate that controls fuel bed height. The method of firing involves a fuel bed that moves along a grate with air being admitted under the grate perpendicular to the fuel flow. As it enters the furnace, the layer of coal is heated by furnace radiation to drive off volatiles and to promote ignition. The coal continues to burn as it is conveyed along the depth of the furnace. The fuel bed decreases in thickness until all the fuel has burned and cool ash discharges into a pit. With this method of fuel entry, the undergrate air must be sectionalized along the length of the grate because the quantities of air required for ignition, burning and burnout are different and must be regulated. This method of fuel entry and combustion inherently produces low ash carryover. However, it is more sensitive to variations in fuel characteristics that affect ignition without a larger ignition arch (discussed below). Mass feed stokers require nonsegregating coal feed hoppers. Without them, the fines migrate to the side walls and severe clinkering can occur.

A water-cooled vibrating grate stoker is shown in Fig. 3. The vibrating grate consists of tuyère grate surface mounted on and in intimate contact with a grid of water tubes. The grate is connected to the boiler or feedwater circulation system for cooling. The entire structure is supported by a number of flexing plates that allow the grid and its grate to move freely in a vibrating action that conveys the coal from the feed hopper to the ash discharge. Vibration of the grates is intermittent and is adjustable to convey fuel along its length and control ash bed thickness and discharge as needed. A rear arch extends over approximately the rear third of the grate as shown in Fig. 3. It assists burnout and directs the higher excess air gases forward to mix with the rich volatile gases from the ignition zone. A short front arch is adequate for most coals. If ignition is inadequate due to low volatile fuel, refractory can be added to the short

arch to increase radiation and assist ignition. This is referred to as an ignition arch.

High pressure air, up to 30 in. wg (7.5 kPa), is injected through the front arch to promote turbulence and combustion. Water cooling of the grates makes this stoker more flexible with gaseous and liquid auxiliary fuels, because a shift to either does not require special grate protection other than the normal bed of ash left from coal firing. Burning rates of these stokers vary with different fuels; in general, the grate heat release rate should not exceed 400,000 Btu/h ft² (1.26 MW_t/m²). Due to the limited number of moving parts, this stoker/grate system typically requires little maintenance.

Chain and traveling grate stokers, shown in Fig. 4, are similar to each other. Both form an endless belt arrangement that passes over drive and idler sprockets or return bends. They both convey coal from the hopper through the furnace to the ash discharge and return under the grate. In the chain grate design, the chain continues around to the return side. The traveling grate unit differs in that it uses a grate bar to provide better control of siftings (fine ash falling through the grate) when firing anthracite. The moving chain stoker requires more maintenance than the water-cooled vibrating grate.

Chain and traveling grate stokers can burn a wide range of solid fuels including peat, lignite, subbituminous, bituminous and anthracite coals and coke breeze. Typical coal characteristic ranges are provided in Table 2. Generally, these stokers use furnace arches (front and/or rear, not shown in Fig. 4) to improve combustion by reradiating heat to the fuel bed. When burning low volatile anthracite or coke breeze, rear arches direct the incandescent fuel particles and combustion gases toward the front of the stoker, where they assist ignition of the incoming fuel.

Burning rates on chain and traveling grate stokers vary with different fuels. The lower ash (8 to 12%) and lower moisture (10%) fuels permit rates to 500,000 Btu/h ft² (1.58 MW_t/m²); higher moisture (20%) and higher ash (20%) fuels would limit the rate to 425,000 Btu/h ft² (1.34 MW_t/m²). For low volatile anthracite, the rate should not exceed 350,000 Btu/h ft² (1.10 MW_t/m²).

Spreader stokers

In the spreader stoker, the fuel is uniformly thrown into the furnace across the grate area. Fines ignite and burn in suspension; the coarser fuel particles fall to

Fig. 3 Water-cooled vibrating grate stoker.

Table 2
Typical Coal Characteristics for Different Stoker Types

	Undergrate Feed Systems		Mass Feed Systems		Spreader Systems

* The ash softening temperature here is the temperature at which the height of a molten globule is equal to half its width under reducing atmosphere conditions.

** Below 2500F (1371C) the moving grate is derated linearly to 70% of its rated capacity at 2300F (1260C) ash fusion temperature. Stationary grates are derated linearly to 70% at 2100F (1149C) ash fusion temperature and use steam for tempering below about 2400F (1316C) fusion temperature.

*** Higher moisture may require preheated combustion air.

the grate and combust on a thin, fast burning bed. Because the fuel is evenly distributed across the active grate area, the air is uniformly distributed under and through the grate. The undergrate air plenums may or may not be compartmented depending on the grate type and application. A portion of the total combustion air is admitted through ports above the grate as overfire air. The modern spreader stoker is the most versatile and the most commonly used stoker system.

Spreader coal firing

Fig. 5 shows a modern boiler equipped with a traveling grate spreader stoker and designed to fire an eastern bituminous coal. A straight, water-cooled membrane furnace wall construction minimizes refractory. For the typical stoker coal-fired application, ignition or combustion arches are not used. The installation consists of:

1. state-of-the-art feeder-distributor units that distribute fuel uniformly over the grate,
2. specifically designed air metering grates,
3. dust collection and reinjection equipment,
4. a combustion air system including forced draft fans for undergrate and overfire air, and

5. combustion controls to coordinate fuel and air supply with steam demand.

Feeders for spreader stokers

Spreader feeders have the capability to uniformly feed coal into a device that can propel it along the depth of a grate in an evenly distributed pattern. Many designs have been used successfully over the

Fig. 4 Traveling grate stoker.

Fig. 5 Typical spreader stoker coal-fired boiler; 290,000 lb/h (36.5 kg/s) steam.

years. The coal feed mechanisms include gravity, reciprocating plates and metering chain conveyors. The mechanisms that propel the coal into the furnace include steam and air injection as well as underthrow and overthrow rotors. Steam or air assist can be used with the rotor systems. Fig. 6 shows a feeder-distributor with overthrow rotor. The metering chain moves coal from a small hopper to an overthrow rotor. The rotor is equipped with blades shaped to uniformly distribute coal over the grate area. Although spreader designs vary, the overthrow design has been the most common.

With increasingly stringent emissions regulations, stoker manufacturers have been studying design variations that reduce the formation of nitrogen oxides (NO_x) and carbon monoxide (CO). Fig. 7 depicts a state-of-the-art mechanical-pneumatic feeder-distributor with underthrow rotor. In this device, the coal is fed from a hopper by a metering chain into an underthrow rotor with air assist. This has improved the feed and distribution capabilities, and 10 to 15% reductions in NO_x have been recorded compared to the overthrow design.

Grates for spreader stokers

As with mass stokers, there has been a wide range of grates used in spreader stoker coal firing. Stationary and dumping-type units are no longer installed as new equipment. Traveling and/or vibrating air-cooled grates are the most common. The traveling grate shown in Fig. 5 is a high resistance air metering grate. The resistance air metering concept eliminates the need for undergrate air plenum compartmentation for good air distribution and control. Moving adjustable air seals are provided at the front and rear. The grates are bottom-supported and therefore require an expansion joint at the interface to the water-cooled furnace.

The grate is a continuous moving chain. It consists of a series of chains to which are attached the grate bars that contain the air metering holes. The grate bars are contoured to interface with adjacent bars, minimizing air leakage between bars. The chains and grate bars are supported by, and slide on, grate rails. The sliding interface between the grate bar and rail also serves as a seal to prevent excessive air from bypassing the air metering holes in the grate. The grate travels from rear to front, or towards the fuel feed end. This permits the optimum fuel distribution pattern and the maximum residence time for burnout of larger fuel particles. The ash is continuously conveyed and spills off the end of the grate into a hopper.

Although the traveling grate is a durable and proven design, it has many moving parts and is subject to wear. To minimize wear, the speed of the grate should generally be kept below 40 ft/h (12.2 m/h). This may limit its use in some high ash fuel applications or it may require limiting the grate plan area release rate and input per unit width of stoker.

The grate is typically driven through the front sprocket and shaft to keep the top of the chain in tension; mechanical and hydraulic drive systems are available. Some systems use a ratchet concept, which results in loading and unloading the chain at each stroke. This leads to higher grate component wear than does a continuous and uniformly torqued drive system.

Other types of traveling grates are similar to that shown in Fig. 4. Many of these consist of a chain with several links to form an endless belt. Air admission is through the gaps in the links. These types of traveling grates typically have compartmented undergrate air plenums to control air distribution.

Fig. 6 Feeder-distributor with overthrow rotor.

Fig. 7 Chain-type coal feeder with underthrow rotor (courtesy of Detroit Stoker Company).

Air-cooled vibrating grates, similar to those shown in Fig. 3, are also used in spreader stoker applications. Except for a smaller size limitation, the application to spreader coal firing is similar to that of the traveling grate.

Carbon reinjection systems

The high degree of suspension burning results in greater carryover of partially combusted fuel particles. To achieve the highest boiler efficiency, these particles are captured in a dust collector, as well as from generating bank, economizer and air heater hoppers, and returned to the furnace for complete combustion. The carbon reinjection system on the unit in Fig. 5 is pneumatic. The carbon particles and some ash are captured by a mechanical dust collector and routed to a pickup box, where air is injected to convey it back to the furnace. Multiple injection ports are located across the width of the unit to uniformly mix the unburned carbon into the combustion zone for enhanced burnout. ReInjection of significant ash is undesirable because it can contribute to boiler surface erosion and grate clinkering. Because a mechanical dust collector is more effective in collecting larger particles, and because the majority of the unburned carbon is the larger size fraction of the total carryover, the bias towards collecting the unburned particles can be effected by limiting the design efficiency of the mechanical collector. Carbon reinjection improves coal-fired boiler efficiency by 2 to 4%.

Combustion air system

In spreader stoker-fired units, 25% excess air is typically provided for stoker combustion at the design full load input. This air is split between the undergrate air, OFA and fuel distribution air. Due to the high degree of suspension burning, air is injected over the fuel bed for mixing to assist fuel burnout and to minimize smoking. This dictates that 15 to 20% of the total air be used as OFA. This air is injected at pressures

of 15 to 30 in. wg (3.7 to 7.5 kPa) through a series of small nozzles arranged along the furnace front and rear walls. (See Fig. 8.)

Spreader stoker firing, with the air split between undergrate and overfire, is a form of staged combustion and is effective in reducing NO_x . By deeper staging, further reductions are possible. To take advantage of this characteristic, the modern unit shown in Fig. 5 is designed for a total excess air of 25%. The total air flow is split 65% undergrate and 35% overfire, which includes any air to the coal feeders. An additional level of overfire air nozzles is installed in the furnace front and rear walls above the coal feeder. (See Fig. 8.) This permits deeper staging and delays adding the remainder of combustion air until the hot fuel bed gases have radiated some heat to the waterwalls and are at a lower temperature. The OFA is admitted at a maximum static pressure of 30 in. wg (7.5 kPa) through nozzles designed for high penetration and mixing.

Spreader stoker coal characteristics

As noted earlier, the spreader method of feeding and combusting coal is versatile. It can operate satisfactorily on the full range of coals from lignite to bituminous. Fuels having less than 18% volatile matter are not generally suitable. Table 2 summarizes the range of coal properties for spreader stoker application.

Bituminous coals readily burn on a traveling grate without the need for preheated air. However, an air heater may be required in the unit design for improved efficiency. In these instances, the design air temperature should be limited to below 350F (177C). The use of preheated air may limit the selection of fuels to the lower iron, high fusion coals to prevent undesirable slagging and agglomerating on the grate. The use of preheated air at 350 to 400F (177 to 204C) is necessary for the higher moisture subbituminous coals and lignites.

Higher ash coals can also be satisfactorily burned. However, to keep grate speeds reasonable, it may be necessary to lower the grate heat release rate and/or reduce the input per unit frontal width.

Coal size segregation can present a problem on any stoker, but the spreader is more tolerant because the

Fig. 8 Stoker overfire air system.

feeder rates can be adjusted; much of the fines burn in suspension and not on the bed. Proper selection of the coal feed equipment can significantly reduce the tendency for coal size segregation.

Selection of a spreader stoker

Spreader stoker-fired traveling grates for coal are typically designed with release rates summarized in Table 1. Higher heat release rates may be allowed for specific fuel characteristics and firing arrangements. The air-cooled vibrating grate is limited to 650,000 Btu/h ft² (2.05 MW_t/m²). The length of the grate is limited to that over which the coal can be distributed. For vibrating grates, the length limit is 18 ft (5.5 m); for the traveling grate, it is 23 ft (7.0 m). The width of the grate is the main variable in providing sufficient total grate area. Sufficient width is also required to install enough feeders and to keep the heat input per foot of width below about 13.5×10^6 Btu/h ft (13.0 MW_t/m). A grate heat release rate of 750,000 Btu/h ft² (2.37 MW/m²) or less also applies with full reinjection from a mechanical dust collector. Higher inputs tend to increase slagging potential and may cause excessive fuel entrainment and carryover.

Traveling grates are available up to 19 ft (5.8 m) wide with a single driveshaft. For higher capacities, two opposite hand grates provide the desired width. With a practical grate width limit of 38 ft (11.6 m) and a length limit of about 23 ft (7.0 m), the largest practical grate area is about 880 ft² (81.8 m²).

Ash removal

When properly sized and operated, the ash discharging from a spreader stoker-fired unit is relatively cool and clinker free. Ash discharges into a hopper and may be removed by a conventional ash transport system, generally without the need for clinker grinders.

Spreader stoker firing of bark, wood and other biomass fuels

Several modern boiler designs are available to meet customer and project-specific requirements to fire bark, wood and other biomass fuels using a spreader stoker design. Fig. 9 shows a top supported Stirling® power boiler with a vibrating grate stoker. Fig. 10 shows a bottom-supported power boiler also with a vibrating grate. Both include state-of-the-art air-swept spouts in widths and numbers required to uniformly distribute the fuel over the grates. These units feature forced draft fans for undergrate and overfire air, mechanical dust collectors, and combustion controls to coordinate fuel and air supply with steam demand.

Several furnace configurations are used to meet project requirements and are available in either top or bottom-supported configurations. Fig. 9 shows the furnace with two arches separating the furnace into lower and upper zones (CCZ or Controlled Combustion Zone furnace) while Fig. 10 shows a straight wall furnace without arches, but including an advanced overfire air injection system. Selection of furnace type depends upon project requirements, fuel characteristics, and detailed numerical combustion modeling analyses.

Bark distributor feeders

Fig. 11 shows a modern air-swept spout. Bark is fed from a metering bin through a chute into the inlet of the spout. High pressure 20 in. wg (5.0 kPa) distribution air is introduced through an annulus across the width of the air-swept spout. In combination with the momentum of the falling bark, the air propels the bark into and across the grate depth. The distribution air is pulsed by rotating dampers or by a preprogrammed distributor to spread the bark uniformly fore-and-aft across the grate depth. A portion of the spout air is injected through small nozzles located at the furnace-side corners of the spout. This air assists the burning of fines and is adjustable to suit the fuel conditions.

The discharge of the air-swept spout is shaped to produce the optimum trajectory of the fuel particles. Some vendors provide an adjustable plate to control the discharge and subsequent distribution; some also supply mechanical bark feeders having features similar to those depicted earlier for stoker coal firing. Sufficient spouts are installed across the width of the unit to feed the necessary quantity of bark and to control the side-to-side distribution and grate coverage.

Of equal importance is the system that feeds the fuel to the air-swept spouts. Bark is conveyed across a series of smaller metering bins in a quantity greater than that needed for combustion; the excess is returned to storage. The individual metering bins are equipped with screw feeders that convey the bark in accordance with fuel demand. They are capable of

Fig. 9 Typical wood-fired stoker boiler with Controlled Combustion Zone (CCZ) furnace.

Fig. 10 Bottom-supported boiler with vibrating grate stoker – biomass firing.

speed biasing across the furnace width. This system minimizes fuel shortages at the boiler front, uses smaller bins, has a reduced tendency to have the fuel hang up or bridge in the bins and hoppers, and provides consistent fuel size distribution to the bins and across the width of the unit. Other types of feed systems, such as large live-bottom bins, are successful when applied with the proper fuel characteristics. Some bark and other biomass fuels are stringy and can agglomerate and segregate. These characteristics must be considered when designing feed systems for the air-swept spout.

Grates for firing bark and other biomass fuels

A traveling grate for bark firing is very similar to that used for spreader stoker coal firing. The bark is fed over the fuel bed and distributed uniformly across the grate area. This design is essentially an air-cooled grate; therefore, it is important to retain a layer of ash on the grate to shield the grate bars from furnace radiation. When firing low ash barks, it is common to operate the grates intermittently so that an inventory of ash can build and be retained. In addition, high alloy grate bars having higher resistance to thermal degradation can be used.

Bark is a high volatile fuel that, in combination with the fines, has a high degree of suspension burning. High volatile and low ash characteristics permit sizing traveling grates with heat release rates to 1,100,000 Btu/h ft² (3.47 MW_t/m²). The width limitation of dual traveling grate stokers is also about 38 ft (11.6 m) and the depth is mechanically limited to about the equivalent furnace depth of 23 ft (7.0 m). At these size limits, steam flow capabilities are limited to about 550,000 lb/h (69.3 kg/s).

The ash in bark, predominately silica, is very abrasive. This, in combination with high temperature grate bar exposure, causes high maintenance. As a result, some vendors have reintroduced the water- or air-cooled vibrating grate stoker. A water-cooled version is shown in Fig. 12. The combustion concept is no different than that for traveling grates. A complement of grate bars with air metering holes is attached to and supported by a water-cooled tubular grid connected to the boiler or feedwater circuitry. A heat conducting cement may be used to enhance grate cooling. The water-cooled grid is then supported by a complement of flexible straps. To convey ash, a back-and-forth motion is imparted to the grid which, supported on the flexible straps, imparts a looping motion to the grate. This motion, at predetermined intervals, is sufficient to convey and discharge the ash to the hopper. A variant of the water-cooled grate is the air-cooled type. In the air-cooled grate, the water tube grid is replaced by a mechanical grid to support the grate bars; components are then cooled by the flow of undergrate air. The advantages of the water and air-cooled grates are their simplicity, minimal moving parts, and lower maintenance. Grate sections generally range in width from 4 to 11 ft (1.2 to 3.35 m) to meet project functional and economic requirements. Because of their

Fig. 11 Air-swept spout.

Fig. 12 Water-cooled vibrating grate stoker.

independent modular construction, vibrating grate modules can be installed side by side to the mechanical limits of the boiler. Furthermore, grate depths are generally permitted to the limit of fuel throw and distribution of 26 ft (7.9 m). The largest vibrating grate currently in operation is almost 45 ft (13.7 m) wide. When sized to grate release rate limits of 1,100,000 Btu/h ft² (3.47 MW_t/m²), steam flow capacities of 800,000 to 900,000 lb/h (100.8 to 113.4 kg/s) are available on wood, bark and other biomass fuels.

Combustion air system

The excess air for bark, wood and most biomass fuels ranges from 15 to 50%, depending on stoker type and firing conditions. Because biomass fuels are typically highly volatile on a dry basis, heterogeneous in size and tend to burn more in suspension, combustion air systems are designed to provide more overfire air than that used for coal. Modern designs permit undergrate and overfire quantities of 40 to 60% of total stoker combustion air respectively, excluding any combustion air used for auxiliary burners. Overfire air system design and arrangement in combination with furnace geometry play an important role in completely burning the combustibles liberated from the grate. Fig. 9 shows a furnace design that promotes recirculation and mixing at and below the lower furnace bustle (arches). Multiple elevations of large overfire air nozzles allow high energy jets of air to penetrate and mix, enhancing combustion. The system is designed to permit flexibility in distributing the air within the overfire air system as fuel characteristics vary.

Numerical modeling techniques (see Chapter 6) have advanced OFA system design for biomass fuels. Today, fewer levels of OFA with very large ports are arranged to more effectively create turbulence for mixing gaseous combustibles with air without the

need for a lower furnace bustle. Fewer ports mean lower initial cost and simplified operation. Port elevation(s) can be located to optimize CO and NO_x performance. The ports also serve as convenient injection sites for non-combustible/malodorous waste gases. Fig. 13 shows a horizontal rotary overfire air system designed to create a double rotating circulation zone within the furnace. Fig. 14 depicts a B&W PrecisionJet™ air system with ports arranged in an interlaced pattern. Both systems typically require air pressures of less than 20 in. wg (5.0 kPa) and result in both exceptional combustion performance and fairly uniform gas distribution leaving the combustion section. Because the highly turbulent air zone is located well above the fuel feed and grate area, less ash and char are carried out of the furnace.

Combustion carryover and flyash reinjection

Fig. 15 shows the recommended sizing distribution for wood or bark. The degree of grate or suspension burning varies with fuel size. A portion of the fuel that ignites in suspension may be too large to complete burning; it therefore goes out with the flue gas as unburned carbon. Many factors such as fuel sizing, grate release rates, moisture content and reinjection affect the unburned carbon loss. In addition, furnaces sized to a maximum liberation rate of about 18,000 Btu/h ft³ (186 kW_t/m³) can control unburned carbon losses to 1 to 3%. Further reductions can be attained with flyash reinjection in certain biomass-fired units. Because of high maintenance costs due to the high silica content and abrasiveness of wood and bark flyash, reinjection systems are not frequently used with these fuels unless sand classifiers are also installed. As one example, the unit shown in Fig. 9 does not feature a flyash reinjection system.

In cases where the unburned carbon carryover must be further controlled, mechanical particulate collectors can be installed downstream of the generating bank. These collectors are sized to take advantage of the fact that the carbon particles are typically larger and heavier than the inerts in the flyash. This permits a carbon-rich stream to be reinjected into the furnace for further combustion. This mechanical collection and reinjection reduces the ultimate carbon loading in the downstream equipment and the possibility of fires.

Fig. 13 Furnace plan view showing horizontal rotary overfire air system.

Fig. 14 Furnace sectional side view showing single level air system with PrecisionJet™ ports.

Grate sizing

For wood and bark firing with moisture contents at or below 50%, it is common practice to select a grate area that results in a design heat release rate of 1,100,000 Btu/h ft² (3.47 MW_t/m²). At 35% moisture, the release rate may approach 1,250,000 Btu/h ft² (3.94 MW_t/m²). At moisture levels higher than 55%, the fuel becomes more difficult to ignite and burn. Traveling grate stokers are mechanically limited to about 23 ft (7.0 m) of equivalent furnace depth and about 38 ft (11.6 m) in width. Grates are generally longer than they are wide because this design is the least expensive. For a water-cooled grate, the depth is limited by the feeder's ability to distribute the bark over the grate depth. This distance is about 26 ft (7.9 m). Because of its modular construction, the maximum width of a water-cooled grate assembly is limited only by mechanical limits of the boiler.

Combustion air temperature

When firing wood, bark and other biomass fuels, it is necessary to consider the fuel moisture content to determine the need for preheated combustion air. Undergrate air temperatures in excess of that needed for the moisture content of the as-fired fuel contribute to NO_x and particulate emissions. Biomass fuels with less than 35% moisture content do not require preheated air. With seasonal variation in fuel moisture and the growing interest in co-firing wood and bark with sludges, the air heating system should be sized and selected for the maximum expected moisture.

The temperature limit for the air-cooled traveling grate with ductile iron bars is generally 550F (288C). If higher temperatures are needed, the water-cooled vibrating grate can withstand air temperatures to 650F (343C). In some cases, a steam or water coil air heater can provide variable undergrate air temperature when needed.

The decision of whether to use heated or unheated air for the OFA system must consider the overall project goals and economics. Hot OFA is preferred for new systems when maximum heat recovery is of singular importance. Hot air achieves greater penetration than cold air at the same mass flow rate, tends to burn out CO and hydrocarbons better, and reduces the chances for acid dewpoint corrosion of non-condensable gases in port boxes. Cold OFA systems are lower cost to retrofit because they do not require insulated ducts for personnel protection. Because cold OFA requires smaller ports, it is preferred where vertical clearance is tight.

There are many other biomass fuels such as rice hulls, bagasse, peach pits, coffee grounds and demolition debris, that may be fired on spreader-type stokers. Most of the criteria for sizing and using a spreader stoker are similar to those for wood and bark. Loose straw, however, should be mass fed. Use of a spreader stoker can cause uncontrolled carryover of burning lightweight particles into the convection section.

Ash removal

The ash content in wood and bark is only a few percent by weight and predominantly composed of silica. Because it is very abrasive, slow grate speeds and abrasion resistant materials should be used. Bottom ash typically drops into a refractory lined hopper from which it is intermittently removed. Submerged chain conveyors are also suitable. Due to the carbon content and the tendency for fires, the flyash from the hopper and dust collecting equipment is removed continuously. Wet sluice or inert gas (flue gas) systems are generally used to convey the flyash to the storage silos. Wet systems are preferred due to fire and dusting resistance.

Emissions

The installation of any new steam generator or a major rebuild or upgrade to an existing one requires environmental permitting. Therefore, the ability to predict and control the various emissions is important. Add-on pollution control equipment is generally required to meet the increasingly stringent regulated levels. However, it is also important to control or minimize the source emissions where possible to reduce the cost of this add-on equipment.

Table 3 lists typical uncontrolled emission values for spreader stoker firing of various coals and wood/bark. These values will vary with fuel composition and equipment selection.

NO_x is formed from the oxidation of the nitrogen compounds in the combustion air and in the fuel. With stoker firing it is believed that most of the NO_x is de-

Fig. 15 Recommended sizing for wood or bark spreader stoker firing (courtesy of Detroit Stoker Company).

rived from fuel-bound nitrogen (fuel NO_x); the contribution due to oxidation of the nitrogen in the air (thermal NO_x) is small due to relatively low furnace temperatures. NO_x emissions can be effectively reduced by staging combustion, inherent in spreader

stoker firing, and by controlling excess air levels. For both coal and wood/bark stoker firing, the excess air level in low NO_x stoker systems is about 25%. To reduce NO_x to the lower end of the range shown in Table 3, designers are now using deeper staging, i.e., lower undergrate and higher overfire air flows, as well as flue gas recirculation. For spreader firing, feeders are also designed to improve fuel distribution and combustion on the grates. Other factors that reduce NO_x formation include controlling the quantity of fines in the fuel and using ambient temperature combustion air.

Many waste fuels such as straw and other nonwood fibers have high fuel nitrogen content. Commercial wastes such as demolition debris are dry and will combust at higher temperatures, producing higher NO_x . It is therefore important that a thorough investigation of the fuel be made to assess its potential effect on emissions.

For most stoker-fired units burning coal or biomass that contains sulfur, sulfur dioxide (SO_2) will be present in the flue gas. For prediction purposes and for sizing of SO_2 control equipment, it is assumed that all the fuel sulfur becomes SO_2 .

Carbon monoxide (CO) and volatile organic compound emissions are generally a function of the quality of the combustion process and the quantity and control of fines and excess air. CO will tend to increase as NO_x is reduced.

Table 3
Typical Post Combustion Emissions for Spreader Stoker Firing

Fuel	NO_x (as NO_2) lb/10 ⁶ Btu	CO lb/10 ⁶ Btu	Unburned Carbon Loss (% of Heat Input)	
			With Reinjection	Without Reinjection
Bituminous	0.35 to 0.5	0.05 to 0.30	0.5 to 2.0	3 to 6
Subbituminous	0.3 to 0.5	0.05 to 0.30	0.5 to 1.5	3 to 5
Lignite	0.3 to 0.5	0.10 to 0.30	0.5 to 1.5	3 to 5
Wood/bark	0.1 to 0.35	0.05 to 0.50	0.2 to 2.0	2 to 5

Approximate conversion: 1 lb/10⁶ Btu = 1230 mg/Nm³ (dry flue gas 6% excess O_2 , 350 Nm³/GJ).
Includes applicable overfire air systems.

Vibrating grate stoker.

Chapter 17

Fluidized-Bed Combustion

In the 1970s, fluidized-bed combustion technology was first applied to large-scale utility boiler units to explore new ways of burning solid fuels, especially high-sulfur coal, in an environmentally acceptable and efficient manner. In concept, fluidized beds burn fuel in an air-suspended mass (or *bed*) of particles. By controlling bed temperature and using reagents such as limestone as bed material, emissions of nitrogen oxides (NO_x) and sulfur dioxide (SO_2) can be controlled. Additional benefits of fluidized-bed combustion include wide fuel flexibility and the ability to combust fuels such as biomass or waste fuels, which are difficult to burn in conventional systems because of their low heating value, low volatile matter, high moisture content or other challenging characteristics. In coal-fired systems, the fuel is burned in an air-suspended bed of limestone and inert ash particles where SO_2 is absorbed by the limestone, and NO_x formation is limited by lower operating temperatures and staged combustion, when used. This technology is now used in a variety of industrial and utility boiler applications.

Today, bubbling fluidized-bed (BFB) boilers, with a bed of fluidized particles that remain in the lower furnace, are used primarily in specialty fuel applications such as coal wastes and biomass fuels. Circulating fluidized-bed (CFB) boilers, with solids circulating through the entire furnace volume, address most larger steam generator applications and a broader range of fuels.

The fluidized-bed process

The fluidizing process induces an upward flow of a gas through a stacked height of solid particles. At high enough gas velocities, the gas/solids mass exhibits liquid-like properties, thus the term *fluidized bed*.

The following example helps illustrate the process. Fig. 1a shows a container with an air supply plenum at the bottom, an air distributor that promotes even air flow through the bed, and a chamber filled with sand or other granular material.

If a small quantity of air flows through the air distributor into the sand, it will pass through the voids of an immobile mass of sand. For low velocities, the air does not exert much force on the sand particles and they remain in place. This condition is called a *fixed bed* and is shown in Fig. 1b.

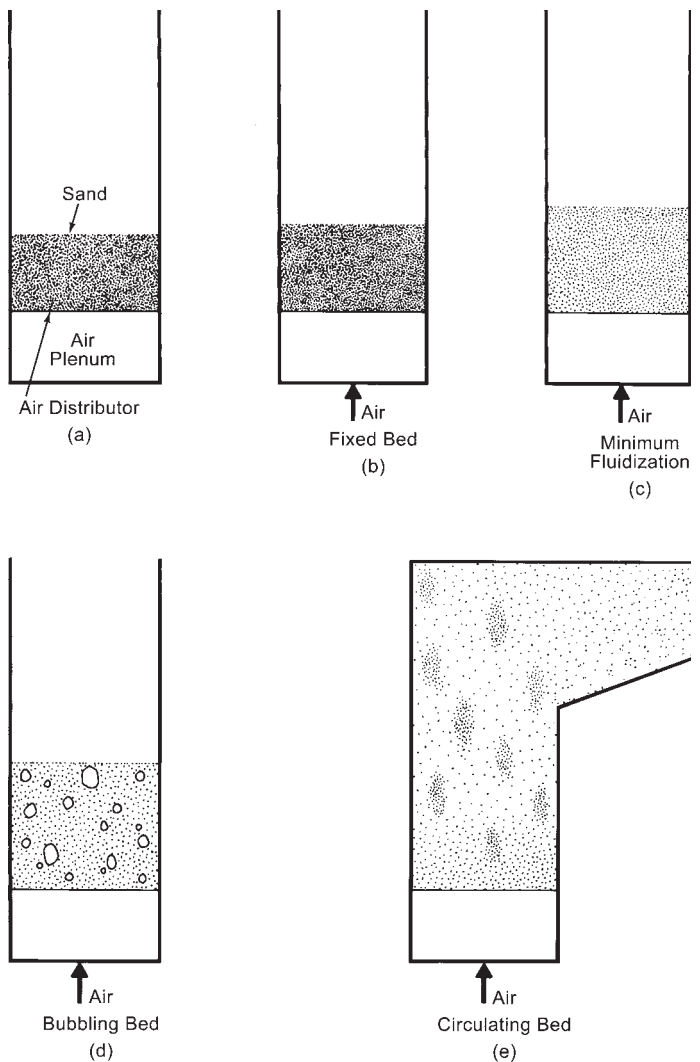

Fig. 1 Typical fluidized-bed conditions.

By increasing the air flow rate/velocity, the air exerts greater forces on the sand and reduces the contact forces between the sand particles caused by gravity. By increasing the air flow further, the drag forces on the particles will eventually counterbalance the gravitational forces, and the sand particles become suspended in the upward stream. The point where the bed starts to behave as a fluid is called the *minimum*

fluidization condition. The increase in bed volume is insignificant when compared with the non-fluidized case (Fig. 1c).

As the air flow increases further, the bed becomes less uniform, bubbles of air start to form, and the bed becomes violent. This is called a *bubbling* fluidized bed (BFB), shown in Fig. 1d. The volume occupied by the air/solids mixture increases substantially. There is an obvious bed level and a distinct transition between the bed and the space above.

By increasing the air flow further, the bubbles become larger and begin to coalesce, forming large voids in the bed. The solids are present as interconnected groups of high solids concentrations. This condition is called a *turbulent* fluidized bed.

A further increase in air flow causes the particles to blow out of the bed and the container. If the solids are caught, separated from the air, and returned to the bed, they will circulate around a loop, defined as a *circulating* fluidized bed (Fig. 1e). Unlike the bubbling bed, the CFB has no distinct transition between the dense bed in the bottom of the container and the dilute zone above. The solids concentration gradually decreases between these two zones.

The pressure differential between the top and the bottom of the container changes with air flow, as shown in Fig. 2. At low air flow, the pressure differential increases with flow through the static bed until reaching the *minimum fluidization velocity*. At this point, the sand is supported by the air, and the pressure differential is determined only by the mass of bed material. The pressure differential is independent of further increases in air flow until the air velocity becomes high enough to convey material out of the container. Then the pressure differential decreases as mass is lost from the system, which is represented by the entrained flow portion of the curve in Fig. 2.

An important parameter for evaluating hydrodynamic and heat transfer performance of particle mixtures is the Sauter (also called volume-surface or harmonic) mean diameter (SMD):

$$SMD = \frac{1}{\frac{X_1}{D_1} + \frac{X_2}{D_2} + \dots + \frac{X_N}{D_N}} \quad (1)$$

Fig. 2 Effect of velocity on bed pressure drop.

where

X_1 to X_N = weight fraction of first to last size cut
 D_1 to D_N = average diameter of first to last size cut, microns

Of these fluidization conditions described above, only bubbling and circulating beds are currently used by the power industry to generate steam.

Bubbling fluidized-bed (BFB) boilers

Fig. 3 shows the main features of a bubbling fluidized-bed boiler while Fig. 4 shows a typical furnace bulk density profile curve. The sharp drop in density indicates the top of the bed.

The bottom of the furnace in a BFB boiler consists of a horizontal air distributor with bubble caps. This provides the fluidizing air to the bed material in the lower furnace. As discussed later, The Babcock & Wilcox Company (B&W) offers two air distributor systems depending upon the fuel and application. The bubble caps are closely spaced so that air flow is distributed uniformly over the furnace plan area. The lower furnace is filled with 2 ft (0.6 m) of sand or other non-combustible material such as crushed limestone or bed material from prior operation. Air flow is forced upward through the bed of material, and the bed expands to a depth of about 3 ft (0.9 m) taking on most of the characteristics of a fluid. The air flow through the bed is very uniform due to a high number of air distributors (bubble caps) and bed pressure drop. The

Fig. 3 Typical bubbling fluidized-bed boiler schematic.

Fig. 4 Typical atmospheric pressure bubbling-bed furnace density profile.

typical slumped (non-fluidized) density of a sand bed is 90 lb/ft³ (1442 kg/m³). The voidage or volume between the particles in the fluidized bed is 65% and the bulk density is 58 lb/ft³ (929 kg/m³). The gas flow rate through the bed is defined as the *superficial bed velocity*, which is calculated by dividing the volumetric gas flow rate at the bed temperature by the plan area of the bed without the solids. A typical nominal design superficial velocity of 8 ft/sec (2.4 m/sec) is enough to fluidize BFB bed material with a particle size distribution between 500 and 1400 microns. The boiler enclosure is made of water-cooled membrane panels.

B&W offers two air distributor systems for its BFB boilers: *open bottom* and *flat floor* systems. The open bottom system shown in Fig. 5 is characterized by the fluidizing air bubble caps and pipes mounted on widely spaced distribution ducts (see also Fig. 6) located in the bottom of the BFB furnace. Stationary bed material fills the hoppers and furnace bottom up to the level of the bubble caps, above which the bed material is fluidized by the air flow. The open spacing is effective in removing larger rocks and debris from the active bed area as bed material moves down through hoppers. This design is particularly attractive in biomass and waste fuel applications, which contain non-combustible debris. In the flat floor system shown in Fig. 7, the floor of the furnace is formed by horizontal water-cooled membrane panels with bubble caps. Air passes from a windbox below the water-cooled panel through the bubble caps to enter and fluidize the bed material. Separate bed drains are provided. The membrane panel floor must form an airtight seal with the furnace walls, must support the weight of a slumped bed, and must resist the uplift generated from the air pressure drop during operation. This design is attractive for firing coal where there is much less large debris present.

Coal-fired bubbling-bed boilers normally incorporate a recycle system that separates the solids leav-

Fig. 5 Open bottom air distributor system with bubble caps.

ing the economizer from the gas and recycles them to the bed. This maximizes combustion efficiency and sulfur capture. Normally, the amount of solids recycled is limited to about 25% of the combustion gas weight. For highly reactive fuels such as biomass, this recycle system is usually omitted.

The typical operating temperature range of a bubbling bed is 1350 to 1650F (732 to 899C), depending on the fuel moisture, ash content, and alkali content

Fig. 6 Air distributor ducts and bubble cap system.

Fig. 7 Furnace distributor plate and bubble caps for a flat floor system.

in the ash. Even at these low combustion temperatures, the high convective and radiative heat transfer from bulk bed material to the fuel particles provides sufficient ignition energy to evaporate moisture, heat the ash, and still combust the remaining fuel without significantly changing the instantaneous bed temperature. This is why the bubbling bed can burn low-grade fuels, which burn at low combustion temperatures due to their high moisture and ash contents.

Heat transfer surface may be placed within the bed depending upon the fuel being burned. For biomass and other low heating value fuels, no in-bed surface is usually required because other methods of bed temperature control can be used. For coal firing with its high heat content and lower relative volatility, the heat transfer surface, in the form of a tube bundle, is placed in the bed to achieve the desired heat balance and bed operating temperature. The bed temperature is uniform, plus or minus 25F (14C), as a result of the vigorous mixing of gas and solids.

BFB combustion systems are attractive retrofits to older boiler designs where a change in fuels or wider fuel flexibility is required. Fig. 8 shows a sectional side view of a process recovery (PR) boiler that was retrofitted with a B&W open bottom BFB combustion system. The black liquor firing capacity was no longer needed and the owner wanted a power boiler capable of firing wood waste, primary clarifier sludge, and tire-derived fuel. Fig. 9 shows an isometric of the BFB combustion system in the bottom of the boiler. The air dis-

tributor, fluidized bed of material, and overfire air systems are clearly identified.

Fig. 10 shows a sectional side view of a small BFB boiler firing wood, wood waste and byproduct sludge. This Towerpak® boiler design is a version of the Stirling® power boiler (SPB, see Chapter 27) with two drums and bottom support for ease of installation. This unit is capable of supplying 120,000 lb/h of steam flow (15.12 kg/s).

All fossil fuel boilers require closely coordinated control of fuel, air, water and steam parameters. Fluidized-bed boilers require additional control. Selected key parameters for fluidized-bed boiler design include: bed temperature control (fuel dependent), bed inventory control, bed density (for heat transfer control), and emissions.

Bed temperature control and fuel feed

The most fundamental control function of a BFB combustion process is bed (combustion) temperature control. The control method depends upon the fuel

Fig. 8 B&W open bottom BFB furnace retrofit of a process recovery boiler.

Fig. 9 Isometric of BFB furnace bottom.

being fired. Bed temperature is controlled to limit emissions of NO_x and SO_2 , and to limit bed material agglomeration. Agglomeration is caused by sodium and potassium combining with alumina and silica to form low melting point eutectics that can coat the bed particles. If the alkali concentration in the coating is too high, the coating can start to melt and cause particles to stick together. As a result, the larger particles do not fluidize and, if the process continues, the bed can solidify and the combustion process can stop. The agglomeration process is quite temperature-sensitive and some fuels have strict requirements for the maximum

peak bed temperatures. Also, some fuels have such high alkali contents that the fuel can not be fired in a fluidized bed combustion process. Such fuels are typically agro-based where the plants are fertilized or the ground is rich in alkali. Some process waste can also contain high alkali concentrations.

Biomass firing Biomass firing begins with an inert bed of solid particles in the bottom of the furnace preheated to 1500F (816C) using oil or gas startup burners. Air flows into this bed at 68 to 392F (20 to 200C) and fuel at 68F (20C). The bed material must heat the incoming air and fuel to the bed temperature and the

Fig. 10 Towerpak® bottom supported BFB.

fuel must release the same amount of heat back into the bed to maintain a constant temperature. Too much heat release increases bed temperature, while too little heat release reduces bed temperature. Three methods of bed temperature control are used in biomass firing: primary/overfire air split adjustment, flue gas recirculation (FGR), and fuel feeder selection and operation.

Primary/overfire air split adjustment Biomass bubbling beds operate substoichiometrically with less than theoretical combustion air. In the bed, all available oxygen is completely used. Any additional oxygen would oxidize more fuel and increase the in-bed heat release, while lower oxygen levels would have the reverse effect. Because of this repeatable relationship, an increase in air flow from the windbox through the bed will raise bed temperature while a decrease in air flow will lower bed temperature at steady-state conditions. Overfire air flow increases or decreases in the opposite direction to maintain constant total combustion air flow to the boiler.

Shifting the air flow between the bed and overfire air system shifts the combustion or heat release be-

tween the two. At steady-state conditions, the flue gas temperature above the overfire air nozzles can be varied by 360F (200C) just by shifting air between the bed and the overfire air. The bed temperature is rather slow to respond to changes in the bed air flow. The cycle of increasing the bed temperature 27F (15C) above the set point and returning back to the set point can take 20 minutes or more.

Flue gas recirculation (FGR) When changing the air flow through the bed is not sufficient or fast enough for acceptable bed temperature control, flue gas can be recirculated back from the induced draft (ID) fan outlet into the bed. This *flue gas recirculation* is another mass flow stream entering the bed at a temperature below bed operating temperature. Energy transferred from the bed material to the incoming flue gas to heat it to the new bed equilibrium temperature is greater than the heat released by incremental combustion from the low level of FGR oxygen. As a result, the equilibrium bed temperature declines. The bed temperature response rate for this control method is much more rapid and, at steady-state conditions, FGR

can control the bed temperature to within 20F (11C) of the set point bed temperature.

Fuel feeder selection and operation Two types of feeders are commonly used for biomass fuels in BFB combustion: 1) chute-type feeders that deposit fuel in small areas of the bed, and 2) air distribution feeders that distribute fuel over a wider area. There is a relationship between in-bed heat release and distribution of fuel over the bed plan area. This is because the high volatile matter content and low-density char escape from the bed before the inherent churning motion of the bed material can distribute the fuel within the bed. If the fuel is not distributed evenly, some air simply passes through the bed without contributing to the in-bed combustion process. To obtain the highest amount of in-bed heat release, the fuel must be distributed as widely and uniformly as possible to match the uniform air flow. The lowest in-bed heat release results from dumping fuel to one spot. Therefore, the fuel feeder should be able to function as either a chute or as an air distribution feeder. When the fuel is dry, the feeder air flow can be reduced and the fuel falls into a small portion of the bed. When the fuel is wet, the feeder air flow can be increased and the fuel distributed over the plan area. The in-bed heat release change rate from low- to high-feeder air flows can be as much as 20% of the fuel's heating value.

Coal firing Bed stoichiometry adjustment is not effective for coal-fired BFB combustor temperature control because carbon builds up in the bed when there is less than theoretical combustion air. When the air flow is increased for load, the bed temperature increases rapidly and uncontrollably. In an extreme case, the pressure parts could be damaged, and more commonly, the bed could agglomerate. Therefore, BFBs firing coal are limited to no less than stoichiometric conditions in the bed.

The coal can be blown into the bed from below using pressurized feed pipes, or can be fed over the bed using common rotary flipper-type feeders. The under-bed feed system is more expensive and the coal must be dry and less than 0.25 in. (6.35 mm). The feed pipes are prone to erosion and plugging, and the nozzles at the ends of the pipes erode. The in-bed heat release is higher and the carbon loss is lower using the under-bed feed system, but the disadvantages typically cause the over-bed system to be preferred.

With the overfeed system, the in-bed heat release is 75 to 85% of the coal's heating value. For the coal falling on the bed, all of the fixed carbon and 70% of the volatile matter combusts while in the bed. The fines burn in suspension and reduce the overall in-bed heat release. With this high in-bed heat release, the adiabatic bed temperature would be significantly higher than the desired 1500 to 1600F (815 to 871C) range. To lower the bed temperature to the desired range, tube bundles are submerged in the bed. This in-bed surface can be either steam-generating surface or superheater surface. Water circulation in the steam-generating surface can be either natural or forced.

The fluidizing air is provided from a windbox mounted below the bed. The windbox is typically compartmentalized, with individual air flow control to each

compartment. Bed temperature varies with the firing rate. Therefore, as the boiler load is reduced, the firing rate is reduced, and the bed temperature declines. When the bed temperature reaches a certain minimum, an outer portion of the bed is shut down by shutting off the air flow and fuel flow to that portion of the bed. The air flow and fuel flow to the remaining active bed area is increased which raises the bed temperature in the operating beds. Boiler load is increased by re-fluidizing out-of-service (slumped) compartments and firing to larger portions of the bed.

Bed inventory control

The air/flue gas pressure drop through the bed is directly related to the bed material mass when the bed is fluidized. Pressure drop through the bed is approximately 0.75 to 1.0 in. wg (0.19 to 0.25 kPa) per inch (2.54 cm) of bed height. For biomass-fired systems, the bed inventory is set to a pressure drop of 30 to 36 in. wg (7.5 to 9 kPa). This is sufficient mass to prevent the bed temperature from significantly changing in a short period following a sudden large change of fuel properties, such as moisture content. For a coal-fired BFB, the bed height must ensure that the in-bed surface is submerged. If the bed height is below the top of the in-bed tube bundle, heat transfer decreases significantly and bed temperature increases. Pressure taps in the bed enclosure walls provide the measurement of the bed pressure drop over a known height.

Bed inventory can change over time. The ash and tramp material that enter with the fuel can increase the overall inventory when these materials are too large to be blown out of the bed. The bed material can break down due to mechanical or thermal attrition and leave the bed with the flue gas. Oversized particles, such as rocks and metal, are removed by the bed drain system and attrited material is replaced with new (makeup) material when necessary.

Bed density and heat transfer (in-bed)

The following equations are for the bed pressure loss and the overall in-bed heat transfer coefficient used to size in-bed surface.

Equation 2 is used to calculate the flue gas bed pressure loss across a bubbling bed.

$$\Delta P = (C) (1 - e) (\rho_s - \rho_g) (L) \quad (2)$$

where

ΔP = pressure loss

C = units conversion constant

e = bed void fraction

ρ_s = particle density

ρ_g = gas density at bed conditions

L = bed height

The void fraction, e , is primarily a function of particle size, particle density, bed gas velocity and gas viscosity. Various methods are used to predict bed voidage or void fraction, including those proposed by Leva,¹ Babu,² and Staub and Canada.³

The equation for the overall heat transfer coefficient for any tube bundle immersed in the bed is:

$$U_o = \frac{1}{\frac{1}{h_c + h_r} + R_m + R_{ft}} \quad (3)$$

where

- U_o = overall heat transfer coefficient, Btu/h ft² F (W/m² K)
 h_c = convection heat transfer coefficient for the tube bank, Btu/h ft² F (W/m² K)
 h_r = radiation heat transfer coefficient for the tube bank and walls, Btu/h ft² F (W/m² K)
 R_m = metal wall resistance, h ft² F/Btu (m² K/W)
 R_{ft} = tube fluid film resistance, h ft² F/Btu (m² K/W)

The convection heat transfer coefficient h_c is given by Equation 4. Two equations are used to evaluate the convective heat transfer coefficient (h_{st}) for an isolated or single tube depending upon average bed particle size. Equation 5 is a modified Vreedenberg⁴ form and applies primarily to beds with particles less than an 800-micron average. Equation 6, a Glicksman-Decker⁵ type, applies well when the average particle size in the bed exceeds 800 microns.

$$h_c = (h_{st}) (FAB) \quad (4)$$

$$h_{st} = 900 (1-e) \left(\frac{k}{d_t} \right) \left[\left(\frac{G d_t \rho_s}{\rho_g \mu} \right) \left(\frac{\mu^2}{D_p^3 \rho_s^2 g} \right) \right]^{0.326} (\text{Pr})^{0.3} \quad (5)$$

for $D_p < 800$ microns

$$h_{st} = \frac{k(1-e)}{D_p} \left[C_1 + (C_2) \left(\frac{3600 D_p \rho_g C_p V}{k} \right) \right] \quad (6)$$

for $D_p > 800$ microns

where

- h_{st} = convective heat transfer coefficient for a single tube, Btu/h ft² F
 e = bed voidage, dimensionless
 k = gas thermal conductivity, Btu/h ft F
 d_t = tube outside diameter, ft
 G = mass velocity or flux of the gas, lb/s ft²
 ρ_s = particle density, lb/ft³
 μ = gas viscosity, lb/ft s
 ρ_g = gas density, lb/ft³
 D_p = average particle diameter, ft
 g = acceleration constant, 32.2 ft/s²
 Pr = Prandtl number, dimensionless
 C_1 = experimental constant, dimensionless
 C_2 = experimental constant, dimensionless
 C_p = gas specific heat, Btu/lb F
 V = nominal bed gas velocity, ft/s

To convert the single-tube heat transfer coefficients to those suitable for tube banks, the following equation is applied:

$$FAB = \left[1 - \left(\frac{D_o}{S_n} \right) \left(\frac{2D_o + S_p}{D_o + S_p} \right) \right]^{0.25} \quad (7)$$

where

- FAB = bank arrangement factor (staggered arrangement only), dimensionless
 D_o = tube outside diameter
 S_n = tube spacing normal to flow
 S_p = tube spacing parallel to flow

Other variables are as defined previously. The equation for FAB is as derived by Gel'perin.⁶

For the radiation heat transfer component, h_r , the following equation can be used:

$$h_r = (\sigma) (\varepsilon) \left[(T_b)^4 - (T_w)^4 \right] / (T_b - T_w) \quad (8)$$

where

- σ = 0.1713×10^{-8} Btu/h ft² R⁴
 ε = average overall emissivity, dimensionless
 T_b = absolute bed gas temperature, R
 T_w = absolute wall temperature, R

The average overall emissivity in bubbling beds will be about 0.8 depending on wall emissivity and particle size. Typically, the overall heat transfer coefficient (Equation 3) for an in-bed tube bundle is between 40 and 60 Btu/h ft² F (227 and 341 W/m² K).

BFB emissions

Biomass firing can require the control of carbon monoxide (CO), volatile organic compounds (VOCs), NO_x, SO₂ and hydrochloric acid (HCl). The CO and VOCs are controlled by good fluidization, uniform fuel distribution and high-velocity overfire air nozzles, and are easily controlled below 100 ppm and 10 ppm respectively at 7% O₂ dry. NO_x is controlled by bed temperature control with a two-stage overfire air system and/or a selective non-catalytic reduction (SNCR) system (see Chapter 34). The staged overfire air system provides approximately 15 to 25% reduction, and the SNCR system provides approximately 55 to 60% reduction. SO₂ and HCl are controlled by adding limestone to the bed. SO₂ can be reduced 80% with a significant Ca/S molar ratio because of the very low sulfur content in most biomass fuels. However, the air flow through the bed must be high enough to complete the sulfation process. HCl is reduced by the excess lime leaving the bed and by using a fabric filter baghouse for particulate collection, providing the proper temperature and solids/gas contact. See the *CFB emissions* section for the limestone and sulfur reactions.

Coal firing requires SO₂ emission control. SO₂ reduction can be as high as 90% with a high-solids recycle rate from a multi-cyclone dust collector (MDC). NO_x is only moderately low from a coal-fired BFB boiler. The bed and furnace temperatures are low, which reduces thermal NO_x formation. However, air flow through the bed is at or above theoretical combustion air. Therefore, the NO_x reduction possible by staging the combustion air is not available for coal-fired BFB boilers. Typical NO_x values are 0.4 to 0.5 lb/10⁶ Btu (0.47 to 0.59 g/Nm³ at 7% O₂ dry). Additional information on NO_x control is provided in the CFB discussion.

Circulating fluidized-bed (CFB) boilers

Fig. 11 shows the main features of a circulating fluidized-bed boiler and Fig. 12 shows the furnace density profile. 50 to 70% percent of the total combustion air enters the furnace through the windbox and air distributor with the balance of the combustion air injected through overfire air (OFA) ports. A typical flue gas superficial velocity at full load, thereby converting the process to a circulating bed above the OFA ports, is 16 to 17 ft/s (4.9 to 5.2 m/s). While single particles reaching the furnace exit could be up to 2000 microns in size, typical average particle size (SMD) is 100 to 200 microns in the upper furnace and 300 to 400 microns in the dense bed.

Fig. 11 Typical circulating-bed boiler schematic.

Fig. 12 Typical atmospheric pressure circulating-bed furnace density profile.

The upward flow of solids decreases with increased furnace height as heavier particles recirculate back down the furnace, resulting in declining local density with increasing furnace height. In the B&W internal recirculation (IR-CFB) design, U-beam collectors (see Fig. 13) located in the top of the furnace enclosure collect most (up to 97%) of the solids that remain in the flue gas and return them to the furnace (recirculation) while passing the flue gas to the convection pass heat transfer surfaces. Most of the remaining solids entrained in the flue gas are then collected in multi-cyclone dust collectors (MDC) located in the backpass, providing up to 99.7% overall particle recycle to the furnace. The furnace enclosure is water-cooled membrane panels.

Unlike coal-fired BFB boilers, the dense bed does not contain any in-bed tube bundle heating surface. The furnace enclosure and in-furnace heating surfaces (water-cooled panels or water/steam wing walls) provide the required heat removal surface. This is possible because of the large quantity of solids that are recycled internally within the furnace. Because the mass flow rate of recycled solids is many times the mass flow rate of the incoming fuel, limestone, air and resultant combustion gas, the bed solids temperature remains relatively uniform throughout the furnace height. Also, the heat transferred to the furnace walls is adequate to provide the heat absorption required to maintain the target bed temperature of 1500 to 1600F (816 to 871C).

B&W IR-CFB boilers use a single chute-type feeder installed above the air distributor. The upward action of the bed inventory and the intense mixing of the incoming fuel, with the large mass of active inventory, adequately distributes the fuel as compared to the BFB.

The B&W coal-fired CFB uses the flat floor air distributor system shown in Fig. 7, with the horizontal water-cooled membrane panel floor and bubble caps discussed previously. Separate bed drains are provided.

Fig. 13 CFB primary particle collection system.

Key operating requirements for a CFB are controlling furnace temperature and maintaining the vertical temperature distribution within a relatively narrow temperature window for SO_2 absorption (a temperature-dependent process). To accomplish this, the solids inventory is distributed throughout the furnace with a large amount of solids recirculation. A major portion of the heat transfer in a CFB is controlled by the solids inventory in the furnace. Therefore, by changing furnace inventory, the heat transfer from the gas and solids to the furnace walls can be varied and the furnace temperature can be controlled.

Fig. 14 shows the side view of a B&W 150 MW IR-CFB utility unit designed to burn bituminous coal, providing main and reheat steam to the turbine island. The unit contains full-height, water-cooled panels and steam-cooled wing walls in the upper furnace. Boiler design is based on a completely water-cooled setting. This feature provides a gas-tight enclosure suitable for operating with a positive pressure in the furnace. The B&W IR-CFB has no high-temperature refractory-lined flues, and thus has reduced furnace refractory main-

tenance. This construction is possible due to the U-beam particle collectors integrated into the boiler enclosure.

Fuel and sorbent are fed to the bed through the lower furnace walls. Ash and spent sorbent are removed through drain pipes in the floor or lower walls. Solids collected by the U-beams are returned directly to the furnace and solids collected in the multi-cyclones are returned to the lower furnace through the rear wall.

Primary air enters the furnace through the air distributor and secondary air is injected above the air distributor.

The lower furnace above the air distributor is covered by a thin layer of highly conductive refractory held to the water wall tubes by pin studs. Refractory in the lower furnace protects the tubes from corrosion and erosion. The remaining portion of the furnace enclosure consists of bare tubes.

Selected key issues for CFB design include: furnace temperature and heat transfer control, solids separation, solids inventory control, and emissions.

Furnace temperature and heat transfer control

A CFB furnace contains a substantial solids inventory that is distributed over the entire furnace volume. Fig. 15 shows the solids flow streams. Although the solids concentration or solids bulk density in the upper portion of the furnace is much less than that in the furnace bottom, the solids still represent a significant mass fraction of the gas/solids mixture at any given furnace location. For example, in a pulverized-coal (PC) furnace, the combustion gas carries a portion of the fuel ash as it flows through. In general, this PC fuel ash represents less than 10 lb (4.54 kg) of solids per 1000 lb (454 kg) of gas. Also, the PC heat transfer from the gas to the furnace enclosure walls is predominately by radiation. In a CFB furnace, the amount of solids in the gas leaving the furnace may

Fig. 14 150 MW utility reheat internal recirculation circulating fluidized-bed (IR-CFB) boiler.

exceed 5000 lb (2268 kg) of solids per 1000 lb (454 kg) of gas. As a result, the heat transfer to the walls of a circulating bed includes significantly higher solids/gas convection and less solids/gas radiation.

Furnace temperature is primarily controlled by furnace heat transfer to the pressure parts. Most of the furnace heat absorption is accomplished by the surface located in the zone above the overfire air level. The main factor controlling furnace heat transfer rate is local solids bulk density; the greater the bulk density, the higher the heat transfer rate (see Fig. 16) and the lower the furnace exit gas temperature. Most of the solids leaving the furnace are captured by the U-beams and returned to the upper portion of the furnace by gravity.

A secondary solids collection device, or multi-cyclone, is located downstream in the convection pass. The solids from the multi-cyclone hoppers are returned to the furnace, and this recycle stream controls the solids bulk density in the upper furnace. As more multi-cyclone solids are returned to the furnace, the upper furnace bulk density increases and the furnace exit gas temperature is reduced. At steady-state boiler operation, a balance is maintained between the solids flow to the multi-cyclone hoppers and the solids

Fig. 15 CFB boiler solid material flows.

Fig. 16 Heat transfer coefficient versus density in a circulating fluidized bed for 170 and 250 micron mean diameter sand.

flow to the furnace, with any excess solids purged to the plant ash disposal system.

The solids recycle flow to the furnace can be limited by not having enough solids caught by the multi-cyclone. If, after reaching the maximum recycle rate, the upper furnace temperature is still high, increasing the primary air flow entrains more solids from the lower bed to the upper furnace. This increases the upper furnace bulk density and heat transfer rate. Changes in bed air flow can have an additional impact on the temperature in the lower furnace, which is fuel dependent. For some fuels, the increase in bed air flow causes an increase in the lower furnace temperature due to higher local fuel burnout. For others, the diluting effect of greater bed air flow prevails, causing the local temperature to decline.

Solids separation

A unique feature of B&W's CFB boiler design is the two-stage solids separation system shown in Fig. 15. The primary solids separator is an array of U-shaped beams (U-beams) located in the high temperature region at the furnace exit, with the secondary stage located downstream of the convection surfaces in a low gas temperature region, which varies from 400 to 900F (204C to 482C) depending upon unit design. As the gas flow passes the U-beams, the momentum of the particles causes a large fraction to be collected within the U-beam channel while the gas and remaining fine particulate fraction flows around the beams. As shown in Fig 13, the first two rows of U-beams are installed in the furnace (in-furnace) and the collected material is returned directly to the furnace, falling down along the rear wall. The second group of two to four U-beam rows after the furnace exit plane (external U-beams) collects additional material that falls down and also returns to the furnace.

The range of overall IR-CFB solids collection efficiency by particle size is shown in Fig. 17. The U-beams and MDC effectively collect and recycle all particles greater than 80 microns. The overall efficiency of the furnace and external U-beams is 97% or greater.

The fine particles fraction that passes the U-beams is collected in the secondary stage of solids separation, the mechanical dust collection multi-cyclones. These collect 90 to 95% of the remaining particles, for an overall collection efficiency of up to 99.7%.

Solids inventory control

The measure of furnace solids inventory is by air/flue gas pressure loss. The total furnace pressure loss or solids inventory is important. The typical overall furnace pressure loss is 42 in. wg (10.5 kPa). The upper furnace (above the air ports) pressure loss should be at least 17 in. wg (4.2 kPa), which results in adequate inventory in the upper furnace to maintain a constant furnace temperature profile.

Flue gas pressure loss in a CFB furnace conforms to the basic equation:

$$\Delta P = (C) (\rho_b) (L) \quad (9)$$

where

ΔP = pressure loss

C = units conversion constant

ρ_b = average bulk density in the furnace segment associated with L

L = height of the furnace segment of interest

To use Equation 9, a density profile as shown in Fig. 12 is developed. This curve is a function of many variables and has been derived from empirical data. The important variables are:

D_p = average particle size above the dense bed zone

D_{DB} = average particle size in the dense bed zone

V = nominal gas velocity

T = nominal furnace temperature

W_s = external solids flux, lb/h ft² (kg/s m²)

ρ_s = particle density

ϕ = particle shape factor

D_e = furnace equivalent diameter

For a fluidized bed to operate properly, there must be a continuous and sufficient supply of particles of the proper size distribution. If the particles are too coarse, the lower furnace bed will be too deep and defluidize, or slump. If the particles are too fine, they will blow out of the furnace making it impossible to maintain an adequate overall solids inventory. There is a range of bed particle size distribution that is needed to maintain a stable fluidized-bed process in the lower furnace and an adequate inventory in the upper furnace to control the furnace exit gas temperature. The supply and retention of these particles must be controlled to provide the required inventory.

The solids inventory is maintained by adding makeup material, typically limestone or sand of the proper size distribution or bed material that had previously been drained and saved. When firing coal,

limestone will normally be used for both the inventory control or makeup material. However, there needs to be enough sulfur to continuously generate material that will stay in the system. Calcium oxide is quite soft and does not hold up well in the fluidized bed environment. Once sulfated, the calcium sulfate is hard enough to maintain a solids inventory.

The amount of makeup material needed depends on whether, or to what degree, the fuel ash is contributing to the inventory and how well the inventory material maintains its integrity. For example, coal may contain very fine ash as well as large diameter particles or small rocks. A portion of the larger particles will remain in the lower portion of the furnace and provide stable fluidization in the dense bed portion. The small particles can be so small that the U-beams and multi-cyclone dust collector do not capture and return them back to the process. The intermediate size particles blow out of the dense bed, are large enough to be captured by the U-beams or dust collector, and return to the furnace for solids inventory. If the coal ash and reacted limestone particles continuously provide the proper amount of large and intermediate size particles, purchased makeup material for inventory control will not be required.

CFB emissions

Sulfur dioxide emissions control When sulfur-bearing fuels burn, most of the sulfur is oxidized to SO₂. Limestone can be added as a sorbent for sulfur capture. When limestone is added to the bed, it undergoes a transformation called calcination and then reacts with the SO₂ in the flue gas to form calcium sul-

Fig. 17 Overall grade efficiency range of B&W IR-CFB solids collection system.

fate (CaSO_4) through *sulfation*. The calcining reaction is endothermic and is described by:

Once formed, solid CaO (lime) reacts with gaseous SO_2 and oxygen exothermically to form CaSO_4 according to the following reaction:

SO_2 reductions of 90 to 95% are typically achieved in a circulating bed with calcium to sulfur (Ca/S) mole ratios of 1:1.8 to 1:2.5, depending on the sulfur content of the fuel and the reactivity of the limestone. The lower the sulfur concentration in the fuel, the greater the calcium-to-sulfur mole ratio must be for a given removal in the furnace. Systems external to the CFB process can be applied to further enhance SO_2 capture and limestone utilization.

Certain temperature limitations affect the sulfur capture process. If the furnace temperature is below 1470F (799C), calcination of CaCO_3 is not complete and results in less CaO yield from a given amount of limestone, thereby increasing limestone consumption. If the furnace temperature is above 1650F (899C), CaSO_4 dissociates to CaO and SO_2 which again reduces sulfur capture efficiency. Therefore, it is important to maintain the furnace within a certain temperature window to reach minimum limestone consumption and not exceed a specified level of SO_2 emissions. This is a primary reason the IR-CFB combustion process controls furnace temperature over the entire furnace height.

Limestone properties such as reactivity, attrition, and size distribution have a major effect on limestone consumption. These parameters are carefully considered when providing recommendations for limestone selection and preparation. The IR-CFB process also allows for post-furnace SO_2 capture through various flash recirculation schemes.

Nitrogen oxides emissions control The nitrogen oxides present in the flue gas come from two sources: the oxidation of nitrogen compounds in the fuel (fuel NO_x) and the reaction between nitrogen and oxygen in the combustion air (thermal NO_x). See Chapter 34. By maintaining the furnace temperature below 1650F (899C), thermal NO_x formation is low in CFB boilers.

Fuel NO_x can be reduced through combustion controls. The following operating parameters have a significant effect on emissions:

1. lowering primary air,
2. lowering overall excess air, and
3. minimizing limestone input or Ca/S molar ratio.

When burning fuels containing nitrogen, volatile nitrogen is released in a very unstable monatomic state. The monatomic nitrogen atom will either combine with another nitrogen atom to form N_2 , or will react with oxygen to form NO_x . Part of the NO_x can be reduced back to N_2 when NO_x is in the presence of

char and/or CO in a reducing atmosphere. Reducing the primary air to substoichiometric conditions increases the concentration of carbon and CO in the lower furnace and limits the availability of oxygen in the presence of monatomic nitrogen. This effect is more pronounced for high-volatile fuels.

Limestone is a catalyst for the nitrogen and oxygen reaction, which increases the fuel NO_x emissions. Controlling to a low Ca/S ratio minimizes this reaction.

Higher overall excess air means higher oxygen concentration in furnace gases and increased NO_x emissions. Limiting the overall excess air below 3% O_2 minimizes NO_x formation while providing low carbon loss due to high solids recycle to the furnace.

The combination of low temperatures and staged combustion allows fluidized-bed boilers to operate with low NO_x emissions. Typical uncontrolled values are within 0.1 to 0.15 lb/10⁶ Btu (126 to 188 mg/Nm³ at 6% O_2 dry) for coal-fired CFB boilers. Further NO_x can be controlled to lower values through the use of a selective noncatalytic reduction (SNCR) system consisting of ammonia injection near the U-beam elevation (see Chapter 34).

Carbon monoxide and hydrocarbons When designing a boiler, it is necessary to maximize combustion efficiency by minimizing unburned carbon and the quantity of CO and hydrocarbons in the flue gas. This is accomplished by choosing the proper number of fuel feed points, by proper design of the overfire air system, and by providing sufficient furnace residence time for combustion. Typical flue gas concentrations are less than 0.15 lb/10⁶ Btu (188 mg/Nm³) for CO and 0.005 lb/10⁶ Btu (6.3 mg/Nm³) for hydrocarbons, both at 6% O_2 dry, in a CFB boiler burning coal.

Pressurized fluidized-bed combustion (PFBC)

BFB and CFB boilers discussed above operate effectively at atmospheric pressure and are generally referred to as atmospheric fluidized-bed combustors (AFBC). Pressurized fluidized-bed combustors (PFBC) are an outgrowth of this technology. The underlying concept is to create a combined cycle plant where a coal-fired system with a steam turbine is combined with a gas turbine to increase overall cycle efficiency. A simplified schematic and process explanation is shown in Fig. 18. In its simplest form, a compressor pressurizes the combustion air to 12 to 20 atmospheres (174 to 232 psi or 1.2 to 2.0 MPa). This air is then fed to a pressure vessel that fully encloses a fluidized-bed combustor where coal is burned in a bed of limestone (removing the SO_2) to produce steam plus a pressurized gas stream. The steam is used in a conventional steam turbine cycle to generate part of the electric power, and the pressurized gas is cleaned sufficiently of particulate and other key contaminants and used in a gas turbine to generate the balance of the electric power and compressed air for the combustion process.

Three basic cycle configurations have been proposed: 1) turbocharged cycle, 2) combined cycle, and 3) advanced combined cycle. The major differences involve how the gas from the pressurized fluidized-bed combustor is treated prior to use in the gas tur-

Fig. 18 Simplified combined cycle PFBC diagram and process overview.

bine. In the turbocharged cycle, the gas is cooled to between 800 and 1000F (427 and 538C) so that current state-of-the-art hot gas cleanup technology can be used to remove the particulate and other contaminants. This increases the steam production capacity but reduces the power from the gas turbine. This cycle incorporates more conventional technology at the expense of cycle efficiency. In the full combined cycle system, advanced hot gas cleanup technology is used to clean the gas from the fluidized bed at approximately 1580F (860C) so that hotter and higher pressure gas can be sent to the gas turbine. In this case, 80% of the power is produced in the steam turbine and the balance is produced in the gas turbine. Finally, in the advanced combined cycle, a partial coal gasification process is added. The char from gasification is burned in the fluidized-bed combustor. The clean gas leaving the PFBC boiler, which still contains oxygen, can be mixed with the fuel gas (from the partial gasifier) and then burned in a gas turbine combustor at temperatures of 1800 to 2500F (982 to 1371C) for even higher efficiencies.

The bubbling fluidized bed operating inside the pressure vessel behaves basically the same as the atmospheric fluidized bed although the higher pressure (and higher gas density) combustion affects three key areas: fluidization, heat transfer, and combustion. The overall effect is to provide a very compact and cleaner combustion system. A more complete summary of this

technology is provided in the 40th edition of this text.⁷

B&W designed, fabricated and installed a 70 MW PFBC system as a demonstration to repower one unit at the American Electric Power, Ohio Power Company Tidd plant near Brilliant, Ohio, in the United States (Fig. 19). The design was based on the combined cycle configuration utilizing the bubbling fluidized-bed combustion process. This PFBC combined cycle system consisted of a gas turbine, boiler, and associated systems including hot-gas cleaning, load control, fuel

Fig. 19 Pressure vessel arrival at Tidd site.

preparation and feeding, sorbent preparation and feeding, and ash removal. Many of these systems were either partially or totally contained in the pressure vessel. This system operated on an experimental basis in the 1990s to demonstrate the feasibility of the process and to define and overcome the challenges in a new first-of-a-kind engineered power system.

PFBC technology offers the prospect of improving cycle efficiency and reducing emissions while reducing power plant size and initial plant cost. In concept, PFBC boiler modules could be barge-shipped to sites effectively ready for installation or in a few large pieces to minimize erection expense. This technology awaits further development and evaluation.

Chapter 18

Coal Gasification

What is gasification

Coal gasification is a process that converts coal from a solid to a gaseous fuel through partial oxidation. Once the fuel is in the gaseous state, undesirable substances, such as sulfur compounds and coal ash, may be removed from the gas by various techniques to produce a clean, transportable gaseous energy source.

When coal is burned, its potential chemical energy is released in the form of heat. Oxygen from the air combines with the carbon and hydrogen in the coal to produce gaseous carbon dioxide (CO₂) and water plus thermal energy. Under normal conditions, when there is sufficient oxygen available, nearly all of the chemical energy in the coal is converted into heat and the process is called *combustion*.

However, if the available oxygen is reduced, less energy is released from the coal and new gaseous reaction products appear from the incomplete combustion. These byproducts, including hydrogen (H₂), carbon monoxide (CO) and methane (CH₄), contain unreleased or potential chemical energy which can be transported and used to provide energy to other processes such as combustion to power a gas turbine, chemical synthesis for use in fuel cells, or as a substitute for natural gas. If the objective is to maximize the chemical energy in the gas byproducts, it would appear logical to continue decreasing the available oxygen. However, a point is reached where an increasing percentage of the carbon in the coal remains unreacted, and less is converted to gas, rendering the process inefficient. When the oxygen supply is controlled such that both heat and a new gaseous fuel are produced as the coal is consumed, the process is called *gasification*.

Coal gasification has been practiced for more than 200 years and until the 1940s was a major industry. The most significant advances leading to current gasification technologies occurred during World War II in Germany, where coal was used to derive liquid fuels for military use. Following this, the increased availability of natural gas and petroleum products in the industrialized nations resulted in a decline of gasification until the oil embargo of 1973 and concerns about natural gas supply. Major efforts to develop gasification systems to produce synthetic natural gas (SNG) and liquid fuels were made in the United States

(U.S.) and Europe during the 1970s and 1980s, but declines in gasoline and natural gas prices curtailed many of these efforts as economic justification declined. Recently, a desire for high-efficiency electric power generation to reduce emissions, availability of high-performance gas turbines, and the introduction of fuel cells have resulted in a resurgence of interest in gasification systems.

By recovering waste heat from a gasifier and gas turbine exhaust for steam production, a gas turbine (Brayton) cycle and steam turbine (Rankine) cycle can be efficiently combined into an *integrated gasification combined cycle* (IGCC). Although technically viable, this approach to power generation from coal has been demonstrated but not applied commercially because conventional combustion systems are less costly and less complicated. However, further development continues as increasingly stringent environmental regulations and interest in production of hydrogen for fuel cells and other co-products have renewed interest in IGCC.

Basic gasification reactions

Combustible gases such as carbon monoxide and hydrogen are the most common products of incomplete combustion. With partial combustion, only a fraction of the carbon in the coal is completely oxidized to CO₂. The heat released provides most of the energy necessary to break chemical bonds in the coal and raise the products to reaction temperature.

Although the chemistry of coal gasification is complex, the following are the major reactions involved:

Exothermic reactions – releasing heat

Endothermic reactions – absorbing heat

Many fuel and operating variables, such as fuel composition, operating pressure, and steam and oxygen inputs influence the final gas composition. Gasifiers are designed for pressures ranging from atmospheric to 600 psi (4140 kPa) and higher. The methanation reactions are important in lower temperature systems and are favored by high pressures as shown in Fig. 1.¹ The other reactions are more prominent in high temperature, lower pressure systems. The combination of these reactions is autothermic, meaning sufficient heat is initially released by the carbon combustion reactions to provide energy for the endothermic reactions.

Sulfur in coal is converted primarily to hydrogen sulfide (H₂S) and a small amount of carbonyl sulfide (COS). High temperatures and low pressures favor coal nitrogen conversion to N₂, while the opposite conditions favor some ammonia (NH₃) formation and small amounts of hydrogen cyanide (HCN). In lower temperature processes [$< 1200^{\circ}\text{F}$ ($< 649^{\circ}\text{C}$)], tars, oils and phenols are not destroyed and therefore exit with the raw gas. Many other minor impurities are produced depending on their presence in the raw fuel. These include chlorides, vaporous alkali species and heavy metals. Heavy hydrocarbons are also produced in lower temperature gasifier processes.

The gasification reactions occur in two main stages: devolatilization and char gasification. Devolatilization is a transition stage in which coal becomes char, or fixed carbon, as the temperature rises. Weaker chemical bonds are broken and tars, oils, phenols and hydrocarbon gases are formed. The char that remains after devolatilization is gasified by reaction with oxygen, steam, carbon dioxide and hydrogen.

Fig. 1 Methane formation with pressure.¹

The type of gasification process has a strong bearing on the devolatilization products. In fixed-bed or moving-bed gasifiers (see below), these products exit the gasifier with the product gas due to the low temperatures and lack of oxygen. In fluidized-bed and entrained-flow processes, uniform high temperature causes hydrocarbon cracking, or breaking down the more complex molecules to simpler ones. Also, oxygen is available to react with the devolatilization products, producing H₂, CO and CO₂. These reactions are most complete in an entrained-flow process.

The basic objective of gasification is to convert coal into a combustible gas containing the maximum remaining heating value. If the gas is used for chemical synthesis rather than fuel for combustion, its composition must be adjusted for the stoichiometry of the synthesized product. Hydrogen for synthesis gas (syngas) production must be provided by the steam-carbon reaction or by the water-gas shift. The influence of the end product may affect the choice of gasification process. The water-gas shift reaction can be promoted by supplying extra steam in the fuel bed or in a separate catalytic conversion stage downstream. This produces increased hydrogen. Where hydrogen is the only product required, CO₂, which is an inevitable product of splitting water by reaction with carbon, must be removed. Limestone may also be injected along with the coal and/or steam to capture sulfur.

In the case of synthetic natural gas (SNG) production with low temperature, high pressure moving-bed processes, much of the methane can be produced in the fuel bed by carbon hydrogenation (Reaction 5). However, all of the methane can not be produced by direct hydrogenation. Some must be produced indirectly in a separate catalytic stage, e.g., by Reaction 4.

Oxygen for the gasification process can be supplied either in pure form (oxygen-blown) or in air (air-blown). There are advantages and disadvantages to both methods. Oxygen-blown gasification results in smaller components, higher cold gas efficiency and purer gas composition, but requires additional oxygen separation and safety systems. The cold gas efficiency is defined as the ratio of the heating value of sulfur-free gas to coal heat content expressed as:

$$\frac{\text{HHV of sulfur-free gas at } 60^{\circ}\text{F}}{\text{HHV of feed coal}} \times 100 \quad (9)$$

where

HHV = higher heating value

Raw gas from an oxygen-blown unit consists primarily of CO, H₂, CO₂, CH₄ and H₂O, while N₂ is a major constituent when air is used as the oxidant.

Coal gas has traditionally been classified by heating value, expressed in Btu per dry standard cubic foot [Btu/DSCF (MJ/Nm³)].¹ Air-blown gasification produces a low Btu gas due to nitrogen dilution. This gas ranges from 90 to 200 Btu/DSCF (3.5 to 7.9 MJ/Nm³). Oxygen-blown units produce a medium Btu gas at the lower end of the 270 to 600 Btu/DSCF (10.6 to 23.6 MJ/Nm³) range. Post-gasifier shift and methanation reactions are required to produce heating values at

the higher end of the medium Btu range and ultimately to produce high Btu gas of approximately 1000 Btu/DSCF (39.3 MJ/Nm³). High Btu gas is pipeline quality and is therefore referred to as synthetic natural gas (SNG).

Raw gas composition as a function of gasifier type and oxidant is listed in Table 1. Heating values vary widely between product gases from air- and oxygen-blown moving-bed gasifiers, which can influence the combustion characteristics of the gas. Raw gas from a moving-bed gasifier contains significant quantities of ammonia and heavy condensable organics such as tars, oils and phenols. It also has a higher heating value than gas from entrained-flow processes due to the increased methane content. The two advanced entrained-flow gasifiers produce negligible quantities of organics due to their high temperature operation. The slurry-fed process produces a product gas lower in CO and higher in H₂, CO₂ and H₂O compared to the dry feed process. The data presented in Table 1 also contrast different gasification conditions.

Gasifier types and applications

Gasifier types (see Table 2) are described in terms of two parameters: 1) the direction of flow of the incoming oxidant relative to the outlet gas flow (up-flow, down-flow and cross-flow), and 2) the relative velocity of the solids (fixed or moving, fluidized, entrained, and transport).

Up-flow (countercurrent)

The oldest and simplest type of gasifier is the up-flow (countercurrent) gasifier as shown in Fig. 2a and 2d. The oxidant enters at the bottom of the gasifier vessel and the gas leaves at the top (up-flow), while the fuel flows in the opposite direction (countercurrent) of the gas. The combustion reactions occur near the grate at the bottom, followed by reduction reactions somewhat higher up in the gasifier. In the upper part of the gasifier, heating and pyrolysis of the feedstock occur as a result of heat transfer by forced convection and radiation from the lower zones. The tars and volatiles

produced during this process remain in the gas stream while ashes are removed from the bottom.

The advantages of up-flow gasifiers are: 1) simplicity, 2) fuel flexibility, 3) high cold gas efficiency, and 4) high char burnout and internal heat exchange leading to low gas exit temperatures. Major drawbacks are: 1) potential for *channeling* that can lead to oxygen breakthrough and dangerous, explosive conditions, and 2) difficulty in disposing of tar-containing condensates resulting from the gas cleaning (except when the gas is used for direct heat applications where the tars are burned).

Down-flow (co-current)

In down-flow (co-current) gasifiers, the oxidant and fuel are introduced at the top of the gasifier. The product gas and ash or slag are removed at the bottom of the vessel. This solves the problem of tar entrainment in the gas stream. The down-flow configuration is shown in Fig. 2b. Depending upon where the oxidant is introduced (below the coal feed or with the coal feed as shown), there may be some or no (plug-flow) mixing of the gas with the particles.

As the gas flows downward, the acid and tarry distillation products from the fuel pass through the bed of burning char where they are converted to hydrogen, carbon dioxide, carbon monoxide and methane gases. The efficiency of this conversion depends on the temperature and residence time.

The advantage of down-flow gasifiers is the potential to produce tar-free gas. However, it is very difficult to achieve this goal over the entire operating range and turndown ratios of 3:1 are common; 5-6:1 is considered excellent. There are also some environmental advantages because the down-flow gasifiers produce a lower level of organic compounds in the condensate. The disadvantages are: 1) reduced fuel flexibility due to co-current flow, 2) greater susceptibility

to slagging with high ash fuels, 3) lower cold gas efficiency due to poorer internal heat exchange resulting in a lower heating value of the gas, and 4) the need to maintain uniform high temperatures over the gasifier cross-sectional area.

Cross-flow

Cross-flow gasifiers, shown in Fig. 2c, are an adaptation for gasification of high fixed carbon, low volatile coals or char. Char gasification produces very high temperatures [2730F (1499C) and higher] in the oxidation zone, which can be a problem for materials of construction. In cross-flow gasifiers, insulation against these high temperatures is provided by the fuel (char) itself. Due to cross-flow gasifiers' inability to convert tars, only low volatile fuels can be used, making this type of gasifier unsuitable for power generation applications.

Fixed (Moving) bed

In a fixed-bed gasifier (Fig. 2a), also referred to as moving-bed, a column or bed of crushed coal is supported by a grate while the oxidant flows upward through the coal column at a velocity relative to the particle size and insufficient to lift or fluidize the particles. The gasification process involves a series of countercurrent reactions. At the top, the coal is heated and dried while cooling the product gas. The coal is further heated and devolatilized as it descends through the carbonization zone. Below this area, the devolatilized coal is gasified by reaction with steam and CO₂. The highest temperatures are reached in the combustion zone near the bottom of the gasifier. The char-steam reaction together with the presence of excess steam keeps the temperature in the combustion zone below the ash slagging temperature. Both the Lurgi (dry ash) and the British Gas/Lurgi (slagging) designs are fixed-bed gasifiers.

Fig. 2 Typical reactors for coal gasification (courtesy of Electric Power Research Institute).^{2,3}

The distinguishing characteristics of a fixed-bed gasifier are:

1. produces hydrocarbon liquids such as tars and oils,
2. has limited ability to handle fine particles,
3. requires special steps to handle caking coals,
4. produces relatively high gas methane content, and
5. has low oxidant requirements.

The main differences among these gasifiers are the ash conditions (dry or slugging) and design provisions for handling fines, caking coals and hydrocarbon liquids. The first full scale fixed (moving)-bed coal gasification plant was constructed in 1936. Since then, 164 Lurgi gasifiers have been built by a number of companies. All of these gasifiers except one have been oxygen-blown units. The SASOL plant in South Africa uses 97 units to produce motor fuel from coal. In addition, the Dakota Gasification Company (Great Plains Synfuels Plant) at Beulah, North Dakota, has 14 gasifiers.

The configuration of the moving-bed dry ash gasifier is shown in Fig. 3. It is a high pressure cylindrical unit, operating at 350 to 450 psig (2410 to 3100 kPa). The main gasifier shell is surrounded by a cooling water jacket. Sized coal enters the top through a lock hopper and moves down the bed under the con-

trol of a rotating grate. The temperature in the combustion zone near the bottom is about 2000F (1093C), whereas the gas leaving the drying and devolatilization zone near the top is approximately 1000F (538C). This moving-bed process is capacity limited. Almost all of these units have a diameter of 13.1 ft (4 m) and a nominal dry gas capacity rating of 33,333 SCFM (14.9 Nm³/s). This is equivalent to about 650 t/d (590 t_m/d) of MAF (moisture- and ash-free) coal. Lurgi and SASOL are operating a 16.4 ft (5 m) diameter Mark V gasifier having a capacity of 1000 t/d (907 t_m/d) and generating about 50,000 SCFM (22.35 Nm³/s).

Fluidized bed

In a fluidized-bed gasifier (Fig. 2d), the oxidant flows upward through the feed coal particles at a sufficient velocity relative to the particle size that, although a discrete bed level exists, the particles are suspended or fluidized by the gas flow, producing good mixing and constant motion. The fluidized bed is maintained below the ash fusion temperature to avoid clinkers which could cause defluidization. (A clinker is a large solid mass of coal ash agglomerated by ash slugging.) Char particles entrained with the hot, raw gas are recovered and recycled to the gasifier. Fluid-

Fig. 3 Moving-bed dry ash gasifier (courtesy of Dravo Corporation).

ized-bed gasifiers, such as KRW's (Kellogg Rust Westinghouse) design, are always up-flow.

The distinguishing characteristics of a fluidized-bed gasifier are:

1. has large char recycle,
2. requires special steps to obtain high carbon conversion of high rank coals,
3. requires special steps to handle caking coals,
4. features uniform and moderate temperature, and
5. requires moderate oxygen and steam inputs.

The main differences among fluidized-bed gasifiers are the ash conditions (dry or agglomerated) and design provisions for char recycle. An agglomerated fluidized bed contains a hot zone where the ash particles are caused to cluster into small pellets prior to removal. Agglomerated ash operation enables the gasification of high rank coals. Dry ash fluidized-bed gasifiers operate most efficiently on low rank coals.

The fluidized-bed gasifier was the first commercial coal gasification unit and was the initial application of fluidized-bed technology. The first of these gasifiers was put into operation in Leuna, Germany in 1926. Since then, about 70 Winkler gasifiers have been constructed worldwide. However, these units were superseded by entrained-flow gasifiers and by pressurized moving-bed units. Only three of these gasifiers at two plants remain in operation today.⁴ Low capacity and high operating costs have limited further use of the conventional Winkler gasifier.

Entrained flow

In an entrained-flow gasifier (Fig. 2b) fine coal particles are fed with the oxidant in such a way that they are suspended, or almost sprayed, co-currently into the process and mixed similar to a pulverized coal burner. The fine pulverized coal particles react with steam and oxidant with very short residence time. They can be up-flow (usually slurry fed) such as the ConocoPhillips/E-Gas [formerly Destec (DOW)], Uhde (Prenflo) and The Babcock & Wilcox Company (B&W) processes or down-flow such as the General Electric (GE)/Texaco and Royal Dutch Shell processes.

An entrained-flow gasifier has the following characteristics:

1. can gasify all coals regardless of rank, caking characteristics or amount of fines,
2. requires substantial heat recovery due to the large amount of sensible heat in the raw gas,
3. is a high temperature slagging operation,
4. has a large oxidant requirement, and
5. requires special steps to avoid molten slag carryover to downstream heat recovery surfaces.

The main differences among entrained-flow gasifiers are the coal feed system (slurry or dense phase) and the design configurations for raw gas cooling and sensible heat recovery. This unit is also called a *suspension* gasifier because it consists of a two-phase system of finely divided solids dispersed in a gas. No distinct bed level exists.

The entrained-flow technology began as an atmospheric pressure process for producing synthesis or fuel gas from solid or liquid carbonaceous fuels. The original bench-scale development of this gasifier type was done by Dr. Friedrich Totzek in the late 1930s while working for Heinrich Koppers GmbH of Essen, Germany. The process was jointly piloted in the U.S. by H. Koppers GmbH; Koppers Company, Inc. of Pittsburgh; and the U.S. Bureau of Mines. The first commercial entrained-flow gasification plant was built in France in 1949. Since then, 39 units have been built in various countries with most still in operation. The primary application is hydrogen production for ammonia synthesis.

Fig. 4 shows the entrained-flow atmospheric pressure gasifier. The coal is pulverized and fed by screw conveyors through opposing burners into a horizontal, elliptically-shaped gasifier. The fuel is oxidized, producing a flame zone temperature of about 3500F (1927C). Heat losses and endothermic reactions reduce the gas temperature to about 2700F (1482C). The hot product gas is further cooled by direct water quenching to about 1700F (927C) to solidify entrained liquid slag particles before they enter the heat recovery (waste heat) boiler.

The cold gas efficiency of the original Koppers-Totzek oxygen-blown gasifier was 67%. Although this appears to be low, an additional portion of the coal's energy was converted into heat which was recovered by the cooling jacket and heat recovery boiler. Combining these energy sources yielded an overall efficiency of 85%. More recent improvements in modern entrained-flow gasification systems can increase the

Fig. 4 Entrained-flow gasifier (courtesy of Dravo Corporation).

total efficiency into the high 90s. Most gasifiers use a design featuring two opposing burners. These have a total capacity of 10,583 SCFM (4.73 Nm³/s), which is equivalent to about 230 t/d (209 t_m/d) of MAF coal. Two plants with four headed designs have about twice this capacity each. Current demonstration plants are exceeding 2500 t/d (2268 t_m/d) coal.

Transport

A transport gasifier is a circulating fluidized-bed gasifier in which the oxidant flows upward through the feed coal particles at a velocity high enough that no discrete bed level exists. The particles are fully suspended or highly fluidized by the gas flow, producing excellent mixing. As with the fluidized bed, the process is maintained below the ash fusion temperature to avoid clinkers which could cause defluidization. Due to the greater degree of mixing and the circulating loop inherent in the design, and particle size, char burnout is excellent. This type of gasifier, initially developed by MW Kellogg (now Kellogg Brown & Root), is now being tested at the U.S. Department of Energy's (DOE) Power Systems Development Facility (PSDF) near Wilsonville, Alabama. (See Fig. 5.)

The distinguishing characteristics of a transport gasifier are:

1. high carbon conversion (> 95%),
2. cold gas efficiency of 70-75%,
3. handles a broad range of coals,
4. uniform and moderate temperature [1600F (871C)], and
5. requires moderate oxygen and steam inputs.

Fig. 5 U.S. Department of Energy's (DOE) Power Systems Development Facility.

Major gasifier process developers

GE/Texaco

The GE/Texaco entrained-flow coal gasification process is shown in Fig. 6. The downflow gasifier is fed with a coal-water slurry of 60 to 65% solids by weight, and oxygen. It operates at up to 900 psi (6205 kPa) and is refractory lined. The raw gas leaves the unit at 2300 to 2700F (1260 to 1482C) and is separated from the slag. The syngas is cooled by a radiant boiler, followed by a convection boiler, which generates 1600 psi (11,031 kPa) saturated steam. These boilers are called *syngas coolers*.

There are several options for gas cooling. One is to use the radiant and convection coolers (as shown in Fig. 6) which results in maximum efficiency. A second

Fig. 6 Typical entrained-flow process (courtesy of Texaco Development Corporation).

involves replacing the radiant cooler with a direct water syngas quencher and eliminating the convection cooler, which minimizes cost. A third option is to use the radiant cooler only, which provides partial recovery of the syngas heat and is intermediate in efficiency and cost.

The cold gas efficiency for the process shown in Fig. 6 is 77%. If the energy of the steam produced is added to that of the fuel gas, the unit efficiency increases to 95%. Overall carbon conversions of 96.9% and 97.8%, respectively, are obtained with Illinois No. 6 and Pittsburgh No. 8 coals.^{2,5} Carbon conversion is defined as the percent of carbon in the coal converted to gases or liquid (tar) products.

Royal Dutch Shell

The Shell gasification process is shown in Fig. 7. The coal is pulverized, dried, and fed to lock hoppers for pressurization. An operating pressure of 350 psig (2410 kPa) is lower than that of the GE/Texaco unit. The membraned walls are water cooled. Burners are opposed and in a reactor configuration similar to that of the Koppers-Totzek design. The raw gas leaves the unit at 2500 to 3000F (1371 to 1649C) and most of the coal ash exits through the slag tap in molten form. The syngas contains a small quantity of unburned carbon and a significant fraction of molten ash. To keep the ash particles from sticking together, the hot exiting gas is quenched with cold recycle gas. Further cooling takes place in the syngas cooler, consisting of radiant and convective sections. Some steam superheating is achieved with the hot, raw syngas.

The Shell gasifier cold gas efficiency is at least 80%. The combined chemical and thermal energy recovery is at least 97%. Feed coal drying reduces the net efficiency for low rank coals. The efficiency is also reduced when direct coal combustion is not used for drying. The effect of coal drying could lower the efficiency to approximately 94%. Finally, the net efficiency is about 84% when the energy required for oxygen production is also included.^{2,6} Better than 99% carbon burnout has been obtained for most coals.⁷

ConocoPhillips/E-Gas [Destec (Dow)]

The ConocoPhillips/E-Gas gasifier is a two-stage, slurry feed, entrained-flow, slagging gasifier unit. Coals are slurried with water to produce a solids loading of 50 to 55% by weight. About 75% of the slurry is gasified with oxygen in the first stage. The hot gas leaving this stage at 2400 to 2600F (1316 to 1427C) is used to gasify the remaining 25% of the coal in the second stage. Both stages are refractory lined and uncooled. The first stage reactor is similar to the Koppers-Totzek unit with two opposing burners and slag removal. This arrangement assures high carbon conversion and optimal slag removal.

The direct injection of coal slurry at the second stage entrance quenches the hot gas and gasifies the additional coal, providing an exit gas temperature of about 1900F (1038C). This eliminates the need for a radiant boiler and requires reduced heat recovery downstream. There is no requirement for quench recycle gas or the compression energy associated with recy-

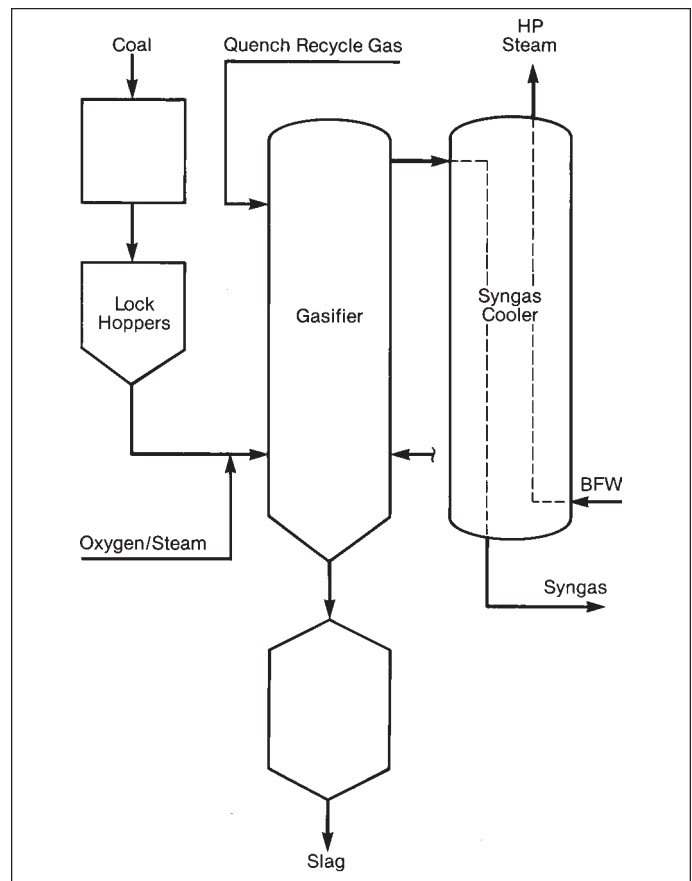

Fig. 7 Typical process with syngas cooler (courtesy of Synfuels Business Development, a division of Shell Oil Company).

cling large volumes of cooled gas. The ConocoPhillips/E-Gas unit includes a fire tube boiler followed by a steam superheater and economizer to recover heat from the raw product gas.⁸

British Gas/Lurgi

Lurgi has worked with the British Gas Corporation (BGC) in developing the BGC/Lurgi process. This gasifier, shown in Fig. 8, is very similar to the conventional dry ash Lurgi process. The key difference is that the BGC/Lurgi process slags the coal ash. This process partly alleviates the coal acceptability problems associated with the dry ash Lurgi process by permitting the use of higher rank, low ash coals. Tars and oils are re-injected, providing a cold gas efficiency of 88%. The value rises to about 90% when considering additional hydrocarbon liquids.² A substantial advantage of slagging the coal is that the steam requirement is only about 15% of that for the conventional Lurgi process when gasifying bituminous coal.

Winkler

The High Temperature Winkler (HTW) process is an extension of the old Winkler fluidized-bed technology. The HTW process is being developed by Rheinbraun (Rheinische Braunkohlenwerke AG) in Cologne, Germany in cooperation with its engineering partner, Uhde GmbH, Dortmund. The dry ash gasification of reactive German brown coal along with peat and wood is being researched. Recycling of fines

ded and covered with refractory to maintain the high temperatures necessary to keep the slag fluid. In the upper portion of the gasifier (the freeboard zone), the tubes are exposed to provide maximum cooling. Use in Cyclone wet bottom boilers (see Chapter 15) has proven the durability of this construction. This gasifier, featuring a 2 in. (51 mm) thick vessel wall, is designed for relatively low pressure operation [50 psig (345 kPa)]. Temperature in the combustion zone is about 3400F (1871C) and the gas leaving the unit is at 1800F (982C).

The advantages of the dry feed, entrained-flow gasifier include:

1. Insensitivity to coal characteristics – Unlike moving-bed or fluidized-bed gasifiers, it can accept caking coals, fines and any rank coal. With dense-phase coal feed, as contrasted to slurried coal, it can accommodate the wide range of coal moisture contents.
2. Larger unit size potential due to ease of handling and mixing of the coal – Basically, as in pulverized coal-fired boilers, unit size can be increased by adding burners. The higher throughput velocity allows a high quantity of coal per hour to be treated in a given size gasifier.
3. Rapid control response – This is due to its low solids inventory compared to other gasifiers.
4. Easy disposal of the dense granular slag – Similar material from slag-tap boilers has been used as road fill. It does not create a dust or water pollution problem.
5. High yield of synthesis gas ($\text{CO} + \text{H}_2$) – Conversely, the yield of CO_2 and H_2O is low. For example, the dry-bottom, moving-bed product gas can contain 60% (by volume) H_2O and 10% CO_2 as contrasted to about 2% each of these components in a dry feed entrained gasifier.
6. No hydrocarbon liquids generated – Tars, phenols and oils are absent. Special handling problems associated with production of such chemicals and special treatment requirements for scrubber water are avoided. Re-injection of unreacted char is considerably simpler than such tar-like streams.
7. High reliability (no moving parts in furnace) – The requirement for mechanical devices, such as a rotating grate, is eliminated because the pulverized coal is dispersed through the gasifier and rapidly heated through the plastic temperature range without coming into contact with adjacent coal particles.
8. Reduced maintenance due to the cooled membrane wall construction – The durability of the studded tube, refractory-coated gasifier cooling enclosure has been proven in Cyclone furnace and slag-tap boilers. This contrasts to the higher maintenance requirements of non-cooled, refractory-lined gasifiers.

The disadvantages are:

1. May not be economical for very small sizes – With its high gasification capacity for a given size vessel, fewer gasifiers are needed to supply the required gas. Scaledown would require a detailed evaluation of the scaling factors for the pressure vessel, up front coal preparation plant (pulverizers), and downstream heat recovery equipment.

2. Generates negligible methane (if methane is desired) – Methane production is generally favored in a lower temperature, high pressure, moving-bed type gasifier.
3. Control of coal feed rate is more complex – Maintenance of uniform heat release and slagging conditions requires precise control of coal flows. Dense-phase pulverized coal feed systems require inerting for safety. Coal feed and char recycle are simplified with coal slurries and higher pressures are possible, but there are associated penalties in carbon burnout and flexibility of coal feed sourcing.
4. Turndown may be limited with some coals – Turn-down to approximately 25% of capacity should generally be possible, but certain high ash-fusion temperature coals may constrain proper slagging at low loads.
5. Relatively high oxygen and waste heat recovery duty – These characteristics are associated with the high temperature of the entrained-flow process. Heat recovery costs exceed those of the fluidized or moving bed. Because the gasifier walls and heat recovery boiler absorb about 85% of the energy released as sensible heat (25% of the energy in the coal), it has been estimated that the total recovered and chemical energy efficiency of the gasifier can exceed 96% for most coals.

B&W gasifier development dates back to 1951. Several pilot plants were built in-house and a full scale commercial gasifier was built to produce synthesis gas.

The first gasifier designed and constructed by B&W (Fig. 10) was put into operation in 1951 at the U.S. Bureau of Mines station at Morgantown, West Virginia (currently DOE's National Energy and Technology Laboratory). Operating at atmospheric pressure, this unit was oxygen-blown and was capable of gasifying 500 lb/h (0.063 kg/s) of coal, producing about 330,000 ft³/d (147.3 Nm³/h) of synthesis gas. It was refractory lined and was comprised of a primary and secondary reaction zone. The primary zone produced temperatures exceeding 3000F (1649C) and the secondary zone operated at about 2200F (1204C). The unit was operated successfully for more than 1200 hours.

B&W also assisted the U.S. Bureau of Mines in its early pressurized gasification studies. One unit designed by B&W featured a down-fired axial coal feed [500 lb/h (0.063 kg/s)] with tangential steam and oxygen feeds. This unit was designed for operation at 450 psig (3100 kPa). It was operated during the 1950s and 1960s and was occasionally used in the 1980s.

A reduced-scale gasifier was constructed at Belle, West Virginia in 1951.¹¹ This unit was rated at 3000 lb/h (0.38 kg/s) of coal and produced 1389 SCFM (0.62 Nm³/s) of synthesis gas. When installed, it was the largest pulverized coal gasifier in the U.S. The unit operated for more than 5000 hours and established the design basis for a full scale gasifier at the same plant.

In 1955, a full scale gasifier began operation at Belle, West Virginia. The unit was 15 ft (4.6 m) in diameter and 88 ft (26.8 m) tall. It was designed to gasify 17 t/h (15.4 t_m/h) of coal, producing 17,360 SCFM (7.75 Nm³/s) of carbon monoxide and hydrogen. The gasification zone was refractory lined and the floor

Fig. 10 Early B&W oxygen-blown gasifier.

and walls were water cooled. The gasifier operated for more than a year, then shut down when low cost natural gas became available.

In the early 1960s, another pilot unit was constructed by B&W at its research facility in Alliance, Ohio (Fig. 11). This air-blown unit was used in a co-operative program with General Electric to study combined gas turbine/steam turbine cycles. It consisted of a 3 t/h (2.7 t_m/h) gasifier with char recycle, mechanical gas cleanup equipment, and a gas-cooled cyclone combustor. This facility was operated for three years beginning in 1960, and horizontal and vertical slag-tap, vortex-fired gasifiers were studied.

B&W also built a 5 t/h (4.5 t_m/h), 1500 psig (10,340 kPa) gasifier for the Bi-Gas pilot plant at Homer City, Pennsylvania (Figs. 12 and 13). This plant, which opened in 1976, demonstrated the production of synthetic natural gas from coal. The project was sponsored by the Office of Coal Research, the U.S. Department of Interior, and the American Gas Association.

Development issues

Although there are other issues such as removal of acids from the gas, as well as solid and liquid effluents, there are three primary areas where further development is needed for integrated gasification combined cycle (IGCC) to achieve its potential. Due to materials issues, current systems must significantly

cool the gas leaving the gasifier to remove sulfur and particulates prior to entering the gas turbine (resulting in an efficiency penalty). In addition, these coolers have experienced failures resulting in plant downtime. Ideally, the sulfur and particulates would be removed with minimal cooling of the gas.

Gas cooling

Syngas cooler material failures have accounted for a substantial percentage of downtime at the IGCC demonstration plants. Material selection in syngas coolers requires special attention.^{12,13}

There are major differences between syngas coolers and coal-fired boilers:

1. The highly reducing and corrosive raw syngas presents a different environment for material qualification. Protective oxide scales which usually form on low alloy boiler steels do not readily form in syngas coolers, where H₂S and HCl are present.
2. Because of the high operating pressure, generally 300 to 600 psi (2070 to 4140 kPa), the syngas dew point is generally much higher than that in atmospheric pressure boilers. This is especially true when the steam content of the syngas is high, as with a coal-water slurry feed system. Precautions are required to prevent operation below the acid dew point and to avoid aqueous corrosion during downtime.
3. Pressurized operation, requiring a vessel enclosure for the exchangers, constrains the design layout. This requires special attention to assure accessibility for inspection and repair.

Low alloy steels are not suitable for syngas coolers because of excessive corrosion rates caused primarily by sulfidation, and also by chlorination. For low alloy steels, the sulfidation rate is dependent on the H₂S partial pressure and the rate is higher with high sulfur coals. Iron sulfide (FeS) and mixed sulfide-oxide

Fig. 11 Pilot plant for gasification research.

Fig. 12 B&W bi-gas gasifier.

scales form; these are generally less protective than oxide scales. Because low alloy steels experience excessive corrosion rates, stainless steels are used. Corrosion rates must be less than about 4 mils/yr (0.1 mm/yr) to obtain a service life of 25 years.

The effects of syngas chlorides are not clearly defined. Sulfidation rates in syngas with 300 to 500 ppm HCl become variable and are generally higher, presumably because of FeCl_2 formation and spalling during thermal cycling. Chlorides greatly accelerate aqueous corrosion during downtime if condensation occurs.

The presence of HCl in syngas increases its dew point 54 to 90F (30 to 50C).

Preliminary material selection guidelines aimed at a 25 year service life have been formulated by the Electric Power Research Institute (EPRI) based on currently available laboratory and field data.^{12,13} Actual service life will depend on the severity of the conditions to which the individual material components are exposed, which in turn are dependent on the specific design, fuel used, and operating conditions.

Particulate removal

Particulate removal at as high a temperature as practical is desirable to avoid significant heat losses and resulting loss of efficiency. Rigid, porous ceramic barrier filters have been the focus of development for hot particulate removal at temperatures around 1800F (982C). The ceramic material must be porous enough to allow gas penetration while capturing fine particulate, permitting solids removal and pressure drop recovery. It must also be resistant to chemical attack from the high temperature reducing environment and have sufficient ductility to resist the thermal and mechanical shocks imposed during operation. A variety of filter arrangements have been developed with these objectives including candle, granular bed, cross-flow and tubular designs (see Fig. 14). Although much testing has been done and applications have been attempted at a few of the IGCC demonstration facilities, ceramic filtration remains incapable of commercial reliability and all of the gasification plants to date cool the product gas to 1000F (538C) or lower to utilize lower temperature sintered metal filters to remove particulates.

Candle filters consist of thousands of ceramic or sintered metal *candles*, which are hollow tubes closed at one end, with the other end suspended from a tube sheet within a pressure vessel. The dirty gas enters the pressure vessel and flows around the outside of the candles and through the filter wall to the inside, leaving the entrained dust on the outside of the candle. The clean gas flows up through a common collector and out the top of the vessel. When the pressure drop through the candles reaches a prescribed value, pressurized gas is *pulsed* in the reverse direction to the normal gas flow (back-pulse), loosening the filter cake from the outside of the candles and allowing it to fall into an ash hopper. It is then removed through lock hoppers. High temperature ceramic candle filters have received a great amount of testing. The greatest hurdles to reliability have been cracking due to thermal shock from back pulsing, from thermal upsets caused by carbon carryover, or from ash that has been allowed to accumulate until it reached the candles. Most ceramic filter medium is monolithic and very brittle. In the late 1980s, B&W developed a continuous fiber ceramic composite (CFCC) material to provide more ductility than monolithic ceramic tubes. CFCC is woven from ceramic fibers and offers predictable permeability with considerable flexibility.

In granular bed filters, dirty gas is forced to pass through a moving bed of solids that traps the particulate. The bed material enters at the top and is removed

Fig. 13 Bi-gas gasifier prepared for shipment.

at the bottom. The ash is then cleaned and the filtration medium is returned to the process.

Cross-flow filters are composed of an array of ceramic structures much like a honeycomb with passages perpendicular to each other separated by ceramic walls. The dirty gas flows into the filter through one set of passages, permeates the ceramic wall to the perpendicular path, and flows out. Cross-flow filters have been arranged in several ways, usually within a pressure vessel utilizing a back-pulse cleaning system as previously described.

Tubular filters are made up of hundreds of ceramic tubes, open at both ends and sealed at both ends to a tube sheet. Dirty gas enters the vessel surrounding the outside of the tubes, flows through the ceramic tube wall and leaves the entrained dust on the surface of the tube. The clean gas passes up the center of the tube and out the top of the vessel. As with candle filters, the tubes are cleaned by back pulsing.

Until there is a breakthrough in hot gas filtration, gasification processes will be forced to cool the gas and suffer an efficiency penalty.

Sulfur removal

The U.S. DOE has funded research on hot gas desulfurization since the 1970s, testing mixed metal oxide sorbents such as zinc ferrite (ZnFe_2O_4), titanate (ZnTiO_3), copper oxide (CuO) and iron oxide (Fe_2O_3) as candidates for regenerable systems. At small scale,

most have shown high removals of gas phase sulfur species and can still be regenerable.¹⁴

The general process consists of metal oxide pellets housed in a reactor vessel through which the sulfur-laden acid gas passes. Some systems are fixed beds in parallel, with hot valves diverting gas between beds as they absorb and regenerate. Other systems use a moving-bed or a fluidized concept, as shown in Fig. 15. The sorbent is regenerated by passing a controlled flow of air through the pellet bed; the air reacts exothermically to produce a concentrated SO_2 off gas which must be further treated. Depending on the metal oxide used, the temperature must be carefully controlled between 1200F (649C) and 1400F (760C) to prevent potentially hazardous zinc vaporization and sintering.¹⁵ Sorbent life is the critical operating consideration due to its high cost.

Zinc ferrite has been tested in bulk removal and polishing modes. Bulk removal uses the sorbent to perform the total sulfur removal duty. In the polishing mode, the sorbent is a secondary means of sulfur removal; primary removal is achieved within the gasifier. Fluidized-bed gasifiers using a throwaway sorbent such as limestone or dolomite can capture some sulfur. Entrained-flow units have been fed with iron oxide or dolomite to capture sulfur in the slag.¹⁶

Many development issues must be resolved before hot gas cleanup systems can be offered commercially. In addition to particulate and sulfur removal issues,

Fig. 14 Ceramic filter arrangements.

the effects of raw gas chlorides, alkali species and other trace volatile elements on the performance of downstream equipment must be addressed. Ammonia in the gas will not be condensed and may result in high NO_x emissions from a gas turbine combustor. The challenge is to achieve the excellent environmental performance of conventional processes while being reliable, efficient and economical.

IGCC for power generation

Production of power from gasifying coal and combusting the fuel gas in a combined cycle power plant requires a high degree of component integration, as shown in Fig. 16. In simple terms, the hot, combusted fuel gas is expanded in a gas turbine to drive the air compressor and generator, with some of the compressed air used to gasify the coal. The byproducts, such as char, are often burned in secondary processes to produce additional steam and/or power. The gas turbine exhaust, hotter than 1000F (538C) with modern machines, passes through a heat recovery steam generator (HRSG) to produce superheated steam to drive a steam turbine-generator (see Chapter 27) comprising a combined cycle. The gasification process releases significant thermal energy which must also be recovered into the steam cycle to achieve high overall plant efficiency.

Demonstrations of coal gasification processes in the 1980s and early 1990s include plants at Plaquemine, Louisiana (155 MW Destec or Dow process), Cool Water at Daggett, California (92 MW Texaco process), Puertollano, Spain (288 MW ELCOGAS or Prenflo process), and the first fully integrated IGCC plant at Buggenum in the Netherlands (250 MW Shell process). Significant investment was made to commercialize IGCC plants for power generation in the DOE's

Clean Coal program from in the mid-1980s to 1990s including plants at Wabash River near Terra Haute, Indiana (262 MW Destec/Dow process), the Polk Power Station near Tampa, Florida (250 MW Texaco process), the Piñon Pine project at Sierra Pacific Power's Tracy station near Reno, Nevada (99 MW KRW process), and the Kentucky Pioneer Energy project near Trapp, Kentucky (400 MW British Gas/Lurgi process).

The design of an IGCC system is quite complex, with many factors to consider to achieve the right balance of capital cost, plant efficiency, operability, and environmental requirements for a given application. For example, the choice of gasifier type affects the amount of fuel gas heat recovery duty.

An oxygen-blown, entrained-flow gasifier with its high operating temperature requires more raw gas cooling in efficiently designed cycles. These coolers

Fig. 15 Moving-bed zinc ferrite process schematic (courtesy of GE Environmental Services, Inc.).

must perform in a harsh gas environment and are a critical component in plant reliability. Integrating this large quantity of lower level steam energy (limited by metal temperatures) into the steam cycle tends to complicate plant control and operation. In contrast, cooling the raw gas by quenching eliminates the capital cost and complexity of heat recovery, but at a substantial efficiency penalty (as much as 10% less efficient than with total heat recovery).

Oxygen plant integration is another design issue. Fig. 16 shows the turbine-driven air compressor directly feeding the oxygen plant, which produces oxygen more efficiently by reducing external compression requirements. However, this imposes more demand on turbine controls due to the large system volume between the compressor and turbine.

Other technical factors, such as fuel characteristics, influence process design. A high inherent moisture fuel such as lignite may not be a good candidate for a coal-water slurry fed gasifier due to reduced efficiency. Gas turbines have varied abilities concerning fuel gas minimum heating value, emissions performance, and compressor range for handling the larger mismatch between air flow and gas flow when firing relatively high volume, low Btu coal gas. Ambient temperature effects and utility load demand characteristics add to the list of design considerations.

Plant size is determined by the available size of the gas turbine. A single gas turbine/steam turbine installation can produce more than 250 MW, with about 60% of the power from the gas turbine. Larger plants require multiple gas turbines, with economies of scale realized in maintaining a single steam turbine and in larger balance-of-plant systems such as fuel handling, electrical and controls, and water treatment. Phased construction of an IGCC plant by incrementally installing a natural gas-fired turbine (simple cycle), then steam turbine and HRSG (combined cycle) and finally a gasification system (IGCC) has been proposed to provide owner flexibility in meeting changing power demands from peaking to base load and accommodating a relative rise in fuel costs of natural gas versus coal. However, this apparently simple concept has proven impractical due to the significant modifications to the gas turbine and steam side heat balance necessary to switch from natural gas to coal gas.

The myriad of technologies available and the external design factors combine to make IGCC plant design a complex, site- and fuel-specific process. Concurrently, this flexibility offers opportunity to produce a highly optimized system for each application.

Future IGCC development

The major force behind development and implementation of IGCC is the demand for a cleaner environment. Conventional pulverized coal (PC) plants continue to add environmental controls to meet ever-tightening emissions requirements (see Chapters 32 through 36). An IGCC plant has the potential to achieve very low emissions. Oxygen-blown gasifiers with a cold gas cleanup system are particularly well suited to deliver low emissions of SO_2 , NO_x , solid wastes, and air toxins such as mercury.

Sulfur removal efficiencies in excess of 99% are possible with an IGCC plant equipped with a H_2S removal process, a Claus (elemental sulfur recovery) plant, and a tail-gas cleanup system. Wet scrubbers in a PC plant can be practically designed with equivalent performance through use of more enhanced sorbents and/or increased sorbent-to-gas interaction.

With fuel nitrogen compounds removed in the cold gas cleanup system, NO_x emissions from an IGCC system are strictly determined by gas turbine combustor performance. NO_x values less than $0.05 \text{ lb}/10^6 \text{ Btu}$ (21.5 g/GJ) are feasible with state-of-the-art combustors, depending on fuel gas fired heating value (moisture and/or nitrogen can be added) and turbine inlet temperature, both of which affect peak flame temperature and thermal NO_x generation. By comparison, PC plants can also reach such values through low NO_x combustion techniques (see Chapter 14) in combination with post-combustion NO_x controls (see Chapter 34).

Solid byproducts from an IGCC plant with an entrained-flow gasifier consist primarily of non-reactive quenched slag and elemental sulfur. If the sulfur is sold as a byproduct, the disposal stream is reduced to the fuel ash. Depending on fuel sulfur content, a PC plant may produce up to twice as much solid waste due to sulfur dioxide (SO_2) byproducts. (See Chapters 1 and 32.) However, this may be partially offset by the production of saleable gypsum in conventional scrubber systems or other byproducts from regenerable scrubber systems (such as fertilizer from sodium-based systems).

The environmental impacts of heavy metals in fuel

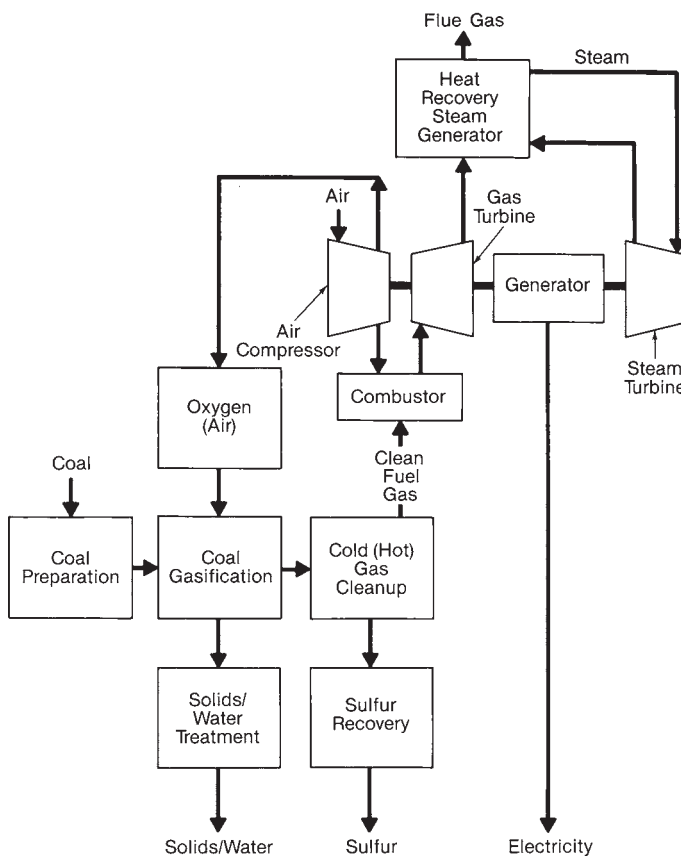

Fig. 16 Integrated coal gasification combined cycle schematic.

ash, emissions of air toxins, especially mercury, and extremely fine particulate matter are now being scrutinized. Techniques for mercury removal in PC plants are nearing commercial application and use of wet electrostatic precipitation can reduce sulfuric acid and fine particulate emissions to very low amounts, similar to what is possible in IGCC systems with high efficiency filters.

Because a gas turbine is employed in IGCC, the net plant efficiency is usually expressed in terms of the coal's lower heating value (LHV). It should be noted that due to the difference in the way the heat of vaporization of water is considered in the heat rate calculation, there is a significant difference (2-3%) between efficiencies on a lower versus higher heating value basis (HHV being the lesser). Net plant efficiencies as high as 45% LHV (42 to 43% HHV) have been reported, but most plants have actually achieved efficiencies in the range of 38 to 43% depending on capital cost tradeoffs, degree of plant integration, fuel type, and other specifics. Higher efficiencies are possible as gas turbines with higher firing temperatures are developed. Current projections of efficiency using advanced high temperature gas turbines not yet commercially available and supercritical heat recovery steam cycles are in the mid to upper 50% LHV range (high 40% range with HHV). Operational success of IGCC plants has varied widely, primarily depending on the degree of integration and the method of gas cleaning (hot or cold).

With heightened awareness worldwide of CO₂ emissions, efficiency is becoming as much an environmental issue as an economic factor related to fuel costs. A large state-of-the-art supercritical Rankine cycle steam plant operating at steam temperatures of 1100F (593C) (single reheat) with environmental controls can achieve an efficiency of 40% (HHV) or higher (depending on cooling water temperature and condenser backpressure and turbine cycle configuration), while modern subcritical steam cycles have achieved efficiencies of 37% (HHV).

Modern supercritical pulverized coal fired plants with advanced steam conditions provide very attractive economics, heat rate (efficiency) similar to current state-of-the-art IGCC plants (which determines CO₂ emissions), and comparable emissions of SO_x, NO_x, mercury and particulates. Considering the state-of-the-art and the fact that development of gasification systems has been driven by chemical production rather than the utility power generation industry, coal gasification is likely to develop as a co-production plant. The DOE's Vision 21 program promotes this approach of using gasification systems to produce high value chemicals with electricity as a byproduct rather than a workhorse technology for power generation. Ultimately, the cost of producing power with an IGCC system, advanced Rankine cycle steam plants and other competing systems, such as pressurized fluidized-bed power systems, will determine the extent to which each system will be used in the future.

Chapter 19

Boilers, Superheaters and Reheaters

In a modern steam generator, various components are arranged to efficiently absorb heat from the products of combustion and provide steam at the rated temperature, pressure, and capacity. These components include the boiler surface, superheater, reheater, economizer, and air heater. They are supplemented by systems for steam-water separation (see Chapter 5) and the control of steam outlet temperature. The steam generator can be divided into two general sections, the furnace and the convection pass. The furnace provides a large open volume with water-cooled enclosure walls inside of which combustion takes place, and the combustion products are cooled to an appropriate furnace exit gas temperature (FEGT). The convection pass contains tube bundles, which compose the superheater, reheater, boiler bank, and economizer. The air heater usually follows the convection pass. The boiler, or evaporation-circulation system, typically includes one or more of the following subsystems: the furnace enclosure walls, mix headers, steam drum, steam-water separation equipment, boiler bank, and associated connecting piping (downcomers, supplies, and risers as discussed in Chapter 1). This chapter focuses on the boiler, superheater, and reheater components, plus systems for steam temperature control, steam bypass, and unit startup. Chapter 20 discusses economizers and air heaters.

Boilers

Boiler surface is defined as the tubes and drum shells that are part of the steam-water circulation system, and that are in contact with the hot gases (flue gas). Although the term *boiler* now frequently refers to the overall steam generating system, the term *boiler surface* excludes the economizer, superheater, reheater, or any component other than the steam-water circulation system itself.

While boilers can be broadly classified as fire tube and water tube types, as discussed in the *Introduction to Steam*, modern high capacity boilers are of the

water tube type. In the water tube boiler, the water and steam flow inside the tubes and the hot gases flow over the outside surfaces. The boiler circulation system is constructed of tubes, headers, and drums joined in an arrangement that provides water flow to generate steam while cooling all parts. The water tube construction allows greater boiler capacity and higher pressure than shell or fire tube designs. The water tube boiler also offers greater versatility in arrangement; this permits the most efficient use of the furnace, superheater, reheater, and other heat recovery components.

Boiler configurations

Modern high capacity boilers come in a variety of designs, sizes, and configurations to suit a broad range of applications. Sizes range from 1000 to 10,000,000 lb/h (0.13 to 1260 kg/s) and pressures range from one atmosphere to above the critical pressure.

The combustion system, fuel, ash characteristics, operating pressure, and total capacity largely determine the boiler configuration. Figs. 1 through 5 illustrate the diversity in configurations.

Fig. 1 Integral Furnace industrial boiler for oil and gas firing.

Typical industrial and small power boilers The Integral Furnace boiler shown in Fig. 1 is an oil- and gas-fired, low pressure two drum package boiler. In small capacities, it can be entirely shop assembled and shipped to the site. (See Chapter 1, Fig. 1.) Because it burns a clean fuel, there is no provision made for fly-ash collection or surface cleaning, and a small furnace volume can be used. A boiler bank (closely spaced tubes between a steam drum and lower drum) provides the heat transfer surface necessary for the rated steaming capacity. Fig. 2 illustrates a two drum Stirling® power boiler (SPB) designed for effective firing of high moisture wood and biomass. (See also Chapter 30.) A stoker (see Chapter 16) firing system is supplied and a boiler bank is provided for sufficient steam generating surface.

Additional unique designs include fluidized-bed boilers, process recovery boilers, and waste-to-energy boilers discussed in Chapters 17, 28 and 29, respectively.

Large utility boiler designs As discussed in Chapter 26, all utility boilers feature gas-tight, fully water-cooled furnace enclosure walls and floors made of all-welded membrane panel construction. Each design normally includes a single reheat section, although the supercritical once-through boiler has also been supplied as a double reheat unit. Fig. 3 is a supercritical 750 MW pulverized coal unit for variable pressure operation. Sloped tubes, commonly angled at 25 degrees

Fig. 3 Variable pressure 750 MW boiler for pulverized coal firing. Design pressure 3825 psig (26.4 MPa); 1054F (568C) superheat and 1105F (596C) reheat steam temperatures; capacity 5,000,000 lb steam/h (630 kg steam/s).

Fig. 2 Two drum Stirling® power boiler for bark firing.

from horizontal, wrap around the lower furnace in a single pass (spiral wound construction). Each tube passes through the various heat flux patterns typically encountered in the lower furnace, creating an essentially uniform heat absorption profile. At a point below the furnace nose, the furnace tubes transition to the vertical tube arrangement for the lower heat flux zone of the upper furnace. The consistency of the heat absorption profiles and outlet enthalpy patterns of the furnace afforded by the spiral wound construction allows for true variable pressure operation and on/off cycling by reducing thermal upsets. The inclined tube arrangement also reduces the number of flow paths through the furnace. Other Universal Pressure (UP®) designs are available for supercritical pressure operation with vertical tubing in both the lower and upper furnace. (See Chapter 26.)

Figs. 4 and 5 illustrate two variations of The Babcock & Wilcox Company's (B&W) Radiant boiler (RB) for natural circulation drum type steam generating systems. Fig. 4 shows an RB unit for coal firing. This is the Carolina-type design (RBC) with downflow convection backpass, which minimizes overall steam generator height. Provision is made for sootblower surface cleaning and for flyash collection. A Tower-type (RBT) configuration is also available that features fully drainable convection pass surfaces and a minimum plan area. (See Chapter 26.) A special type of radiant boiler, the RBW, is available for anthracite combustion. The RBW, named for the W shape its flame forms during combustion, has a similar design to the RBC, with the exception of the lower furnace and combustion system. (See Chapter 26.) Fig. 5 is a Radiant boiler of the El Paso (RBE) configuration for

Fig. 4 Carolina-type Radiant boiler for pulverized coal firing. Design pressure 2975 psig (20.61 MPa); superheat and reheat steam temperatures 1005F (541C); capacity 6,600,000 lb steam/h (832 kg steam/s).

oil and gas firing. The relatively clean liquid or gaseous fuels normally burned in this unit allow for a very compact design that minimizes the boiler footprint (plan area) and support steel. The RBE design excludes ash hoppers and ash pits, but provision may be made for cleaning equipment.

Boiler design

Regardless of the size or configuration, modern boiler design remains driven by four key factors: 1) efficiency (boiler and cycle), 2) reliability, 3) capital and operating cost, and 4) environmental protection. These factors, combined with specific applications, produce the diversity of designs presented above and discussed at length in Chapters 26 through 31. However, all of these units share a number of fundamental elements upon which the site- and application-specific design is based.

The boiler evaluation begins by identifying the overall application requirements specified in Table 1. These are generally selected in an iterative process balancing initial capital cost, operating costs (especially fuel), steam process needs, and operating experience. The selection of these parameters can dramatically affect cost and thermal efficiency. Chapters 1 and 37 address these further.

From a boiler evaluation perspective, the temperature-enthalpy diagram shown in Fig. 6 (for a typical high pressure, single reheat unit) provides important design information about the unit configuration. In this example, the relative heat absorption for water preheating, evaporation, and superheating are 30%,

32%, and 38%, respectively. Reheating the steam increases the total heat absorption by approximately 20%. For cycles at supercritical operating pressures, a second stage of reheat may be added. For process applications, only the preheating and evaporation steps may be required.

Boilers can be designed for subcritical or supercritical pressure operation. At subcritical pressures, constant temperature boiling water cools the furnace enclosure, and the flow circuits must be designed to accommodate the two-phase steam-water flow and boiling phenomena addressed in Chapter 5. At supercritical pressures, the water acts as a single-phase fluid with a continuous increase in temperature as it passes through the boiler. These designs require special consideration to avoid excessive unbalances in tube metal temperatures, caused by variations in heat pickup across different flow circuits. In addition, special heat transfer phenomena must also be addressed. (See Chapter 5.)

Two basic fluid circulation systems are used, natural circulation and once-through. In natural circulation systems, which operate at subcritical pressures, water only partially evaporates in the boiler circuits producing a steam-water mixture at the tube outlets. Steam-water separation equipment is provided to separate the steam and water, supply saturated (dry) steam to the superheater, and recirculate water back to the boiler circuits. Natural circulation is the result of the density difference between the colder, denser fluid in the downcomers and the hotter, less dense fluid in the upflow portion of the boiler. In B&W UP once-through designs, the steam drum and internal steam separation equipment are eliminated and a separate startup system is added. UP boilers have been designed for both subcritical and supercritical operation. Supercritical pressures increase overall power cycle efficiency, but at a higher initial capital cost.

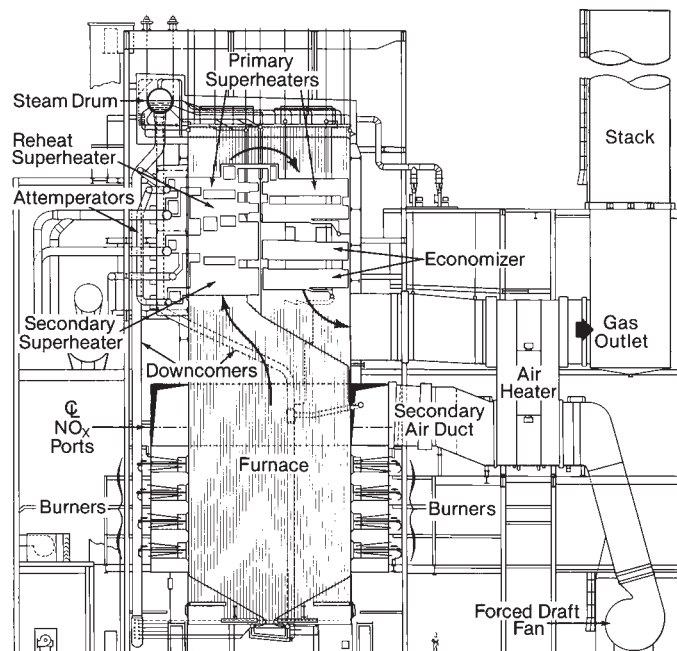

Fig. 5 El Paso-type Radiant boiler for gas firing. Design pressure 2550 psig (17.58 MPa); superheat and reheat steam temperatures 955F (513C); capacity 3,825,000 lb steam/h (482 kg steam/s).

Table 1
Use-Derived Specifications for Boiler Design

Specified Parameter	Comments
Steam use	Flow rates, pressures, temperatures — for utility boilers, the particular power cycle and turbine heat balance.
Fuel type and analysis	Combustion characteristics, fouling and slagging characteristics, ash analysis, etc.
Feedwater supply	Water source, analysis and economizer inlet temperatures.
Pressure drop limits	Gas side and steam side.
Government regulations	Including emission control requirements.
Site-specific factors	Geographical and seasonal characteristics.
Steam generator use	Base load, cycling, etc.
Customer preferences	Specific design guidelines such as flow conditions, design margins, equipment preferences and steam generator efficiency.
Economic evaluation criteria	Efficiency, fan power, reheat pressure drop and spray flows.

Design criteria Within the preceding framework, the important items in boiler design are the following:

1. Define the energy input based upon the steam flow requirements, feedwater temperature, and an assumed or specified boiler thermal efficiency.
2. Evaluate the energy absorption needed in the boiler and other heat transfer components.
3. Perform combustion calculations to establish fuel, air, and gas flow requirements. (See Chapter 10.)
4. Determine the size and shape of the furnace, considering the location and space requirements of the burners or other combustion system, and incorporating sufficient furnace volume for complete combustion and low emissions. Provision must be made for handling the ash contained in the fuel and cooling the flue gas so that the furnace exit gas temperature (FEGT) meets design requirements.
5. Determine the placement and configuration of convection heating surfaces. For utility applications, the superheater and reheater, when provided, must be placed where the gas temperature is high enough to produce effective heat transfer, yet not so high as to cause excessive tube metal temperatures or ash fouling. All convection surfaces must be designed to minimize the impact of slag or ash buildup and permit surface cleaning without erosion of the pressure parts.
6. For industrial applications, provide sufficient saturated boiler surface to generate the remainder of the steam not generated in the furnace walls. This

can be accomplished, for example, with the addition of saturated enclosure surface, a boiler (generating) bank, an economizer, or a combination of these items.

7. Design pressure parts in accordance with applicable codes using approved materials.
8. Provide a gas-tight boiler setting or enclosure around the furnace, boiler, superheater, reheater, and economizer.
9. Design pressure part supports and the setting for expansion and local conditions, including wind and earthquake loading.

Fuel selection and specification are particularly important. Boiler systems are designed for specific fuels and frequently encounter combustion, slagging, fouling, or ash-handling problems if a fuel with characteristics other than those originally specified is fired. All potential boiler fuels must be assessed to determine the most demanding fuel.

Chapter 37 outlines procedures for optimizing the steam cycle and for evaluating the value of specific auxiliary equipment in a given application.

As discussed in Chapter 10, the boiler or combustion efficiency is usually evaluated as 100 minus the sum of the heat losses and credits, expressed as a percentage. Chapter 10 provides procedures for calculating the corresponding fuel, air, and gas flow rates.

Enclosure surface design

The furnace of a large pulverized coal-, oil-, or gas-fired boiler is essentially a large enclosed volume where fuel combustion and cooling of the combustion products take place prior to their entry into the convection pass. Excessive gas temperatures entering the convection pass tube banks could lead to elevated tube metal temperatures or unacceptable fouling and slagging. Radiation basically controls heat transfer to the furnace enclosure walls. These walls are typically cooled with boiling water (subcritical pressure) or high

Fig. 6 Temperature-enthalpy diagram for subcritical pressure boiler absorption – one reheat section.

velocity supercritical pressure water. Occasionally, superheat or reheat steam is used.

The convection pass enclosure contains most of the superheater, reheater, and economizer surfaces. (See Fig. 4.) These enclosure surfaces can be water or steam cooled.

The furnace enclosures and convection pass enclosures are usually made with all-welded membrane construction. These enclosures have also been made from tangent tube construction or closely spaced tubes with an exterior gas-tight seal. For a membrane construction, the tube wall and membrane surfaces are exposed to the combustion process on the furnace side, while insulation and lagging (sheet metal) on the outside protect the boiler, minimize heat loss, and protect operating personnel. (See Chapter 23.)

Furnace size versus cycle requirements Besides providing the volume necessary for complete combustion and a means to cool the gas to an acceptable FEGT, the furnace enclosure also provides much of the steam generating surface in a boiler. These roles may not perfectly match one another. In coal-fired units, the minimum furnace volume is usually set to provide the fuel ash specific FEGT. Frequently this results in too much evaporator surface in high pressure boilers and too little surface in low pressure units to meet the thermodynamic requirements for the desired steam exit temperature.

Fig. 7 illustrates the effect of the steam cycle and the operating pressure and temperature on the relative energy absorption between the boiler/economizer and superheater/reheater. As the pressure and temperature increase, the total unit absorption for a given power production progressively declines because of increased cycle efficiency. The boiler and economizer absorption represents the relative amount of heat added to the entering feedwater to produce saturated steam or reach the critical point in a supercritical pressure UP boiler. As the operating pressure increases, the amount of heat required to produce saturated steam declines. Conversely, the amount of heat required for the superheater and reheater increases. The change in required boiler/economizer absorption may not seem significant. However, a 1% shift in absorption is equivalent to approximately 10F (6C) of superheat or reheat temperature.

On low pressure units, the furnace and economizer surfaces are typically not adequate to produce all of the required saturated steam. As a result, a boiler bank with water cooled walls is usually installed after the superheater. (See Figs. 1 and 2.) On a high-pressure unit, the heat absorbed by the furnace and economizer is adequate to produce all the saturated steam required.

Furnace design criteria The furnace is a large open volume enclosed by water-cooled walls for combustion. Fuel and combustion system selection establish the shape and volume of the furnace. For wall firing using circular burners (see Chapter 14), minimum clearances between individual burners, between burners and walls, as well as between burners and the furnace floor, are established based upon physical clearances and functional criteria for complete combustion.

Fig. 7 Relative heat absorption for selected power cycle operating conditions normalized to absorption per kWh in the 2400 psig cycle.

These clearances prevent fuel stream and flame interaction, assure complete combustion, avoid unacceptable flame impingement on the walls (which could lead to tube overheating or excessive deposits), and minimize the formation of nitrogen oxides (NO_x). The maximum fuel input rate, number of burners, and the associated clearances establish: 1) the furnace cross-sectional area, 2) the height of the combustion zone, 3) the height of the overfire air injection zone (if used), and 4) the distance between the burner zone and the furnace hopper or floor. Where the fuel is burned on stokers, the furnace cross-sectional area is established by a specified heat release rate per unit bed area. (See Chapter 16.)

As discussed in detail in Chapter 14, combustion system design and its impact on furnace volume and shape have become complex and critical as emissions limits have been reduced. Use of low NO_x burners, such as the B&W DRB-4Z[®], reduce NO_x emissions. Other techniques, such as in-furnace staging with overfire air (NO_x ports), fuel reburning, and reactant injection are also successful in further reducing NO_x emissions. Some techniques for furnace sorbent injection to reduce sulfur dioxide (SO_2) emissions have also been developed. (See Chapter 35.) Each technique can have an impact on the furnace size and configuration.

Several criteria establish the overall furnace height and volume. For clean fuels, such as natural gas, the furnace volume and height are generally set to cool the combustion products to an FEGT that will avoid superheater tube overheating. For fuels such as coal and some oils that contain significant levels of ash, the furnace volume and height are established to cool the products of combustion to an FEGT that will prevent excessive fouling of the convection surfaces. Chapter 4 explores the relationships between furnace volume and FEGT. The specific effects of ash on furnace design are discussed below and in Chapter 21. The furnace height must also be set to provide at least the minimum time to complete combustion and to meet minimum clearance requirements from the burners

and NO_x ports to the arch and convective surface.

Ash effects In the case of coal and to a lesser extent with oil, an extremely important consideration is the ash in the fuel. If this ash is not properly considered in the unit design and operation, it can deposit on the furnace walls, sloping surfaces, and throughout the convection pass tube banks. Ash not only reduces the heat absorbed by the unit, but it increases gas-side resistance (draft loss), erodes pressure parts, and eventually can result in unit outages for cleaning and repairs. (See Chapter 21.)

Ash problems are the most severe in coal-fired furnaces. There are two general approaches to ash handling: the dry-ash, or dry-bottom, furnace and the slag-tap, or wet-bottom, furnace.

In the dry-ash furnace, which is particularly applicable to coals with high ash fusion temperatures, a hopper bottom (Figs. 3 and 4) and sufficient cooling surface are provided so that the ash impinging on furnace walls or the hopper bottom is solid and dry; it can be removed essentially as dry particles. When pulverized coal is burned in a dry-ash furnace, about 80% of the ash is carried through the convection banks. The chemistry of the ash can have a dramatic impact on the furnace volume necessary for satisfactory dry-bottom unit operation. Fig. 8, which compares the furnace volume required for a nominal 500 MW boiler burning a low slagging bituminous or subbituminous coal to that for a high slagging lignite coal, illustrates this. Chapter 21 discusses the relationships defining the furnace size requirements in detail.

With coals having low ash fusion temperatures, it can be difficult to use a dry-bottom furnace because

the slag is molten or sticky; it clings and builds up on the furnace walls and hopper bottom. The slag-tap or wet-bottom furnace was developed to handle these coals. The most successful form of the slag-tap furnace is that used with Cyclone furnace firing. (See Chapter 15, Figs. 7 and 8.) This furnace comprises a two-stage arrangement. In the lower part of the furnace, sufficient gas temperature is maintained so that the slag drops onto the floor in liquid form. Here, a pool of liquid slag is maintained and tapped into a slag tank containing water. In the upper part of the furnace, the gases are cooled below the ash fusion point, so ash carried over into the convection banks is dry and does not cause excessive fouling. Because of high NO_x emissions, slag-tap designs became less popular for new boiler designs. Recently, however, considerable reductions in NO_x levels have been demonstrated in Cyclone units firing western fuels and employing staged combustion.

Water-cooled walls Most boiler furnaces have all water-cooled membrane walls. In this type of construction, furnace wall tubes are spaced on close centers to keep membrane temperatures and thermal stresses within limits. The membrane panels (see Fig. 9) are composed of tube rows spaced on centers wider than a tube diameter and joined by a membrane bar securely welded to the adjacent tubes. This results in a continuous wall surface of rugged, pressure-tight construction capable of transferring the radiated heat from the furnace gas to the water or steam-water mixture in the tubes. The width and length of individual panels are suitable for economical manufacture and assembly, with bottom and top headers shop-attached prior to shipment for field assembly. Shipping clearances and erection constraints frequently govern size limitations. The lower furnace walls of Cyclone-fired, refuse, and fluidized-bed units use membrane construction with refractory lining.

Convection boiler surface

Some designs include boiler tubes as the first few rows of tubes in the convection bank. The tubes are spaced to provide gas lanes wide enough to prevent ash and slag pluggage and to facilitate cleaning for dirty fuels. These widely spaced boiler tubes, known as the *slag screen* or *boiler screen*, receive heat by radiation from the furnace and by both radiation and convection from the combustion gases passing through them. Another option is the use of wide spaced water- or steam-cooled surface (see Fig. 4) in the upper furnace. This provides additional radiant heat transfer surface in the furnace while allowing the furnace size to be optimized.

In the larger high pressure units, superheater surface generally forms the furnace outlet plane. The gas temperature entering the superheater must be high enough to give the desired superheat temperature with a reasonable amount of heating surface and the use of economical materials. The arrangements in Figs. 1 through 5 illustrate various configurations of superheater surface at the furnace outlet. To optimize superheater design, the furnace may also incorporate widely spaced steam-cooled platens, as shown in Figs. 3 and 4, or wingwalls in the upper furnace. Fig. 10

Fig. 8 Boiler size comparison for alternative coal types.

Fig. 9 Membrane wall construction at burner openings.

shows a plan arrangement of convection surface and the change in average gas temperature.

Design of boiler surface after the superheater depends on the type of unit (industrial or utility), desired flue gas temperature drop, and acceptable draft loss through the boiler surface. The preceding *Boiler design* section of this chapter illustrates typical arrangements of boiler and superheater surface for various types of boilers. The objective of convection heating surface design is to establish the proper combination of diameter, length, spacing, number, and orientation of tubes, as well as gas baffling, to provide the desired gas temperature drop with allowable flue gas resistance.

The quantity of heating surface (ft^2 or m^2) needed in the gas-side design of convection surfaces for a given load or duty (Btu/h or W) often inversely relates to gas side flow resistance or pressure loss. Design changes that increase resistance, such as tightening tube spacing perpendicular to flow, result in higher heat transfer rates (Btu/h ft^2 or W/m^2). This in turn reduces the amount of heating surface needed to carry the desired total thermal load. An optimal gas mass flux and design result from balancing the capital cost of the heating surface against the operating cost of fan power and the maintenance costs due to flyash erosion.

For a given flue gas flow rate, a considerably higher gas film heat transfer coefficient, heat absorption, and draft loss result when the gases flow at right angles to the tubes (cross flow) compared to flow parallel to the tubes (long flow). Gas turns between tube banks generally add draft loss and poor distribution with little benefit to heat absorption. Turns leaving the upstream bank and entering the downstream bank of tubes should then be designed for minimum resistance and optimum distribution.

Chapter 22 illustrates the determination of the amount of radiation and convection boiler surface required for a specified heat transfer.

Numerical analysis

When one-dimensional analysis and experimental data are insufficient for design alone, three-dimensional numerical computer modeling can be used to determine local heat transfer and flue gas conditions in boilers, superheaters, and reheaters. These numerical tools are complex, multi-dimensional computer

Fig. 10 Schematic plan arrangement of convection surface and change in average gas temperature.

codes that solve conservation equations for mass, momentum, energy, and species.

A numerical model of the superheater and/or reheater regions generally includes the boiler enclosure, burners, and any other geometric aspects which may affect the flow. Required numerical inputs include:

1. geometric data – boiler and heat exchanger surface configurations,
2. performance data – heat exchanger pressure drops and heat absorptions,
3. operating data – stoichiometry and furnace exit gas temperature,
4. burner setup – vane angles and turbulence intensity, and
5. fuel properties – fuel and flue gas quantities, composition and coal fineness, if applicable.

Numerical analyses fall into three general categories: 1) verification of proposed designs, 2) evaluation of design modifications, and 3) investigation of localized problems. Fig. 11 illustrates the use of numerical analysis to characterize the temperature profiles that exist at the furnace exit of a typical coal-fired utility boiler.

Accurate modeling of boilers and boiler components depends heavily upon the availability of information to determine the proper inlet conditions, boundary conditions, and fluid properties. Careful qualification of the model is required and is augmented by known global characteristics such as pressure drop and heat absorption. Correct application of accurate information to develop numerical models will improve designs and determine the cause of localized problems. See Chapter 6 for an in depth discussion of three-dimensional numerical modeling.

Design of pressure parts

Boilers have achieved today's level of safety and reliability through the use of sound materials and safe practices for determining acceptable stresses in drums, headers, tubes, and other pressure parts. Boilers must be designed to applicable codes. Stationary boilers in the United States (U.S.) and many parts of the world are designed to the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code. (See Chapter 8 and Appendix 2.) The allowable design stress depends on the maximum temperature to which the part is subjected; therefore, it is important that pressure part design temperatures are known and not exceeded in operation. Drum boiler enclosure material temperatures are a function of upset spot heat flux, design pressure, metal conductivity, and the saturation temperature corresponding to the maximum boiler operating pressure. These parameters also determine each tube's outside diameter and thickness. For boiler tubes, temperatures are maintained at known levels by providing a sufficient flow of water to prevent the occurrence of CHF, or critical heat flux phenomena. (See Chapter 5.) An adequate saturated water velocity must exist for each tube, and particular attention must be given to high heat flux zones and sloped tubes with heat on top, such as furnace floor tubes.

Because steam drums have thick walls, it is necessary to limit the heat flow through them to avoid ex-

cessive thermal gradients during startup, shutdown, and normal operation. This is particularly important where the drum is exposed to flue gas. A number of tube holes penetrate the drum, and the flow of water through these holes serves to cool the drum wall. Where the heat input through a drum would be too high because of high gas temperature or velocity, insulation may be provided on the outside of the drum, or the drum could be relocated out of the heat.

The required steam purity is dependant on the intended use of the steam being produced. The most stringent requirements are typically associated with power generation applications. Fundamental to maintaining steam purity is maintaining the feedwater quality. (See Chapter 42.) In a drum boiler it is also important to properly design the steam separation equipment because entrained moisture will contain dissolved solids. (See Chapter 5.) In a once-through unit all of the moisture evaporates in the tubes, and steam separation equipment is not a factor in steam purity.

Boiler safety valves constitute very important protection items to ensure the safe design and operation of pressurized boiler components. (See Chapter 25.) Before drum safety valve set pressures are established, steam drum design pressure is determined by the pressure required at the point of use and the intervening pressure drop. As an example, where the steam is used in a turbine, the boiler operating pressure is determined by adding the turbine throttle pressure to the pressure drop through the steam piping, nonreturn valve, superheater, and drum internals at maximum unit steam flow. As a practical matter, to avoid unnecessary losses and maintenance from frequent popping of the safety valves, the first drum safety valve should then be set to relieve at least 5% higher than drum operating pressure. The ASME Code stipulates that the boiler design pressure must not be less than the low-set safety valve relief pressure.

Boiler enclosure

Chapter 23 describes the methods used to provide a tight boiler setting and a tight enclosure around the superheater, reheater, economizer, and air heater.

Boiler supports

Furnace wall tubes are usually supported by the headers to which they are attached, and generating bank tubes and screens are supported by the drum or headers to which they are connected. As discussed in Chapter 8, the following considerations for proper support design are important:

1. The tubes must be arranged and aligned so that they are not subjected to excessive bending-moment stresses in supporting the weight of the tubes, headers, drums, attachments, and fluid within. When the unit is bottom supported, the tubes must satisfy column buckling requirements.
2. The holding strength of the tube seats must not be exceeded.
3. Provision must be made to accommodate the expansion of the pressure parts. For a top supported unit, the hanger rods which support the pressure

Fig. 11 Numerical modeling results – flue gas temperatures at furnace exit.

parts from the structural steel must be designed to swing at the proper angle. They must be long enough to withstand the movement without excessive stresses in the rods or the pressure parts. Bottom supported boilers should be anchored only at one point, guided along one line, and allowed to expand freely in all other directions. To reduce the frictional forces and resultant stresses in the pressure parts, roller saddles or mountings are desirable for bottom supported heavy loads.

Superheaters and reheaters

Advantages of superheat and reheat

When saturated steam is used in a turbine, the work done results in a loss of energy by the steam and subsequent condensation of a portion of the steam, even though there is a drop in pressure. The amount of moisture the turbine can handle without excessive turbine blade wear limits the amount of work the turbine can do. This is normally between 10% and 15% moisture. It is possible to increase the amount of work done with moisture separation between turbine stages, but this is economical only in special cases. Even with moisture separation, the total energy that can be transformed to work in the turbine is small compared to the amount of heat required to raise the water from feedwater temperature to saturation and then evaporate it. Therefore, moisture content constitutes a basic limitation in turbine design.

Because a turbine generally transforms the energy of superheat into work without forming moisture, this energy is essentially all recoverable in the turbine. The temperature-entropy diagram of the ideal Rankine cycle (shown in Chapter 2, Fig. 6) illustrates this. While this is not always entirely correct, the Rankine cycle diagrams in Chapter 2 indicate that this is essentially true in practical cycles.

The foregoing discussion is not specifically applicable at steam pressures at or above the critical pressure. In fact, the term *superheat* is not truly accurate in defining the temperature of the working fluid in this region. However, even at pressures exceeding 3200 psi (22.1 MPa), heat added at temperatures above 705F (374C) is essentially all recoverable in a turbine.

The reduction of cycle heat rate when steam temperatures entering the turbine are raised is an indication of the benefit of superheat. For example, in a simple calculation of a 2400 psig (16.5 MPa) ideal Rankine cycle with a single reheat stage, an increase in superheat temperature from 900 to 1100F (482 to 593C) reduces the gross heat rate from approximately 7550 to 7200 Btu/kWh. This is more than a 4.5% efficiency improvement attributable to the superheat.

Superheater types

Two basic types of superheaters are available depending upon the mode of heat transfer from the flue gas. One type is the *convection superheater*, for gas temperatures where the portion of heat transfer by radiation from the flue gas is small. Convective heat transfer is highly dependent on the characteristics of gas flow (i.e., quantity and velocity). At maximum load, or 100% steam output, the gas weight is highest; therefore, heat transfer is also high. The higher heat absorption results in higher steam temperatures leaving the superheater and a higher boiler output, or higher total absorption in the superheater per pound of steam. (See Fig. 12.)

A *radiant superheater* receives energy primarily by thermal radiation from the furnace with little energy from convective heat transfer. Radiant heat transfer is highly dependent on the high flue gas temperatures produced by the combustion of fuel. The steam temperature leaving the radiant superheater is lowest at higher loads for two reasons. Radiant absorption does not increase as rapidly as boiler output, and at higher loads there is more steam to cool the effects of the ra-

diant absorption. (See Fig. 12.) The radiant superheater usually takes the form of widely spaced [24 in. (609.6 mm) or larger side spacing] steam-cooled wingwalls or pendant superheat platens located in the furnace. It is sometimes incorporated into the furnace enclosure as curtain walls.

In certain cases, the series combination of radiant and convection superheaters coordinates the two opposite sloping curves to give a flat superheat curve over a wide load range, as indicated in Fig. 12. A separately fired superheater can also be used to produce a flat superheat curve.

The design of radiant and convective superheaters requires extra care to avoid steam and flue gas distribution differences that could lead to tube overheating. Superheaters generally have steam mass fluxes of 100,000 to 1,000,000 lb/h ft² (136 to 1356 kg/m² s) or higher. These are set to provide adequate tube cooling while meeting allowable pressure drop limits. The mass flux selected depends upon the steam pressure and temperature as well as superheater thermal duty. In addition, the higher pressure loss associated with higher velocities improves the steam-side flow distribution.

Tube geometry

Cylindrical tubes of 1.75 to 2.5 in. (44.5 to 63.5 mm) outside diameter are typical in current superheaters and reheaters. Steam pressure drop is higher and alignment is more difficult with the smaller diameters, while larger diameters result in thicker tubes.

Superheaters and reheaters are almost exclusively made of bare tubes (see Fig. 13). Extended surface on superheater tubes in the form of fins, rings, or studs can increase metal temperature and thermal stress beyond tolerable limits.

Fig. 12 A substantially uniform final steam temperature over a range of output can be attained by a series arrangement of radiant and convection superheater components.

Relationships in superheater design

Effective superheater design must consider several parameters including:

1. the outlet steam temperature specified,
2. the range of boiler load over which steam temperature is to be controlled,
3. the superheater surface required to give the specified steam temperature,
4. the gas temperature zone in which the surface is to be located,
5. the type of steel, alloy or other material best suited for the surface and supports,
6. the rate of steam flow through the tubes (mass flux or velocity), which is limited by the permissible steam pressure drop but that, in turn, exerts a dominant control over tube metal temperatures,
7. the arrangement of surface to meet the characteristics of the anticipated fuels, with particular reference to the spacing of the tubes to prevent accumulations of ash and slag or to provide for easy removal of these formations in their early stages, and
8. the physical design and type of superheater as a structure or component.

A change in any of these items may require a counterbalancing change in some or all of the other items.

The steam temperature desired in advanced power station design is typically the maximum for which the superheater designer can produce an economical component. Economics in this case requires the assessment of two interrelated costs – initial investment and the subsequent cost of upkeep to minimize operating problems, outages, and replacements. The steam temperature desired is based upon an iterative evaluation of variations in parameters 3 through 7, past operating experience, and the requirements of the particular project. Operating experience has resulted in the use

Fig. 13 Typical superheater elements for a replacement project.

of 1000F (538C) to 1050F (566C) steam temperatures for the superheat and reheat in many large utility boilers. However, advances in tube materials have allowed designers to increase these temperatures without compromising the reliability or economics of the units.

After the steam temperature is specified, the amount of surface necessary to provide this superheat must be established. This is dependent on parameters 5 through 8. Because there is no single correlation, this quantity must be determined by iteration, locating the superheater in a zone of gas temperature that satisfies the design criteria. In standard boilers, unit arrangement and the space designated for superheater surface basically establishes the zone.

After the amount of surface is established for the optimum location and tube spacing, the steam mass flux or velocity, steam pressure drop, and superheater tube metal temperatures are calculated considering material options and thickness requirements. The material determination is then made based on economic and functional optimization of the tubes, headers, and other components. It may be necessary to compare several arrangements to obtain an optimum combination that:

1. requires an alloy of less cost,
2. gives a more reasonable steam pressure drop without jeopardizing the tube metal temperatures,
3. gives a higher steam mass flux or velocity to lower tube temperatures,
4. gives the tube spacings that minimize ash accumulations and flyash erosion potential with various types of fuel,
5. permits closer spacing of the tubes, thereby making a more economical arrangement for a favorable fuel supply,
6. gives an arrangement of tubes that reduces the draft loss for an installation where this parameter evaluation is crucial, and
7. permits the superheater surface to be located in a zone of higher gas temperature, with a subsequent reduction of required surface.

It is possible to achieve a practical design with optimum economic and operational characteristics and with all criteria reasonably satisfied, but a large measure of experience and the application of sound physical principles are required for best results. Chapter 22 gives the calculation methods for superheater performance.

Relationships in reheater design

The fundamental considerations governing superheater design also apply to reheater design. However, the pressure drop in reheaters is critical because too much pressure loss through the reheater system can nullify the gain in heat rate attained with the reheat cycle.

Steam mass fluxes or velocities in reheater tubes should be sufficient to keep the difference between the bulk steam and metal surface temperature below 150F (83C). As a result of the high velocities required, the pressure drop through the reheater tubes is ordinarily 4 to 5% of reheater inlet pressure. This allows another

4 to 5% pressure drop for the reheat piping and valves without exceeding the usual 8 to 10% total allowable pressure loss. For economic reasons, the pressure drop allocated for piping is usually distributed with one-third to the cold (inlet) reheat piping and two-thirds to the hot (outlet) reheat piping.

Tube materials

Oxidation resistance, allowable stress, and economics determine the materials used for superheater and reheater tubes. The design process requires careful attention to all of these criteria to develop an economical and reliable configuration. Chapter 7 gives additional information on these materials, including maximum metal temperatures.

Fig. 14 shows variations in basic superheater heat transfer surface arrangements. These variations in surface arrangement permit the economic tradeoff between material unit costs and differences in the quantity of surface required due to thermal-hydraulic considerations. The comparison of counter flow versus parallel flow designs defines the basic relationships between heat transfer surface requirements and the corresponding tube metal temperatures and requirements.

Supports for superheaters and reheaters

Because superheaters and reheaters are located in zones of relatively high gas temperature, it is preferable to have the major support loads carried by the tubes themselves. For pendant superheaters, the major support points are located outside of the gas stream, with the pendant loops supporting themselves in simple tension. Fig. 15 illustrates standard support arrangements for a pendant superheater outlet section with major section supports above the roof line.

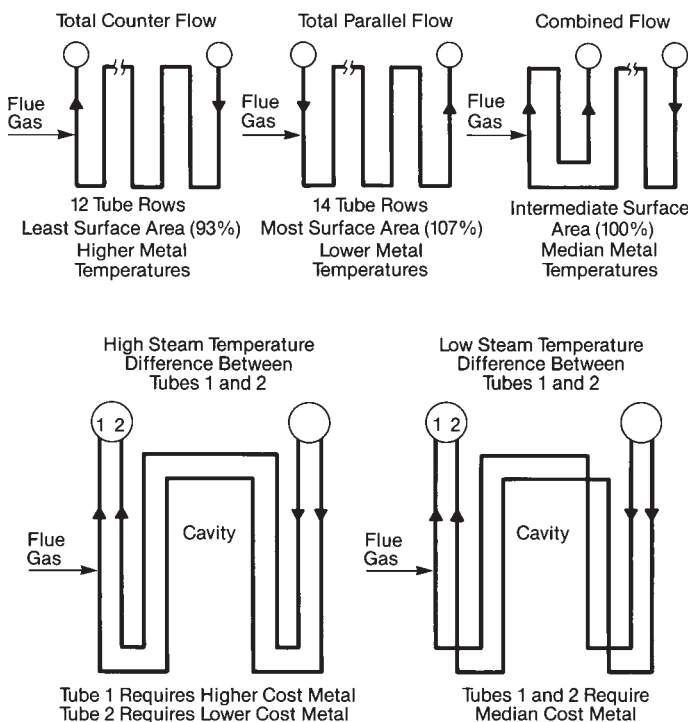

Fig. 14 Typical superheater heat transfer surface arrangements.

Where adequate side spacing is available, high chromium-nickel alloy ring-type guides are used. In addition, in the higher gas temperature zones, steam-cooled side-to-side ties are used to maintain side spacings. For closer side spaced elements, steam-cooled wraparounds are not practical and mechanical ties, such as D-links, are used to maintain alignment as shown in Fig. 16. In this case, the clear backspacing between tubes and the size of attachments have been kept to a minimum. This serves to reduce the thermal stresses imposed on the tube wall. Fig. 16 also shows a typical arrangement of a pendant reheater section and illustrates the support of a separated bank by a special loop of reheater, which permits all major supports to remain above the roof and out of the gas stream.

In horizontal superheaters, the support load is usually transferred to boiler or steam-cooled enclosure tubes or economizer stringer tubes by lugs, one welded to the support tubes and the other to the superheater tubes as indicated in Fig. 17. These lugs are made of

carbon steel through high chromium-nickel alloy. Depending upon design considerations, they must slide on one another to provide relative movement between the boiler tubes and the superheater tubes. Saddle-type supports, also shown in Fig. 17, provide for relative movement between adjacent tubes of the superheater.

As units grow in size, the span of the superheater tubes may become so great that it is impossible to end-support these tubes. Most of the larger units use stringer tubes (see Chapter 20 frontispiece), generally hung from the economizer outlet, to support the superheater tubes. Saddle-type supports maintain tube spacing within the section.

Internal cleaning

The internal cleaning of superheater and/or reheater surfaces is not normally required; however, under certain circumstances these surfaces have been chemically cleaned. Chapter 42 discusses this in depth. During startup, steam line blowing is used to remove residual scale, oils, and residual debris.

External cleaning and surface spacing

Most customers today are striving for long periods of continuous operation, in some cases as long as 18 to 24 months between outages, so gas side cleanability is critical. To enhance cleanability, the superheater sections (platens) of modern utility boilers are spaced according to the gas temperature and the fuel fired. Fig. 10 illustrates the spacing for pulverized coal-fired units. The backspacing in the direction of gas flow is usually set at 0.50 to 0.75 in. (12.7 to 19.1 mm) clear space between tubes. These spacings are empirical; they are based on tube fouling and erosion experience and on manufacturing requirements. Chapter 24 discusses surface arrangement and cleanability under *Sootblowers*.

Steam temperature adjustment and control

Improvement in the heat rate of modern boiler units and turbines results mostly from the high cycle efficiency possible with high steam temperatures.

Important reasons for accurate steam temperature regulation are to prevent failures due to excessive metal temperatures in the superheater, reheater, or turbine; to prevent thermal expansion from dangerously reducing turbine clearances; and to avoid erosion from excessive moisture in the last stages of the turbine.

The control of temperature fluctuations from variables of operation, such as slag or ash accumulation, is also important.

With drum-type boilers, steam output is maintained by firing rate, while the resulting superheat and reheat steam temperatures depend on basic design factors, such as total surface quantity and the ratio of convection to radiant heat absorbing surface. Steam temperatures are also affected by other important operating variables such as excess air, feedwater temperature, changes in fuel that affect burning characteristics, ash deposits on the heating surfaces, and the specific burner combination in service. In the once-

Fig. 15 Pendant superheater section with split ring casting supports.

Fig. 16 Pendant reheater section with supports.

through boiler, which has a variable steam-water transition zone, coordination of the firing rate and the boiler feedwater flow rate control steam output pressure and temperature, leaving reheat steam temperature as a dependent variable. (See Chapter 26.) Standard performance practice for steam generating equipment usually permits a tolerance of $\pm 10^{\circ}\text{F}$ (6°C) in a specific steam outlet temperature.

Definitions of terms

Adjustment is a physical change in the arrangement of heating surface that affects steam temperature, but can not be used to vary steam temperature during operation. This could be the addition or deletion of component surface or boiler surface ahead of the superheater and/or reheater.

Control is the regulation of steam temperature during operation without changing the arrangement of surface. Examples are operation of attemperators, gas proportioning dampers, and gas recirculation fans.

The **attemperator** is an apparatus for reducing and controlling the temperature of a superheated fluid passing through it. This is accomplished by spraying high purity water into an interconnecting steam pipe usually between superheater stages or upstream of a reheater inlet.

The **gas proportioning damper** is used to control reheat steam temperatures. The damper opens to split the flow of hot flue gas between the superheater and reheater.

The **gas recirculation fan** is used for controlling reheat steam temperature by extracting flue gas from the economizer and injecting it into the furnace.

Effect of operating variables

Many operating variables affect steam temperatures in drum-type units. To maintain constant steam temperature, means must be provided to compensate for the effect of these variables.

Load As load increases, the quantity and temperature of the combustion gases increase. In a convection superheater (see *Superheater types*), steam temperature increases with load with the rate of increase being less for superheater surfaces located closer to the furnace. In a radiant superheater (see *Superheater types*), steam temperature declines as load increases. Normally a proportioned combination of radiant and convection superheater surface is installed in series in a steam generating unit to maintain steam temperature as constant as possible over the load range. (See Fig. 12.)

Excess air For a change in the amount of excess air entering the burner zone there is a corresponding change in the quantity of gas flowing over the convection superheater; therefore, an increase in excess air generally raises the steam temperature. However, the degradation of boiler efficiency due to the addition of excess air usually more than offsets the improvement in heat rate, making this technique uneconomical other than in special circumstances.

Feedwater temperature Decreasing the feedwater temperature by taking a feedwater heater out of service will increase the fuel input required to generate a given amount of steam. This will result in high gas weights and temperatures, which will yield higher steam temperatures in the superheater.

Heating surface cleanliness Removal of ash deposits from heat absorbing surfaces ahead of the superheater reduces the temperature of the gas entering the superheater and, subsequently, the steam temperature. Removal of deposits from the superheater surface increases superheater absorption and raises steam temperature.

Use of saturated steam If saturated steam from the boiler is used for sootblowers or auxiliaries, such as pump or fan drives, an increased firing rate is required to maintain constant main steam output. This raises the steam temperature.

Fig. 17 Horizontal superheater section end supports on walls.

Blowdown The effect of blowdown (water bled from the boiler drum or steam supply system to reduce contaminants) is similar to the use of saturated steam, but to a lesser degree because of the low enthalpy of water as compared to steam.

Burner operation The distribution of heat input among burners at different locations or a change in burner adjustment usually has an effect on steam temperature due to changes in furnace heat absorption rate.

Fuel Variations in steam temperature may result from changing the type of fuel burned or from day to day changes in the characteristics of a given fuel.

Adjustment

Steam generating equipment represents a large, long-term capital investment. Over the life of the equipment, it is not unusual for the quality of the fuel or even the steam requirements to change. Ideally, provisions would be made in the original design to accommodate the modifications required by such changes. However, economics and space limitations often limit the designers ability to incorporate these provisions. As a result, if such changes do occur during the life of the equipment, it will usually be necessary to have the new conditions and/or fuel reviewed to determine what design changes can be made within the constraints imposed by the existing equipment.

Control

Control is necessary to regulate steam temperature within required limits in order to correct fluctuations caused by operating variables – particularly boiler load. Besides boiler load variation, ash deposition on heat transfer surfaces and fuel variations are the most frequent cause of steam temperature fluctuations. Changes in the sequence or frequency of sootblower operation can usually correct this condition. Selective operation of furnace wall blowers or implementation of unit load reductions to induce slag shedding from the furnace walls can reduce gas temperatures entering the superheater surfaces. The removal of feedwater heaters or pulverizers from service can also impact steam temperature and require steam temperature control.

The turbine manufacturer in accordance with a safe steam temperature-time curve establishes the time in which a turbine may be brought to full load. Because the temperature of the steam is directly related to the degree of expansion of the turbine elements and, consequently the maintenance of safe clearances, this temperature must be regulated within permissible limits by an accurate control device.

Among the means of control for regulating steam temperature are: attemperation, gas proportioning dampers, gas recirculation, excess air, burner selection, movable burners, divided furnace with differential firing, and separately fired superheaters. With attemperation, diluting high temperature steam with low temperature water or removing heat from the steam regulates steam temperature. By comparison, the other methods of control are based on varying the amount of heat absorbed by the steam superheating surfaces.

Attemperation Attemperators may be classified as two types – direct contact and surface. The spray type exemplifies the direct contact design, where the steam and the cooling medium (water and saturated steam) are mixed. In the surface design, which includes the shell type and the drum type, the steam is isolated from the cooling medium by the heat exchanger surface. Spray attemperators are usually preferred on all units that have attemperation requirements; however, surface type attemperators are occasionally used on some industrial units.

The superheater attemperator may be located either at some intermediate point between two sections of the superheater, or at the superheater outlet. The ideal location for the superheater attemperator for the purpose of *process control* is at the superheater outlet. Control would be direct and there would be no time lag. However, problems with this location include possible water carryover into the turbine and overheating of superheater tubes. Placing the superheater attemperator between superheater stages addresses these concerns, and is generally preferred. In addition, the attemperation fluid so thoroughly mixes with steam from the first stage superheater that it enters the second stage superheater at a uniform temperature. For reheat superheater applications, the attemperator is typically located at the reheater inlet.

The superheater spray attemperator, illustrated in Fig. 18, has proven most satisfactory for regulating steam temperature. High purity water is introduced into the superheated steam line through a spray nozzle at the throat of a venturi section within the line. Because of the spray action at the nozzle and the high velocity of the steam passing through the venturi throat, the water vaporizes and mixes with the superheated steam reducing the steam temperature. An important construction feature is the continuation of the venturi section into a thermal sleeve downstream from the spray nozzle. This protects the high temperature piping from thermal shock. This shock could result from non-evaporated water droplets striking the hot surface of the piping. The reheat attemperator is similar but does not have a venturi section.

The spray attemperator provides a quick acting and sensitive control for regulating steam temperature. It is important that the spray water be of highest purity, because solids entrained in the water enter the

Fig. 18 Spray attemperator showing thermal sleeve.

steam and may cause troublesome deposits on superheater tubes, piping, or turbine blades. High-pressure heater drains are a source of extremely pure water, but require a separate high pressure corrosion resistant pump if used for attemperator supply. Normally, boiler feedwater is satisfactory, provided condenser leakage and makeup do not introduce too much contamination.

Three attemperator arrangements are possible, depending on the boiler performance requirements:

1. *Single-stage attemperator* A single attemperator may be installed in each of the connecting pipes between two stages of superheat.
2. *Tandem attemperator* A single-stage attemperator with two spray water nozzles may be installed in series in the connecting pipe between two stages of superheat. This arrangement is used where the spray quantity exceeds the capacity of a single nozzle or where the required turndown can not be achieved with a single spray water nozzle. The usual application requires a spray control valve for each spray nozzle. The operation is sequential with the control valve for the downstream spray nozzle opening first and closing last.
3. *Multiple-stage attemperator* Multiple single-stage attemperators are used. A spray control valve is required for each stage of spray. The first stage spray attemperator is used first, with the maximum spray flow based on a minimum allowable difference between the temperature of the steam leaving the attemperator and the saturation temperature. When the flow limit is reached on the first stage, the subsequent stages are activated sequentially.

The attemperation system branches from the feedwater piping. The boiler feed pump provides water pressure for all of the piping to the steam drum and the line to the attemperation system. In most instances, the pressure loss from the boiler feed pump through the feedwater heaters, piping, economizer and primary superheater to the attemperator location inside the connecting piping results in a boiler feed pump discharge pressure high enough to provide the required pressure differential in the attemperator system. The attemperator system pressure must be higher than the superheater steam pressure for proper operation. In certain cases, the feed pump discharge pressure is not sufficient due to low pressure loss in the boiler and feedwater system, or due to the high pressure differential the spray systems require to suit particular boiler characteristics. For these situations, a booster stage in the boiler feed pump is desirable to raise the spray water to the required pressure. Other options are a separate spray water booster pump or an additional feed line valve to increase boiler side resistance at the required loads.

In the past, there were problems in industrial steam power cycles involving deposits in the superheater and on turbine blading, which resulted in failures. Many of these problems were due to impurities in the attemperator spray water. To assure high quality spray water, additional cleanup equipment can be installed on the condensate return and feedwater makeup.

For low-pressure units with feedwater purity less

than that required for spray attemperation, the condenser attemperator system is an economical and reliable system used to produce high quality spray water. (See Chapter 27.)

Drum and once-through boilers may use steam attemperation at very low loads, as described in the *Bypass and startup* section of this chapter.

UP boiler attemperator applications UP boilers are supplied with superheater spray attemperators to reduce variations in superheater outlet temperatures during transients. These attemperators may be single or multiple stage. Spray water is supplied from the UP boiler economizer inlet or directly from the boiler feed pump. Spray attemperation corrects main steam temperature deviations only on a temporary basis and is not the primary means of steam temperature control. Under steady-state conditions, the ratio of firing rate to feedwater flow determines steam temperature.

Gas proportioning dampers As shown in Fig. 4, the horizontal convection tube banks in the back end of a boiler can be divided into two or more separate flue gas passes separated by a baffle wall. The use of dampers in these gas passes then permits proportioning of the gas over the heat transfer surfaces and the control of reheat and superheat temperatures.

Design considerations for such systems include the following:

1. Dampers must be placed in a cool gas zone to assure maximum reliability (typically downstream of all boiler heat transfer surfaces).
2. Draft loss through the unit could increase for some designs, particularly with alternate fuels, so this parameter must be optimized.
3. Control system design and tuning are critical because damper control response is slower than with spray attemperators. Therefore, spray attemperators are used for transient control.
4. Under maximum bias conditions, when one damper is almost completely closed and the other is open, the gas temperatures at the dampers and the heat transfer surfaces nearest the dampers will be at their highest. These temperatures then set the tube metal design requirements.

Gas proportioning dampers are combined with spray attemperation for overall optimal steam temperature control systems. Spray attemperators provide for short-term transient temperature control. The gas proportioning dampers provide longer-term control and adjustment between superheat and reheat temperatures with a minimum impact on overall unit efficiency.

Gas recirculation Another method of controlling superheat or reheat is flue gas recirculation. As the name implies, gas from the boiler, economizer, or air heater outlet is reintroduced to the furnace by fans and flues. For the sake of clarity, recirculated gas introduced in the immediate vicinity of the initial burning zone of the furnace and used for steam temperature control is referred to as *gas recirculation*, and recirculated gas introduced near the furnace outlet and used for control of gas temperature is referred to as *gas tempering*. Fig. 19 shows an application of gas recirculation through the hopper bottom and gas tem-

pering in the upper furnace of a Radiant boiler. In most instances, the gas is obtained from the economizer outlet. The recirculated gas must be introduced into the furnace in a manner that avoids interference with the fuel combustion. The amount of recirculated gas is expressed as a percentage of the sum of combustion gas weight and setting infiltration.

While recirculated gas may be used for several purposes, its basic function is to alter the heat absorption pattern within a steam generating unit. Recirculated gas has the special advantage of providing heat absorption adjustment for use as a design factor in initial surface arrangement, and as a method of controlling the heat absorption pattern under varying operating conditions.

Excess air An increase in the amount of excess combustion air in a drum type unit decreases the furnace heat absorption. At fractional loads, the increase in excess air and the decrease in absorption work together to increase the steam outlet temperature of a convection superheater. The resulting greater weight of gas sent to the stack increases the stack loss; however, the increase in turbine efficiency can offset some of this loss.

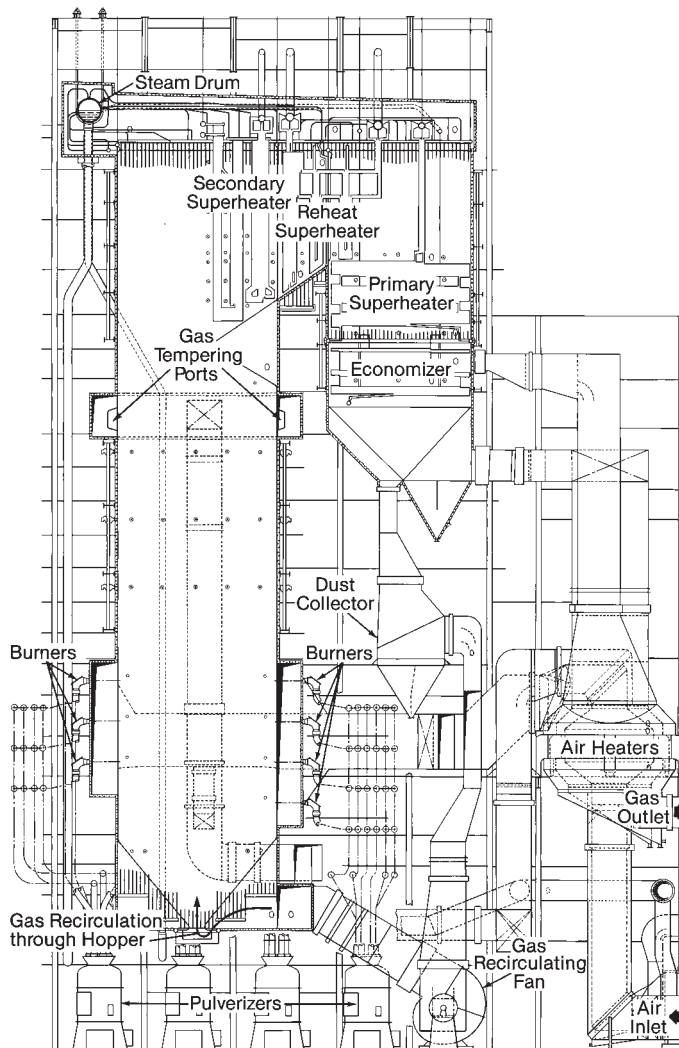

Fig. 19 Radiant boiler with gas tempering for gas temperature control and gas recirculation for control of furnace absorption and reheat temperature.

Burner selection It is often possible to regulate steam temperature by selective burner operation. Higher steam temperatures may be obtained at less than full load by operating only the burners giving the highest furnace outlet temperature. When steam temperature reduction is required, firing may be shifted to the lower burners. Distributing the burners over an extended height of the burner wall can improve this method of control.

Movable burners Using movable burners to raise or lower the main combustion zone in the furnace can also affect the regulation of steam temperature by changing the furnace absorption pattern. Tilting burners are used for this purpose.

Differentially-fired divided furnaces In some divided furnaces, the superheater receives heat from one section of the furnace only, while the other section of the furnace generates only saturated steam or may include a reheater. Changing the proportion of fuel input between the two furnace sections regulates the steam temperature. This arrangement, similar in principle to the separately-fired superheater, was formerly widely used in marine practice. The differentially-fired divided furnace method of steam temperature control is no longer in use today.

Separately-fired superheaters A superheater that is completely separate from the steam generating unit and independently fired may serve one or more saturated steam boilers. This arrangement is not economical for power generation, where a large quantity of high temperature steam is needed.

Bypass and startup systems

High pressure drum and once-through boilers must be capable of rapid, frequent, and reliable unit startups, and rapid load changes, to provide the most economical electrical production. During startup or low load (less than 20%) conditions in which outlet steam temperature tends to follow flue gas temperature, regular water attemperator steam temperature control systems are not sufficiently sensitive to cool the steam, as only a small amount of attemperation is required at low steam loads. However, provisions must still be made to match the differing flow, pressure, and temperature needs of the steam turbine and boiler. To address these special requirements, a variety of bypass and startup systems have been developed for drum and once-through boilers.

UP boiler startup systems

A key requirement of UP startup and bypass systems is the need for minimum design circulation flows in high heat absorbing circuits for cooling before the unit can be fired. Additional important features include providing a turbine bypass until steam pressures and temperatures are matched, reducing the bypass flow pressure and temperature before condenser and auxiliary equipment steam admission, recovering heat during startup, providing clean water for full startup, accelerating the startup processes, and providing greater unit flexibility through dual pressure boiler operation. UP boilers, while originally designed for

base load operation, have been adapted to daily load and on/off cycling. The variable furnace pressure system is capable of on/off cycling, while the constant furnace pressure system is capable of daily low load operation on the bypass system.

Three different UP systems are available – one for constant furnace pressure operation over the load range and two for variable furnace pressure operation over the load range; however, only one variable furnace pressure system will be discussed in detail.

Spiral wound variable pressure startup system For variable furnace pressure systems, the startup system is equipped with pipes, valves, steam-water separators, and a water collection tank. Fig. 20 shows the general arrangement. The startup system controls operation during startup, shutdown, and minimum load operation. The spiral wound universal pressure (SWUP™) once-through boiler requires a minimum flow in the furnace circuits before the boiler can be fired. The flow must remain above this minimum flow during boiler operation. For loads where the steam flow falls below the minimum, the startup system maintains the necessary minimum steam flow through the boiler circuitry and supplies steam to the turbine that was provided to the superheater from the vertical steam separators.

Typical operation Using the boiler feed pump (BFP), water fills the economizer, furnace, vertical steam separator (VSS), and water collecting tank (WCT) until the

WCT reaches normal level. The economizer vent valve (302) opens to vent air from the economizer to the separators. If the WCT water level rises above normal, the separator (WCT) high level control valves (341) will open to control the WCT water level.

During cold startup, the water must circulate through the water cleanup system until feedwater impurities reach an acceptable level before the boiler can be fired. Water flows through the condenser, polishers, and heaters to the boiler, and returns to the condenser by way of the 341 valves. Flow rate is approximately 30% maximum continuous rating (MCR) from the BFP to the condenser at this stage.

After water quality is established, the feedwater flow from the BFP to the boiler is reduced to about 7% MCR flow, where about 4% MCR flows into the economizer to avoid steaming economizer conditions, and about 3% MCR flows to the water collecting tank (WCT) through the subcooling control valve (383). The 383 valve controls the amount of subcooled water to the WCT, protecting the boiler circulation pump (BCP). Provided that the pump cooling system is in service, temperatures are within limits, the BCP inlet shutoff valve (380), the BCP recirculation valve (382), and the 383 valves are all open, the BCP is started, supplying flow to the economizer. The flow from the BFP combined with flow from the BCP provides minimum flow to the boiler. The WCT level control valve (381), which ensures flow to the furnace is over the mini-

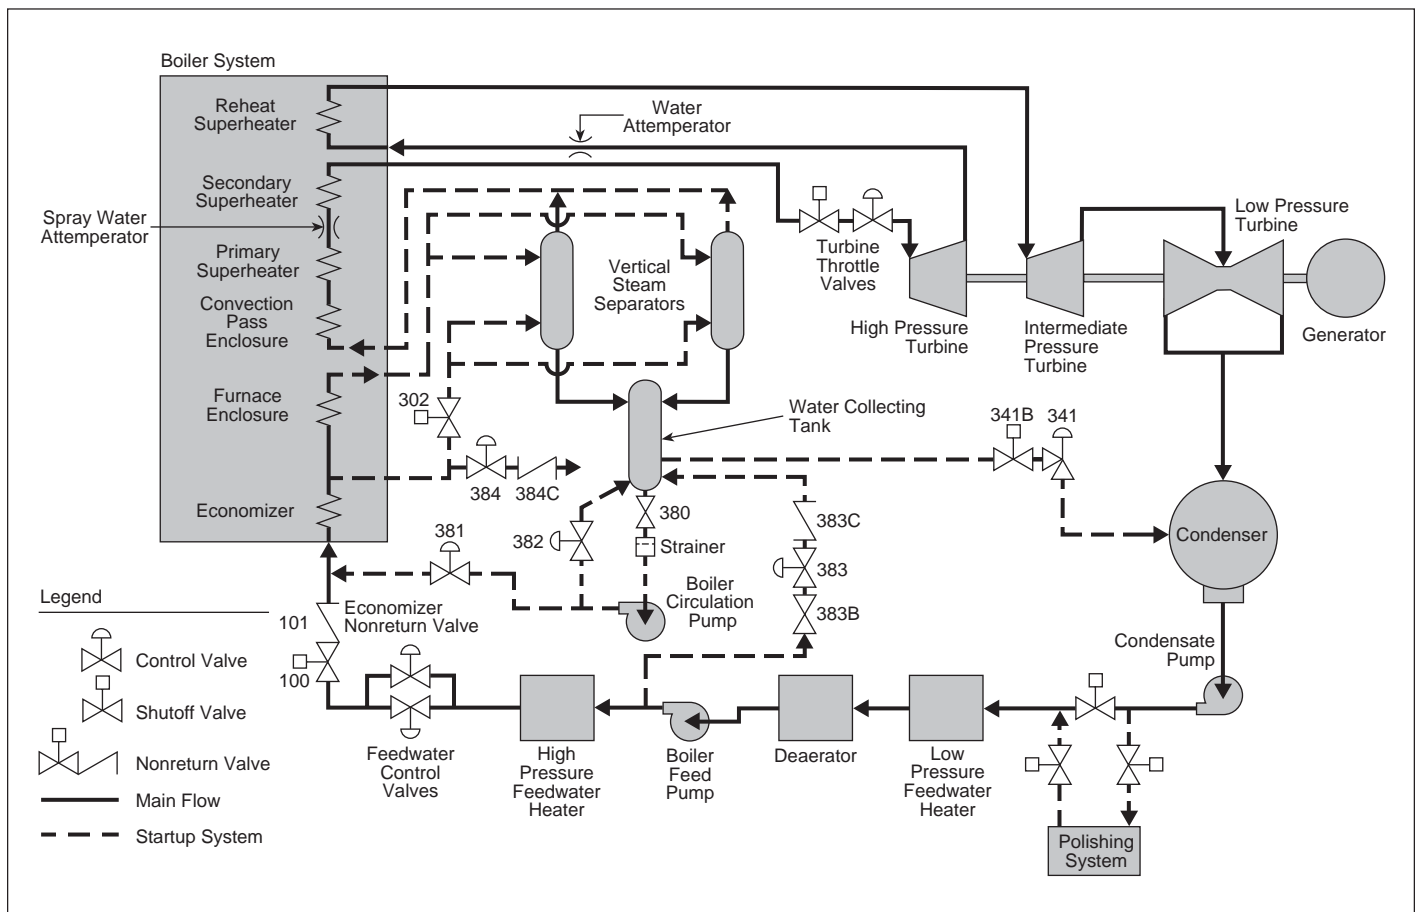

Fig. 20 Spiral wound universal pressure boiler startup system – variable pressure furnace operation.

imum flow required, opens, and tries to maintain the WCT level. With no steam flow, the 381 valve will not be able to regulate the fluid level of the WCT; therefore, the 341 valve controls the level until steam flow exceeds feedwater flow. When the BCP flow is above minimum, the 382 valve will close.

Once the circulation is established, the boiler is fired. A short time after firing, steam bubbles start forming in the furnace, causing a rapid expulsion of excess water to the vertical steam separator and WCT. The 341 valves will open quickly to control the WCT level.

As steam begins to form, some is contained for pressure, some is sent to boiler drains and vents, and the balance is used for steam line warming and eventually flows to the turbine. Once the steam production exceeds the total feedwater flow from the BFP, about 7% MCR, the WCT level will fall causing the 341 valves to close and the 381 valves to take control of the WCT level. The separator high level control block valves (341) are open in the event that an upset causes a high fluid level in the WCT and the 341 valves are forced to open. The feedwater pump system maintains the furnace flow at a minimum.

As steam production continues to increase, the 381 valve closes to control the WCT level. The BCP recir-

culation valve (382) opens to protect the BCP by providing sufficient flow, while the 383 valve begins to close. The BCP flow to the economizer inlet decreases, requiring the flow from the BFP to increase. When steam load reaches approximately 15%, the spray water atomizers release to control steam temperature for the cold turbine. Firing rate and steam temperature control operate in a manner similar to that of a steam drum boiler until the boiler transition point, the load at which the boiler becomes once-through and the startup system is no longer required.

At the transition to once-through, the fluid to the VSS is all steam, causing the WCT level to drop. As the WCT goes dry, the 381 valve closes to maintain WCT level. The BCP shuts down and the 383 valve closes. The 341 opens if the WCT level briefly becomes high. All steam is sent to the VSS and the BFP provides feedwater flow equal to the steam flow to the VSS; thus, the unit is in once-through operation.

Beyond the boiler transition point the startup system is no longer necessary, and the startup system warming system is placed into service. At 35% load the separator high level control block valve (341-B) closes. The warming system control valve (384) opens fully at 40% load to keep the startup system warm, and

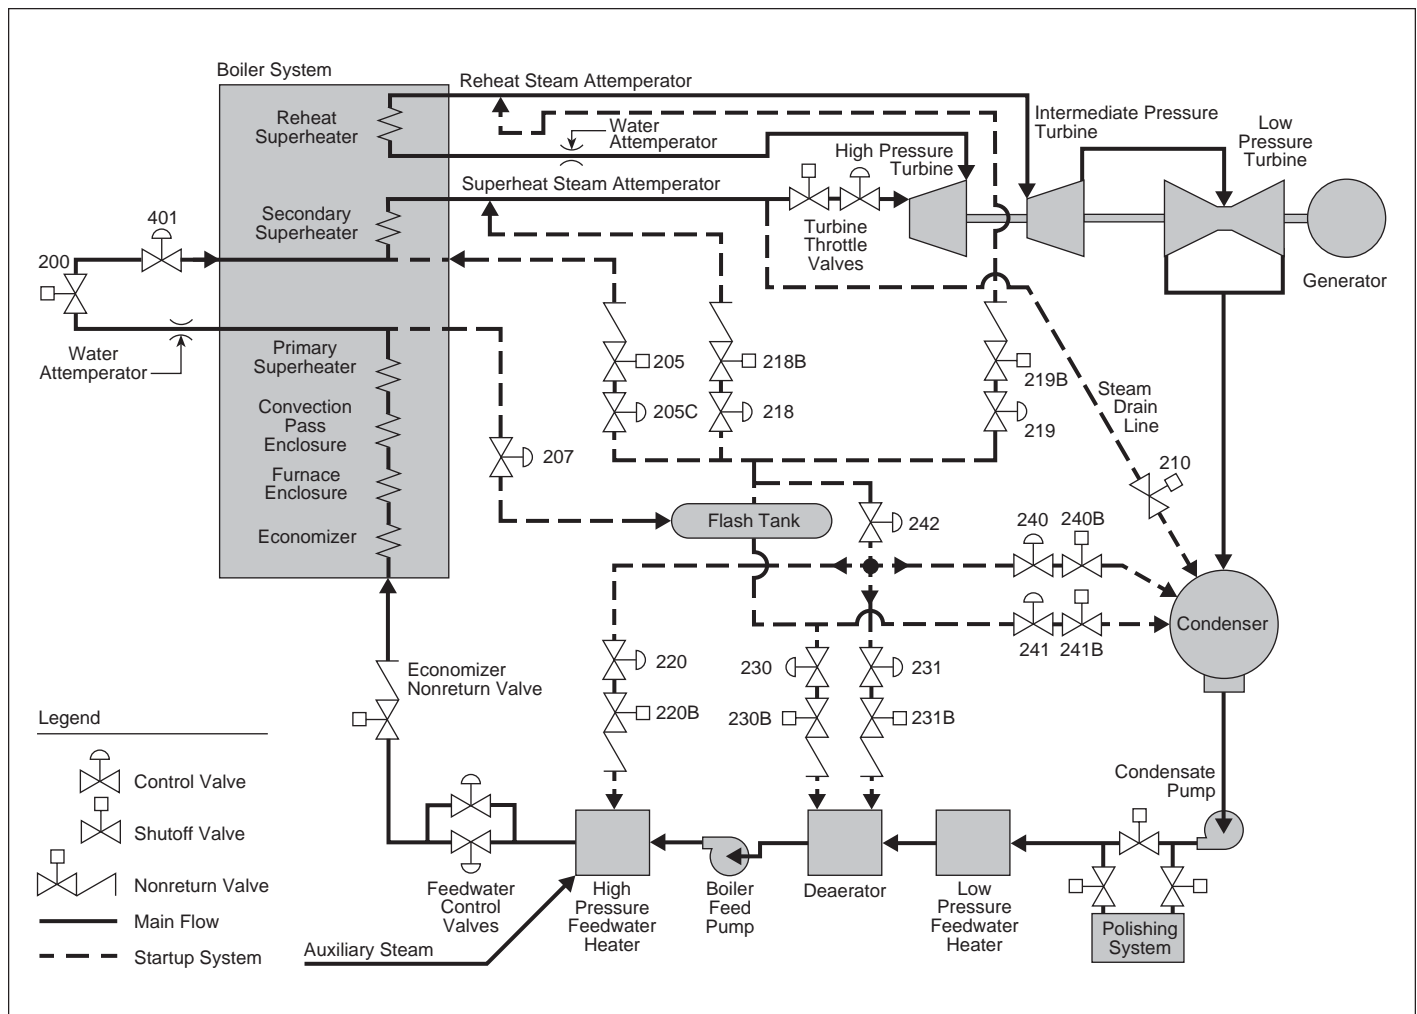

Fig. 21 Universal pressure boiler startup system – constant pressure furnace operation.

closes with increasing load, as more pressure differential is available to drive the warming flow. The 384 valve provides warm flow to the BCP, the 380 line, the 382 line, and the 341 line.

Constant furnace pressure startup system For constant furnace pressure the startup system has the steam separator (*flash tank*) located in a bypass that can be isolated from the boiler during normal operation. Fig. 21 shows the general arrangement.

Typical operation The boiler feed pump supplies the minimum required flow of feedwater during startup and low load operation to protect the furnace circuitry. Included in the startup circuitry are the economizer, furnace, and convection pass enclosures, and primary superheater.

The fluid leaving the primary superheater, at full pressure, is diverted through the pressure reducing valve (207) to the flash tank, where the steam-water mixture is separated during startup.

Drain valves 230 and 241 control the water level in the flash tank, with the 230 valve controlling flow to the deaerator for maximum heat recovery. Excess water above the capability of the deaerator is discharged to the condenser through valve 241. If the drains are not within water quality limits (see Chapter 42), all of the flow is through valve 241 to the condenser and polishing system. When water quality is acceptable, the 230 valve provides flash tank water to the deaerator for maximum heat recovery.

The 242 block valve remains closed until a level is established in the flash tank to assure that water does not enter the steam lines. Once a level is established, the 242 valve is opened and flash tank steam is provided to the deaerator for heat recovery and replacing deaerator auxiliary steam. The deaerator pressure is controlled with the 231 valve. Any excess steam not needed by the deaerator is first sent to the high pressure heater (220 valve), then excess steam not needed by the high pressure heater is sent to the condenser (240 valve).

Flash tank steam is provided to the secondary superheater inlet by the low pressure superheater nonreturn valve (205), secondary superheater low pressure control valve (205C), and associated piping. The 205 valves normally open at 300 psig (2.07 MPa), sending dry steam to the secondary superheater for warming steam lines. The turbine bypass valve (210) normally opens at 300 psig (2.07 MPa) main steam pressure to assist with warming and boiling out the superheater during the initial stage of startup. When sufficient steam is available, the turbine is rolled and placed on line.

The 240 valve relieves excess steam separated in the flash tank to the condenser. This valve also acts as an overpressure relief valve to avoid tripping spring loaded safety valves on the flash tank. The 240 valve has an adjustable set point, which can be set to hold various flash tank pressures at particular load points during startup.

The entire bypass system is sized to handle minimum required flow during startup and to permit operating up to the once-through load on the flash tank. Turbine load is increased from synchronization to once-through by increasing the boiler firing rate. As

load is increased, the 220, 230, 231, 240, and 241 valves will close to provide a higher and higher percentage of the minimum boiler flow as steam from the flash tank to the turbine.

The transition from bypass system to once-through operation is made at the load corresponding to the minimum required flow, typically 25%. At this load, the steam entering and leaving the flash tank is slightly superheated, and all steam entering the flash tank goes to the superheater and turbine. By this load, the 220, 230, 231, 240, and 241 valves are all closed. The transition is made, at constant load, by slowly opening the superheater division valve (401). Opening the 401 causes the 200 block valve to go fully open, and the 207 valve to close to maintain boiler pressure. When the 207 valve is fully closed, the boiler is off the bypass system and the load can be increased. This method provides a very smooth and controlled transition from bypass to once-through operation.

Variable throttle pressure Above the minimum once-through load, the unit can be operated at constant or variable throttle pressure. To operate with variable throttle pressure, the 401 valve is used to vary throttle pressure across the load range, while maintaining full boiler pressure in the upstream circuits. This is called *dual or split pressure operation*. To operate with constant throttle pressure, the 401 valve is fully opened, with all throttling done by the turbine control valves.

The variable throttle pressure feature permits operating the unit with the throttle valves essentially wide open, and has three main advantages. First, this eliminates turbine metal temperature changes resulting from valve throttling and permits rapid load changes without being limited by turbine heating or cooling rates. Second, there can be a low load plant heat rate benefit. Third, shutdown with variable pressure maintains high temperatures in the turbine metals at low loads for reduced turbine stress from load cycling.

Steam temperature control The means for controlling main steam and reheat temperatures at normal operating loads are not effective during startup or very low loads. The startup system shown in Fig. 21 includes provision for steam attemperation from the flash tank to the main and reheat steam outlet headers. Steam attemperation precisely controls steam conditions during startup to meet the turbine metal temperature requirements.

The superheater outlet steam attemperator valve (218) is used at loads less than 20% to introduce saturated steam from the flash tank to the superheater outlet header. Initial rolling of the turbine, for a cold start, may be done with saturated steam passing from the flash tank through the 218 valve. This steam may be mixed with a limited quantity of steam passing through the 205 valves and the secondary superheater to control the high pressure turbine inlet temperature down to about 550F (288C). The 205C control valve achieves the necessary pressure drop between the flash tank and the secondary outlet header to allow steam attemperation to work.

The reheat outlet steam attemperator valve (219) is used at loads below about 20% of full load to introduce flash tank steam to the reheat outlet header. The

ratio of flow through the attemperator valve to that through the high pressure turbine is limited mainly for turbine and turbine control considerations.

Overpressure relief The bypass system is also used to relieve excessive pressure in the boiler during a load trip. The use of the 207 valve, which sends excess steam to the flash tank, accomplishes this.

Bypass retrofits The above bypass system would be provided with any new UP constant furnace pressure boiler. Currently in operation are a variety of UP bypass systems that range from similar to vastly different than those described above. Many of these older units had their bypass systems retrofitted to incorporate some or all of the above features to improve operational flexibility and ease of startup.

Drum boiler bypass system

The B&W Radiant boiler bypass system minimizes startup time, controls shutdowns in anticipation of restarts, provides control of steam temperature to match turbine metal temperature, and allows dual pressure operation of the boiler and turbine for better load response. These features reduce stresses in the turbine for improved turbine availability and reduced maintenance costs. The drum boiler bypass system consists of an engineered system of steam valves and piping, as shown in Fig. 22.

This flexible bypass system can conform to most operating changes. For example, it can adapt to a turbine malfunction by adjusting the steam temperature and flow through any load range from synchronization to high load points. Although the bypass system enhances unit operation, the boiler can be operated as a conventional non-bypass unit at any time.

Operation

Dual pressure The drum boiler bypass system has a combination of valves consisting of a superheater stop valve (500) and a superheater stop valve bypass valve (501), which allows dual pressure operation. During dual pressure operation, the 501 valve controls the throttle pressure independently from the drum pressure. This permits constant pressure operation of the major boiler components and variable pressure operation of the turbine. A dual pressure shutdown keeps the boiler near full pressure and the turbine metal near maximum temperature in preparation for a quick restart, thus minimizing thermal stresses in the boiler and turbine. In addition, it allows more rapid load changes than full variable boiler pressure operation.

The 501 valve is a control valve typically sized for about 70% of full load steam flow. This permits dual pressure operation up to approximately 70% load. This percentage will vary depending on the specifics of the

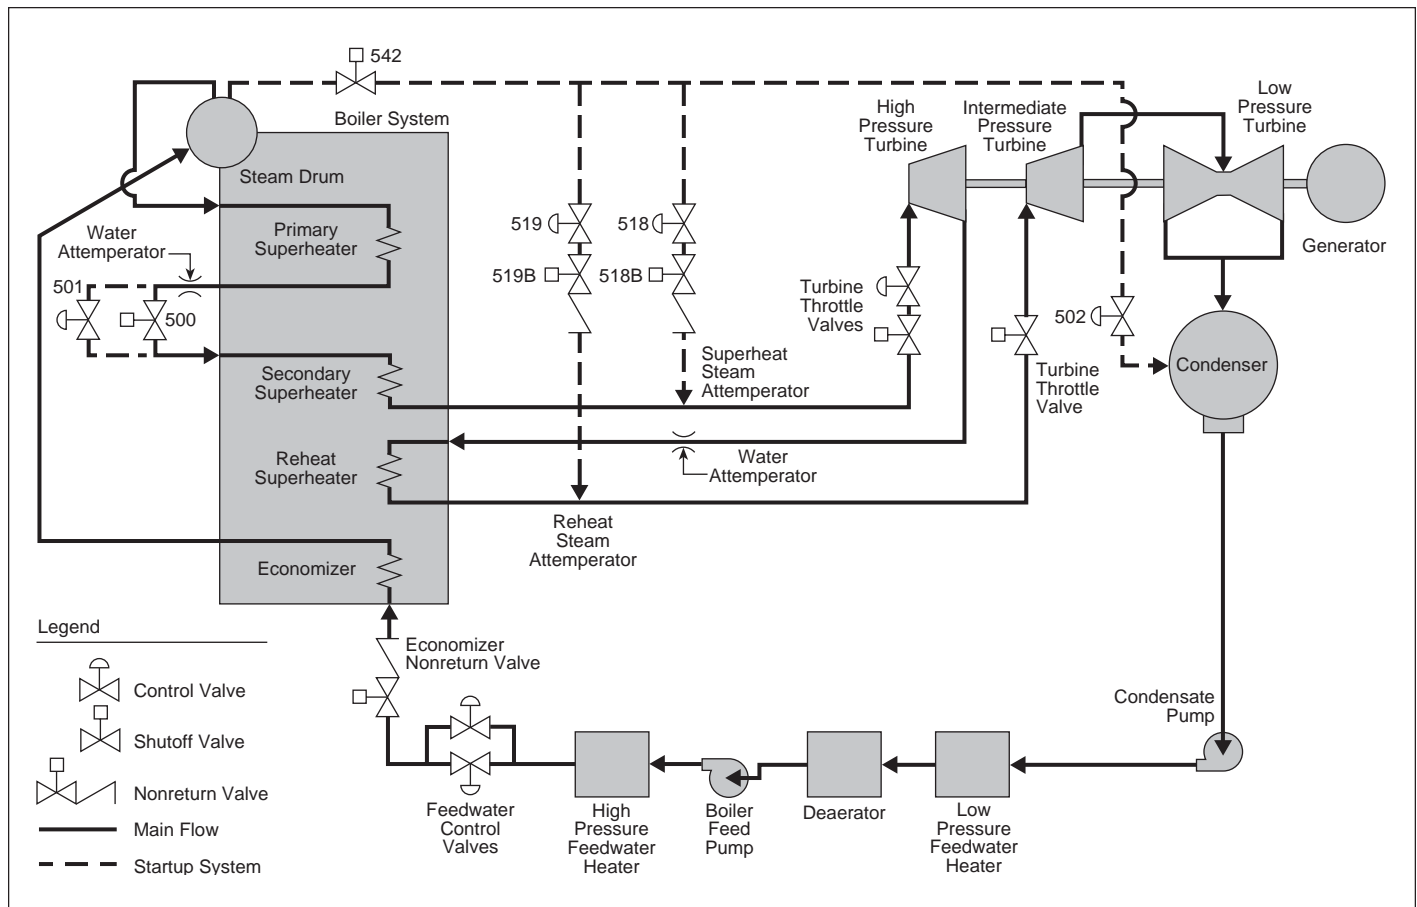

Fig. 22 Drum boiler bypass system schematic.

steam turbine. The 500 valve is a stop valve, which is pulsed open after the 501 is open. Once the 500 valve is completely open, the unit will operate in a constant pressure mode, with the turbine control valves opening to provide the increase from 70 to 100% load.

Steam attemperation The main steam outlet attemperator valve (518) and reheat outlet attemperator valve (519) are used for steam attemperation at low loads, when the normal water attemperation is not effective. Slightly superheated steam is mixed in the outlet headers, via special header internal nozzles, to produce a lower main and reheat steam temperature. Thus, the boiler can be fired to produce drum pressure and steam quickly without concern for the steam temperature to the turbine, reducing startup time and thermal stress in the turbine. The 518 and 519 valves are used for cold and warm

startups, when the turbine metal temperature is low.

Drum pressure control The primary superheater bypass valve (502) controls drum pressure independent of firing rate. This allows the boiler to be fired to maximum furnace exit gas temperature producing the high steam temperature needed by the turbine for a hot startup, without concern for the drum pressure rising above maximum allowable pressure. The excess steam bypasses the primary and secondary superheater, to help provide maximum steam temperature. A primary superheater bypass shutoff valve (542) assures tight shutoff when the 502, 518, and 519 valves are closed.

Startup without bypass system The unit can be started and operated without use of the bypass system. Fully opening the 500 valves allows a conventional drum boiler startup.

Superheater installation in a coal-fired utility boiler.

Chapter 20

Economizers and Air Heaters

Economizers and air heaters perform a key function in providing high overall boiler thermal efficiency by recovering the low level (i.e., low temperature) energy from the flue gas before it is exhausted to the atmosphere. For each 40F (22C) that the flue gas is cooled by an economizer or air heater in a conventional boiler, the overall boiler efficiency increases by approximately 1% (Fig. 1). Economizers recover the energy by heating the boiler feedwater; air heaters heat the combustion air. Air heating also enhances the combustion of many fuels and is critical for pulverized coal firing to dry the fuel and ensure stable ignition.

In contrast to the furnace waterwalls, superheater and reheater, economizers and air heaters require a large amount of heat transfer surface per unit of heat recovered. This is because of the relatively small difference between the flue gas temperature and the temperature of either the feedwater or the combustion air. Use and arrangement of the economizer and/or air heater depend upon the particular fuel, application, boiler operating pressure, power cycle, and overall minimum cost configuration.

Fig. 1 Approximate unit efficiency increase due to an economizer and air heater in conventional boilers.

Increasingly stringent environmental regulations limiting nitrogen oxides (NO_x) and sulfur dioxide (SO_2) emissions can also affect economizer and air heater design. Selective catalytic reduction (SCR) systems for NO_x control operate within an optimal flue gas temperature range, and the arrangement and/or operation of the economizer may need to be modified accordingly. In the United States (U.S.), there has been a substantial increase in the use of low-sulfur Powder River Basin (PRB) coal to reduce SO_2 emissions. However, PRB coal ash has high fouling and plugging characteristics that prohibit extended surface economizers and require the use of sootblowers throughout the boiler.

Economizers

Economizers are basically tubular heat transfer surfaces used to preheat boiler feedwater before it enters the steam drum (recirculating units) or furnace surfaces (once-through units). The term economizer comes from early use of such heat exchangers to reduce operating costs or economize on fuel by recovering extra energy from the flue gas. Economizers also reduce the potential of thermal shock and strong water temperature fluctuations as the feedwater enters the drum or waterwalls. Fig. 2 shows an economizer location on a coal-fired boiler. The economizer is typically the last water-cooled heat transfer surface upstream of the air heater. (See chapter frontispiece.)

Economizer surface types

Bare tube

The most common and reliable economizer design is the bare tube, in-line, crossflow type. (See Fig. 3a.) When coal is fired, the flyash creates a high fouling and erosive environment. The bare tube, in-line arrangement minimizes the likelihood of erosion and trapping of ash as compared to a staggered arrangement shown in Fig. 3b. It is also the easiest geometry to be kept clean by sootblowers. However, these benefits must be evaluated against the possible larger weight, volume and cost of this arrangement.

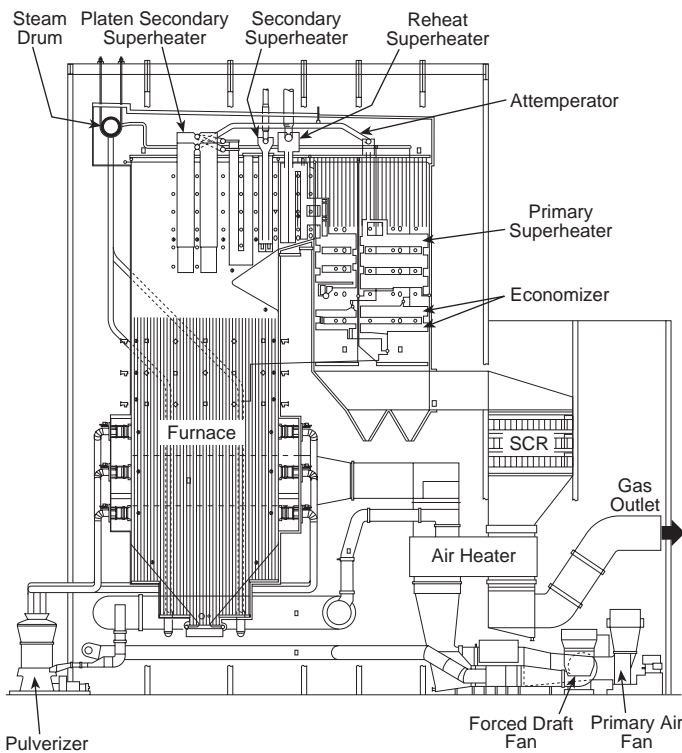

Fig. 2 Economizer and air heater locations in a typical coal-fired boiler.

Fig. 3 Bare tube economizer arrangements.

Fig. 4 Longitudinal fins, staggered tube arrangement. (Fin width exaggerated for clarity.)

Extended surfaces

To reduce capital costs, most boiler manufacturers have built economizers with a variety of fin types to enhance the controlling gas-side heat transfer rate. Fins are inexpensive parts which can reduce the overall size and cost of an economizer. However, successful application is very sensitive to the flue gas environment. Surface cleanability is a key concern. In selected boilers, such as PRB coal-fired units, extended surface economizers are not recommended because of the peculiar flyash characteristics.

Stud fins Stud fins have worked reasonably well in gas-fired boilers. However, stud finned economizers can have higher gas-side pressure drop than a comparable unit with helically-finned tubes. Studded fins have performed poorly in coal-fired boilers because of high erosion, loss of heat transfer, increased pressure loss and plugging resulting from flyash deposits.

Longitudinal fins Longitudinally-finned tubes in staggered crossflow arrangements, shown in Fig. 4, have also not performed well over long operating periods. Excessive plugging and erosion in coal-fired boilers have resulted in the replacement of many of these economizers. In oil- and gas-fired boilers, cracks have occurred at the points where the fins terminate. These cracks have propagated into the tube wall and caused tube failures in some applications. Plugging with flyash can also be a problem (tight spaces).

Fig. 5 Helically-finned tube.

Helical fins Helically-finned tubes (Fig. 5) have been successfully applied to some coal-, oil- and gas-fired units. The fins can be tightly spaced in the case of gas firing due to the absence of coal flyash or oil ash. Four fins per inch (1 fin per 6.4 mm), a fin thickness of 0.06 to 0.075 in. (1.5 to 1.9 mm) and a height of 0.75 in. (19.1 mm) are typical. For 2 in. (51 mm) outside diameter tubes, these fins provide ten times the effective area of bare tubes per unit tube length. If heavy fuel oil or coal is fired, a wider fin spacing must be used and adequate measures taken to keep the heating surface as clean as possible. Economizers in units fired with heavy fuel oil can be designed with helical fins, spaced at 0.5 in. (13 mm) intervals. Smaller fin spacings promote plugging with oil ash, while greater spacings reduce the amount of heating surface per unit length. Sootblowers are required and the maximum bank height should not exceed 4 to 5 ft (1.2 to 1.5 m) to assure reasonable cleanability of the heating surface. An in-line arrangement also facilitates cleaning and provides a lower gas-side resistance.

Rectangular fins The square or rectangular fins, arranged perpendicular to the tube axis in in-line tubes as shown in Fig. 6, have been used occasionally in retrofits. The fin spacing typically varies between 0.5 and 1 in. (13 and 25 mm) and the fins are usually 0.125 in. (3.18 mm) thick. There is a vertical slot down the middle because the two halves of the fin are welded to either side of the tube. Most designs are for gas velocities below 50 ft/s (15.2 m/s). However, because of the narrow, deep spaces, plugging with flyash is a danger with such designs.

Baffles The tube ends should be fully baffled (Fig. 7) to minimize flue gas bypass around finned bundles. Such bypass flow can reduce heat transfer, produce excessive casing temperatures, and with coal firing can lead to tube bend erosion because of very high gas velocities. Baffling is also used with bare tube bundles but is not as important as for finned tube bundles. Tube bend erosion can be alleviated by shielding the bends.

Velocity limits

The ultimate goal of economizer design is to achieve the necessary heat transfer at minimum cost. A key design criterion for economizers is the maximum allowable flue gas velocity (defined at the minimum cross-sectional free flow area in the tube bundle). Higher velocities provide better heat transfer and reduce capital cost. For clean burning fuels, such as gas and low ash oil, velocities are typically set by the

Fig. 6 Rectangular fins, in-line tube arrangement.

Fig. 7 Baffling of bare tube return bends for finned tube bundles.

maximum economical pressure loss. For high ash oil and coal, gas-side velocities are limited by the erosion potential of the flyash. This erosion potential is primarily determined by the percentage of Al_2O_3 and SiO_2 in the ash, the total ash in the fuel and the gas maximum velocity. Experience dictates acceptable flue gas velocities. Fig. 8 provides sample base velocity limits as a function of ash characteristics. Note: PRB coal contains ash with low erosion potential. Velocities above 70 ft/s (21.3 m/s) can typically be allowed for such coals.

Further criteria may also be needed. For example, a 5 ft/s (1.5 m/s) reduction in the base velocity limit is recommended when firing coals with less than 20% volatile matter. In other cases, such as Cyclone boilers, high flue gas velocities can be used because much

Fig. 8 Base maximum allowable velocity for pulverized coal-fired boiler economizers.

less flyash is carried into the convection pass, as much of the ash (> 50%) is collected in the bottom of the boiler as slag. Particles that enter the boiler furnace are also less erosive. (See Chapter 15.)

For a given tube arrangement and boiler load, the gas velocity depends on the specific volume of flue gas which falls as the flue gas is cooled in the economizer. To maintain the gas velocity, it can be economical to decrease the free flow gas-side cross-section by selecting a larger tube size in the lower bank of a multiple bank design. This achieves better heat transfer and reduces the total heating surface.

Other types of economizers

Fig. 9 depicts an industrial boiler with a longflow economizer, often used in chemical recovery boilers. Such heating surfaces consist of vertical, longitudinally-finned (membraned) tubes through which the feedwater flows upward. The gas flows downward in pure counterflow, outside the tubes and fins. While the heat transfer is less efficient than crossflow banks of tubes, there is minimal gas-side resistance and fouling products are removed through hoppers at the bottom of the enclosure.

Steaming economizers

Steaming economizers are defined as meeting the following enthalpy relationships:

$$H_2 - H_1 \geq \frac{2}{3} (H_f - H_1) \quad (1)$$

where

H_2 = enthalpy of fluid leaving economizer (to drum)
 H_1 = enthalpy of fluid (water) entering economizer

Fig. 9 Longflow economizer for a chemical recovery boiler.

H_f = enthalpy of saturated water at economizer outlet pressure

These economizers can be economical in certain boilers. They require careful design and must be oriented so the water flows upward and the outlet is below drum level. This avoids water hammer and excessive flow instabilities. The enthalpy equation accounts for possible steaming due to flow imbalances and differences in individual circuit heat absorptions.

High-pressure, drum-type units are usually sensitive to feedwater temperatures close to saturation. To enhance circulation, feedwater temperature to the drum should normally be at least 50F (28C) below saturation temperature. However, for some applications, due to specific design conditions, use of Equation 1 may result in a feedwater temperature slightly greater than 50F (28C) below saturation temperature.

Performance

Heat transfer

Bare tubes The equations discussed in Chapter 4 can be used to evaluate the quantity of surface for an economizer. For the economizer shown in Fig. 2 with the upflow of water and downflow of gas and nonsteaming conditions, the bundle can be treated as an ideal counterflow heat exchanger with the following characteristics:

1. bundle log mean temperature difference correction factor = 1.0,
2. heat absorbed by the tube wall enclosures and heat radiated into the tube banks from various cavities can generally be neglected,
3. all of the energy lost by the flue gas is absorbed by the water, i.e., no casing heat loss,
4. the water-side heat transfer coefficient is typically in the range of 2000 Btu/h ft² F (11,357 W/m² K) and has only a small overall impact on the economizer performance, and
5. the effect of gas-side ash deposition can be accounted for by a cleanliness factor based upon experience.

In general the heat transfer rate is primarily limited by the gas-side heat transfer for in-line bare tube bundles. In this case, the overall heat transfer coefficient (flue gas to feedwater) used in the heat exchanger calculation can be approximated by the following relationship:

$$U = 0.98 (h_c + h_r) k_f \quad (2)$$

where

U = overall heat transfer coefficient, Btu/h ft² F (W/m² K)

h_c = gas-side heat transfer coefficient for a bare tube bundle, Btu/h ft² F (W/m² K) (Chapter 4, Equations 60 and 61)

h_r = inter-tube radiation heat transfer coefficient, Btu/h ft² F (W/m² K) ≈ 1.0 for coal firing (for finned tubes h_r is very small and is assumed to be 0)

k_f = surface effectiveness factor = 0.7 for coal, 0.8 for oil and 1.0 for gas

Finned tubes Heat transfer performance of finned tube economizers can be evaluated in a similar fashion except that appropriate relationships for extended surfaces should be used. In addition, because the gas-side heat transfer has been enhanced, the water-side heat transfer coefficient and tube wall thermal resistance are more significant and must be included in the evaluation. (See Chapter 4.) As a general guideline, the overall heat transfer coefficient can be approximated by the following relationship for most types of economizer fins:

$$U = 0.95(h_g k_f) \quad (3)$$

where h_g is the gas-side heat transfer coefficient for the heat transfer across finned tube bundles evaluated with the procedures defined in Chapter 4. A calculated example is provided in Chapter 22 for a bare tube economizer tube bundle.

Gas-side resistance

The gas-side pressure loss across the economizer tube bank can be evaluated using the crossflow correlations presented in Chapter 3. The pressure loss should be adjusted for the number of tube rows using the correction factors provided. The gas-side resistance across the in-line finned tube banks is approximately 1.5 times the resistance of the underlying bare tubes.

Water-side pressure drop

The water-side pressure loss can be evaluated using the procedures in Chapter 3 where the total pressure loss ΔP_T is calculated:

$$\Delta P_T = \Delta P_f + \Delta P_l + \Delta P_z \quad (4)$$

where

ΔP_f = friction pressure loss	Ch. 3, Eq. 47
ΔP_l = sum of the local losses (entrance, bends and exits)	Ch. 3, Eq. 52
ΔP_z = static head loss	Ch. 5, Eq. 10

The design pressure is then evaluated by the sum of the drum design pressure and the total pressure loss ΔP_T rounded up to the nearest 25 psig (172 kPa).

If the calculated water-side pressure drop is excessive, the number of parallel flow paths must be increased. If the flue gas velocity can be increased, the water-side pressure drop can also be reduced by increasing the tube size, usually in increments of 0.125 in. (3 mm). As indicated in Chapter 3, the dynamic pressure drop is inversely proportional to the fifth power of the inside tube diameter.

Economizer support systems

Economizers are located within tube wall enclosures or within casing walls, depending on gas temperatures. In general, casing enclosures are used at or below 850F (454C) and inexpensive carbon steel can be used. If a casing enclosure is used, it must not support the economizer. However, tube wall enclosures may be used as supports.

The number of support points is determined by

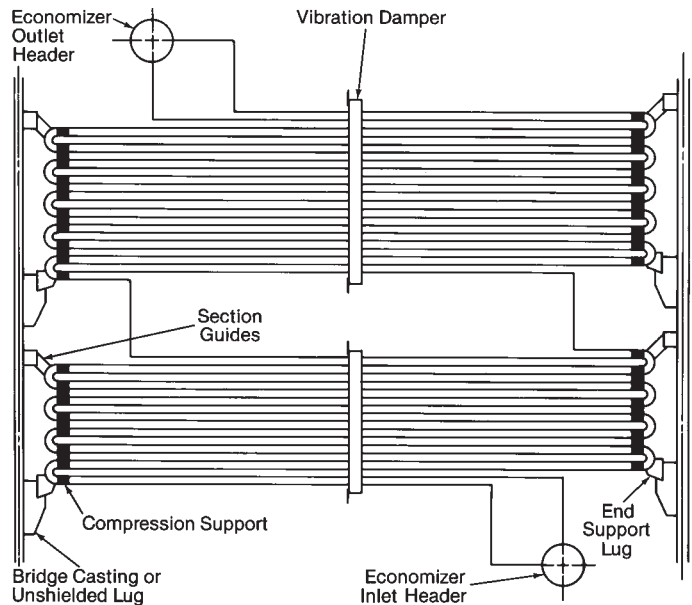

Fig. 10 Economizer supports – sample waterwall support arrangement.

analyzing the allowable deflection in the tubes and tube assemblies. Deflection is important for tube drainability. Figs. 10 through 12 show typical support arrangements for bare tube economizers.

Wall or end supports are usually chosen for relatively short spans and require bridge castings or individual lugs welded or attached to the tube wall enclosures. (See Fig. 10.) Another possibility exists if enclosure wall (usually primary superheater circuitry) headers are present above the economizer (for example, Fig. 11).

Quarter point stringer supports are used for spans exceeding the limits for end supports (Fig. 12). The stringers are mechanically connected to the economizer sections, which are held up by ladder type supports. The supports exposed to hot inlet gases may be made

Fig. 11 Economizer supports – sample lower waterwall header arrangement.

Fig. 12 Economizer supports – sample stringer support arrangement.

of stainless steel, while lower grade material is normally used to support the lower bank which is exposed to reduced gas temperatures. In The Babcock & Wilcox Company (B&W) designs, stringer tubes also usually support other horizontal convection surfaces above the economizer. (See frontispiece.) Bottom support is sometimes used if the gas temperature leaving the lowest economizer bank is low enough.

Bank size

The bank size is limited by the following constraints:

1. type of fuel,
2. fabrication limits,
3. sootblower range,
4. maximum shipping dimensions,
5. construction considerations, especially for retrofits, and
6. maintenance.

Bank depths greater than 6 ft (1.83 m) are rare in new boilers, while carefully designed larger banks can be tolerated in retrofits.

Access requirements

Cavities around the banks are needed for field welding, tube leg maintenance and sootblower clearance. A sufficient number of access doors must be arranged in the enclosure walls to access these cavities. Cavity access can be provided from the outside through individual doors or from the inside through special openings across stringers or collector frames. The minimum cavity height should be 2 ft (0.6 m) of crawl space.

Headers

B&W economizer header designs are typically based on American Society of Mechanical Engineers (ASME) Code requirements. Inlet headers are frequently lo-

cated inside the gas stream and may receive feedwater through one or both ends. Regardless of design, it is necessary to properly seal the inlet pipe where it penetrates the enclosure by using brackets and flexible seals. The seal becomes especially important in pressurized (forced draft) units. Other important considerations are tube leg flexibility, differential expansion and potential gas temperature imbalances and upsets.

The outlet headers, not to be confused with intermediate or transition headers seen in larger boilers and stringer supports, receive the heated feedwater and convey it to the drum or, in the case of once-through boilers, to the downcomer(s) supplying the furnace circuitry. Inlet and outlet headers must be large enough to assure reasonable water flow distribution in the economizer banks. Flow velocities in headers are typically less than 20 ft/s (6.1 m/s).

Vibration ties

Vibration ties or tube guides are required on some end-supported tube sections. These ties may be needed if the natural frequencies within the boiler load range are in or near resonance with the vortex shedding frequency.

Stringer tubes are also subject to vibration. This vibration is magnified by long unsupported stringer tube lengths near the large cavity below the convection pass roof.

Tube geometry, materials and code requirements

Economizer tube diameters typically range between 1.75 and 2.5 in. (44.5 and 63.5 mm). Tubes outside this range are sometimes used in retrofits. Smaller tubes are normally used in once-through, supercritical boilers where water-side pressure drop is less of a consideration. In these units, tube wall thicknesses are minimized.

The ASME Code requires that the design temperature for internal boiler pressure parts is at least 700F (371C). The calculated mean tube wall temperature in economizers seldom reaches this temperature. It usually lies 10 to 20F (6 to 11C) above the fluid temperature, which seldom exceeds 650F (343C) along any economizer circuit.

The minimum tube wall thickness is determined in accordance with procedures outlined in Chapter 8.

In coal-fired boilers, the side spacing is usually determined by the maximum allowable gas velocity and gas-side resistance, which are functions of a given tube size. If fins are used, the side and back tube spacings should permit the fin tips to be at least 0.5 in. (13 mm) apart. For bare tubes, a minimum clear spacing of 0.75 in. (19 mm) is desirable.

PRB coal firing usually calls for increased clear side spacing to avoid plugging and bridging with flyash in the horizontal spaces.

The minimum back (vertical) spacing of the tubes should be no less than 1.25 times the tube outside diameter. Smaller ratios can reduce heat transfer by as much as 30%. Ratios larger than 1.25 have relatively little effect on heat transfer but increase the gas-side resistance and bank depth.

SCR considerations

SCR systems are normally located between the economizer and the air heater. NO_x reduction reactions take place within an optimal temperature range as the flue gas passes through the catalyst reactor (see Chapter 34). Therefore, flue gas temperature entering the SCR is critical to system performance.

Typical temperature control methods include:

1. **Gas bypass** The goal is to maintain a minimum gas temperature to the SCR, typically 600F (316C) to 650F (343C) for coal-fired applications, over the boiler load range in which the SCR will be operated. This can be achieved by extracting flue gas from a cavity above the economizer or between economizer banks, and routing the higher temperature gas to a point upstream of the SCR where it is mixed with lower temperature gas from the economizer outlet. The gas flow through the bypass flue is controlled by a damper.

In retrofits, the bypass gas flow is usually limited by the available gas-side pressure differential and maximum allowable gas velocity through the bypass flue. Existing physical constraints limit the maximum flue size. The increase in flue gas temperature entering the SCR reduces boiler efficiency due to an increase in flue gas temperature leaving the unit. To reduce this loss in boiler efficiency, a separate economizer bank can be installed downstream of the SCR or additional air heater surface can be added if space is available.

2. **Water-side bypass** Water-side parameters (i.e., mass flow) indirectly control the flue gas temperature exiting the economizer by reducing the water flow through some of the economizer surface, thus reducing economizer heat absorption. (Instead of a gas-side damper controlling the gas bypass flow, several control valves regulate water flow to the various economizer banks.) Economizer water outlet temperature should not exceed certain limits dictated by furnace circulation.
3. **Duct burners** Special duct burners (usually natural gas fired) are sometimes used to raise the gas temperature entering the SCR. However, the economics of natural gas firing must be carefully evaluated.

Air heaters

Air heaters are used in most steam generating plants to heat the combustion air and enhance the combustion process. Most frequently, the flue gas is the source of energy and the air heater serves as a heat trap to collect and use waste heat from the flue gas stream. This can increase the overall boiler efficiency by 5 to 10%. Air heaters can also use extraction steam or other sources of energy depending upon the particular application. These units are usually employed to control air and gas temperatures by preheating air entering the main gas-air heaters.

Air heaters are typically located directly behind the boiler, as depicted in Fig. 2, where they receive hot flue gas from the economizer and cold combustion air from the forced draft fan(s). The hot air produced by air

heaters enhances combustion of all fuels and is needed for drying and transporting the fuel in pulverized coal-fired units.

Classification of air heaters

Air heaters are classified according to their principle of operation as recuperative or regenerative.

Recuperative

In a recuperative heat exchanger, heat is transferred continuously and directly through stationary, solid heat transfer surfaces which separate the hot flow stream from the cold flow stream. The most common heat transfer surfaces are tubes and parallel plates. Recuperative heat exchangers function with little cross-contamination, or leakage, between streams.

Tubular air heaters In a typical tubular air heater, energy is transferred from the hot flue gas flowing inside many thin walled tubes to the cold combustion air flowing outside the tubes. The unit consists of a nest of straight tubes that are roll expanded or welded into tubesheets and enclosed in a steel casing. The casing serves as the enclosure for the air or gas passing outside of the tubes and has both air and gas inlet and outlet openings. In the vertical type (Fig. 13), tubes are supported from either the upper or lower tubesheet while the other (floating) tubesheet is free to move as tubes expand within the casing. An expansion joint between the floating tubesheet and casing provides an air/gas seal. Intermediate baffle plates parallel to the tubesheets are frequently used to separate the flow paths and eliminate tube damaging flow induced vibration.

Carbon steel or low alloy corrosion resistant tube materials are used in the tubes which range from 1.5 to 4 in. (38 to 102 mm) in diameter and have wall

Fig. 13 Vertical type tubular air heater.

thicknesses of 18 to 11 gauge [0.049 to 0.120 in. (1.24 to 3.05 mm)]. Larger diameter, heavier gauge tubes are used when the potential for tube plugging and corrosion exists. Tube arrangement may be in-line or staggered with the latter being more thermally efficient.

Tubular air heaters may be fitted with steam or air sootblowers to remove ash accumulations from the gas-exposed side of tubing during operation. Permanent water wash piping above gas-side tube banks may also be used off line to soak and wash tube internal or external surfaces.

The most common flow arrangement is counterflow with gas passing vertically through the tubes and air passing horizontally in one or more passes outside the tubes. A variety of single and multiple gas and air path arrangements are used to accommodate plant layouts. Designs frequently include provisions for cold air bypass or hot air recirculation to control cold end corrosion and ash fouling. Modern tubular air heaters are shop assembled into large, transportable modules. Several arrangements are shown in Fig. 14.

Cast iron air heaters Cast iron tubular air heaters are heavy, large and durable. Their use is mainly limited to the petrochemical industry, but some are used on electric utility units. Cast iron is used because of its superior corrosion resistance. Rectangular, longitudinally split tubes are assembled from two cast iron plates and individual tubes are assembled into air heater sections. Air heaters are usually arranged for a single gas pass and multiple air passes with air flow inside the tubes. Heat transfer is maximized by fins cast into inside and outside tube surfaces.

Plate air heaters Plate air heaters transfer heat from hot gas flowing on one side of a plate to cold air flowing on the opposite side, usually in crossflow. Heaters consist of stacks of parallel plates. Sealing between air and gas streams at plate edges is accomplished by welding or by a combination of gaskets, springs and external compression of the plate stack. Plate materials and spacing can be varied to accommodate operating requirements and fuel types.

Steel plate air heaters were some of the earliest types

Fig. 14 Various tubular air heater arrangements.

used, but their use declined due to plate to plate sealing problems. However, sealing developments have prompted increased use in industrial and small utility applications. Plate modules may be combined to make different size air heaters with a variety of flow path arrangements. A single gas pass, two air pass plate air heater is shown in Fig. 15. Modern plate units are somewhat smaller than tubular units for a given capacity and exhibit minimal air to gas leakage.

Steam coil air heaters Steam coil and water coil recuperative air heaters are widely used in utility steam generating plants to preheat combustion air. Air preheating reduces the corrosion and plugging potential in the cold end of the main air heater. Occasionally, they serve as the only source of preheated combustion air. These heaters consist of banks of small diameter, externally finned tubes arranged horizontally or vertically in ducts between the combustion air fan and main air heater. Combustion air, passing in crossflow outside the tubes, is heated by turbine extraction steam or feedwater flowing inside the tubes. Ethylene glycol is sometimes used as the hot fluid to prevent out of service freezing damage.

Regenerative

Regenerative air heaters transfer heat indirectly by convection as a heat storage medium is periodically exposed to hot and cold flow streams. A variety of materials can be used as the medium and periodic exposure to hot and cold flow streams can be accomplished by rotary or valve switching devices. In steam generating plants, tightly packed bundles of corrugated steel plates serve as the storage medium. In these units either the steel plates, or surface elements, rotate through air and gas streams, or rotating ducts direct air and gas streams through stationary surface elements.

Regenerative air heaters are relatively compact and are the most widely used type for combustion air preheating in electric utility steam generating plants. Their most notable operating characteristic is that a small but significant amount of air leaks into the gas stream due to the rotary operation.

Ljungström The most common regenerative air heater is the Ljungström® type (Figs. 16 and 17), which features a cylindrical shell plus a rotor which is packed with bundles of heating surface elements and is rotated through counterflowing air and gas streams. The rotor is enclosed by a stationary housing which has ducts at both ends. Air flows through one half of the rotor and gas flows through the other half. Metallic leaf-type seals minimize air to gas leakage and flow bypass around the rotor. See Fig. 18. Bearings in upper and lower beam assemblies support and guide the rotor at the central shaft. A rotor speed of one to three rpm is provided by a motor driven pinion engaging a rotor encircling pinrack. Both vertical and horizontal shaft designs are used to accommodate various plant air and gas flow schemes. The vertical shaft design is more common.

The most prevalent flow arrangement has the hot gas entering the top of the rotor as cold air enters the bottom in counterflow fashion, as shown in Fig. 16. Heaters employing this flow scheme are identified as

Fig. 15 Single gas pass, two air pass plate air heater.

hot end on top and cold end on bottom. In operation, the rotor is subjected to a temperature differential, hot top and cold bottom, causing the rotor to expand and bow (or distort) upward. This rotor distortion opens gaps between the rotor and stationary parts through which objectionable air-side to gas-side leakage occurs.

Air to gas leakage is controlled by cold-presetting axial and radial seal plates to minimize gaps at the hot operating condition (Fig. 19). Note that a significant radial gap remains at the hot end which is tolerated in industrial and small utility boiler air heaters. However, for controlling leakage in larger units the hot end radial sealing plate is designed to adjust automatically during operation to follow rotor distortion and maintain a minimum seal gap.

Sootblowing devices in the gas outlet are used to direct superheated steam or dry air via nozzles into the rotor heating surface elements to periodically clean them of fuel residue accumulations during operation. For especially heavy or tenacious deposits, sootblowers may also be used at the air heater gas inlet.

Air heaters operating in dirty flue gas streams (coal, oil, waste, biomass, etc.) are also fitted with permanent water wash piping for soaking and cleaning heavy heating surface ash accumulations. The wash piping is located in the top of the heater above the rotor with nozzles arranged such that all heating surface elements are exposed to the nozzle spray pattern as the rotor turns. Air heaters are normally washed off-

Fig. 16 Ljungström-type air heater.

Fig. 17 Air heater service project at a midwest U.S. power plant.

line as the rotor is turned via an auxiliary drive. Air heater washing through sootblowers may also be done with appropriate piping and valves.

Rothemühle The Rothemühle®-type regenerative air heater uses stationary surface elements and rotating ducts (Fig. 20). The surface elements are supported and contained within a stationary cylindrical shell called the stator. On both sides of the stator, a double wing symmetrical hood rotates synchronously on a common vertical shaft. The central shaft is supported by bearings within the stator and the hoods are driven slowly by a pinion which engages a pinrack encircling the lower hood. Stationary housings surround the hoods. Heat is transferred as flow streams are directed through the heating surface in counterflow fashion, one flow stream inside the hoods and the other outside. Either air or gas may pass through the hoods. However, air is more common because it requires less fan power.

Rothemühle air heater stators distort in a manner similar to Ljungström rotors. Special sealing systems mounted to rotating hoods at the interface with the stator are used to control leakage. Both preset and automated seal systems are used. Sealing at the rotating hood to stationary duct interface is maintained by a ring of spring-backed cast iron seal shoes and a rotating race.

Sootblowers mounted to the outside of rotating hoods are employed on cold and hot ends as fuels dictate. Water wash piping both inside the hoods (rotat-

Fig. 18 Ljungström-type air heater seals.

ing piping) and outside the hoods (stationary piping) assures complete coverage of the heating surface. Special sootblower and rotating wash piping seals are used at the rotating-stationary interface.

Regenerative heating surface Regenerative air heater surface elements are a compact arrangement of two specially formed metal plates. Each element pair consists of a combination of flat, corrugated or undulated plate profiles. The roll formed corrugations and undulations serve to separate the plates to maintain flow paths, increase heating surface area and maximize heat transfer by creating flow turbulence. The steel plates, 26 to 18 gauge thick, are typically spaced 0.2 to 0.4 in. (5 to 10 mm) apart. Closely spaced, highly profiled element pairs exhibit a high heat transfer rate, pressure drop and fouling potential while widely spaced element combinations, where one plate is flat, exhibit a low heat transfer rate, low pressure drop and reduced fouling potential. The combination of plate profile, material and thickness is selected for maximum heat transfer, minimum pressure drop, good cleanability and high corrosion resistance.

Surface elements are stacked and bundled into self-contained baskets and are installed into air heater rotors and stators in two or more layers. The surface layer at the air inlet side, designated the cold layer, is distinguished from other layers by design. Cold layers, which are subject to corrosion and ash fouling, are typically 12 in. (305 mm) deep for economical replace-

Fig. 19 Cross-section through air heater rotor and seal plates.

ment. Heavy gauge, open profile elements are used for corrosion resistance and cleanability. Practically all cold layer elements are low alloy corrosion resistant steel or, when high corrosion potential exists, porcelain enamel coated steel. Hot and intermediate surface layers are more compact than cold layers and use thinner plates. Fig. 21 illustrates several heating surface element profiles and air heater surface arrangements.

Advantages and disadvantages

Many subtle differences exist between air heater designs within a particular type. However, there are some general advantages and disadvantages associated with each type which are listed in Table 1.

Performance and testing

Air heaters are designed to meet performance requirements in three areas: thermal, leakage and pressure drop. Low performance in any area increases boiler operating costs and may cause unit load curtailment.

Thermal performance

The thermal performance and surface area (A) of a recuperative air heater can be evaluated by:

$$A = q / (U \text{ LMTD } F) \quad (5)$$

where q is the rate of heat transfer [Btu/h (W)], U is the overall heat transfer coefficient, LMTD is the log mean temperature difference between the hot and cold fluids, and F is the heat exchanger arrangement factor. The performance, U , LMTD and F can be evaluated using the correlations and methodology presented in Chapter 4. The overall U should include convection

and radiation components as well as the appropriate gas- and air-side fouling factors. U typically ranges from 3 to 10 Btu/h ft² F (17 to 57 W/m² K).

Performance verification Thermal performance is measured by comparing the test gas outlet temperature to its design value. The true outlet temperature is obtained by correcting the measured temperature for air heater leakage and deviations from design conditions.

The ASME Performance Test Code, Section 4.3 (PTC 4.3), provides the following equation which is based on an air heater mass flow heat balance and assumes that the source of all leakage is from the entering air:

$$T_2 = T_{2m} + \left(\frac{\% \text{ } lkg}{100} \right) \frac{c_{pa}}{c_{pg}} (T_{2m} - T_1) \quad (6)$$

where

- T_2 = air heater gas outlet temperature corrected for leakage, F (C)
- T_{2m} = measured gas temperature leaving air heater, F (C)
- $\% \text{ } lkg$ = percent air leakage with respect to inlet gas flow
- c_{pa}, c_{pg} = specific heat of air and gas respectively, Btu/lb F (J/kg C)
- T_1 = air inlet temperature, F (C)

The measured gas outlet temperature must also be corrected for deviations in various operating parameters such as mass flow rates and operating temperatures in order to accurately assess performance. Suppliers and the ASME Performance Test Codes provide various correction curves and factors for this purpose.

Leakage

Air flow passing from the air side to the gas side is called leakage. It is quantified in pounds per hour (kg/s) but is frequently expressed as a percentage of the gas inlet flow. Leakage is undesirable primarily because it represents fan power wasted in conveying air which bypasses the boiler combustion zone. Leakage can also reduce an air heater's thermal performance.

Recuperative units may begin operation with essentially zero leakage, but leakage occurs as time and thermal cycles accumulate. With regular maintenance, leakage can be kept below 3%. Air heater leakage is inherent with the rotary regenerative design. There are two types of leakage, gap and carryover.

Table 1
Advantages and Disadvantages of Air Heater Types

Type	Advantage	Disadvantage
Recuperative	Low leakage No moving parts	Large and heavy Difficult to replace surface
Regenerative	Compact Easy to replace surface	Leakage High maintenance Fire potential

Gap leakage occurs as higher pressure air passes to the lower pressure gas side through gaps between rotating and stationary parts. Its rate is given by the following general expression:

$$w_l = KA (2g_c \Delta P \rho)^{1/2} \quad (7)$$

where

- w_l = leakage flow rate, lb/h (kg/s)
- K = discharge coefficient, dimensionless (generally 0.4 to 1.0)
- A = flow area, ft² (m²)
- g_c = 32.17 lbm ft/lbf s² × (3600 s/h)² = 4.17 × 10⁸ lbm ft/lbf h² (1 kg m/N s²)
- ΔP = pressure differential across gap, lb/ft² (kg/m²)
- ρ = density of leaking air, lb/ft³ (kg/m³)

Carryover leakage is the air carried into the gas stream from each rotor (stator) heating surface compartment as the surface passes from the air stream to the gas stream. This leakage is directly proportional to the void volume of the rotor and the rotation speed.

Regenerative air heater design leakage ranges from 5 to 15% but increases over time as seals wear. Effective automatic sealing systems, which nearly eliminate leakage rise due to seal wear, have been successfully applied. These systems monitor and adjust rotating to stationary seals on-line.

Another source of boiler air to gas flow leakage, which appears as air heater leakage, is outside air infiltration into lower pressure gas streams. Infiltration may occur at casing cracks or holes, flue expansion joints and access doors or gaskets. This sometimes neglected source can be significant and difficult to detect if leaks occur under lagging and insulation.

Air heater leakage can be obtained directly as the difference between air- or gas-side inlet and outlet flows based on velocity measurements. However, because velocity measurements are difficult to obtain accurately in large duct cross-sections, air heater leakage is more accurately based on calculated gas weights using gas analysis, boiler efficiency and fuel analysis data. (See Chapter 10.) Approximate air heater leakage can be determined by the following formula based on gas inlet and outlet oxygen (O₂) analysis (dry basis).

$$\% \text{ Leakage} = \frac{\% \text{ O}_2 \text{ Leaving} - \% \text{ O}_2 \text{ Entering}}{21 - \% \text{ O}_2 \text{ Leaving}} \times 90 \quad (8)$$

Test air heater leakage should be corrected for deviations from design cold end air to gas differential pressure and inlet air temperature before comparison to design leakage.

Pressure drop

In recuperative air heaters, gas- or air-side pressure drop arises from frictional resistance to flow, inlet and exit shock losses and losses in return bends between flow passes. In regenerative air heaters, the main cause is heating surface frictional flow resistance. In both cases, pressure drop is proportional to

the square of the mass flow rate. Typical values at full load flows are 2 to 7 in. wg (0.5 to 1.7 kPa).

Air- and gas-side pressure drop values are the differences between terminal inlet and outlet static gauge pressures. Correction of measured pressure drops for deviations from design flows and temperatures is necessary before comparison to design values.

Operational concerns

There are several operating conditions and maintenance concerns common to most air heaters. These include corrosion, plugging and cleaning, leakage performance degradation, erosion and fires. Air heaters used with high ash and/or high sulfur content fuels require more attention and maintenance than those firing clean fuels such as natural gas.

Corrosion

Air heaters used on units firing sulfur bearing fuels are subject to cold end corrosion of heating elements and nearby structures. In a boiler, a portion of the sulfur dioxide (SO₂) produced is converted to sulfur trioxide (SO₃) which combines with moisture to form sulfuric acid vapor. This vapor condenses on surfaces at temperatures below its dew point of 250 to 300F (121 to 149C). Because normal air heater cold end metal temperatures are frequently as low as 200F (93C), acid dew point corrosion potential exists. The obvious solution would be to operate at metal temperatures above the acid dew point but this results in unacceptable overall boiler heat losses. Most air heaters are designed to operate at minimum metal temperatures (MMTs) somewhat below the acid dew point, where the efficiency gained more than balances the additional maintenance costs. B&W recommends limiting MMTs to the values in Figs. 22 and 23 when burning sulfur bearing fuels.

When fuel sulfur levels are high, or ambient temperatures or operating loads are low, MMTs may be unacceptably low. These situations dictate the use of active or passive cold end corrosion control methods. Active systems used to raise MMT include: 1) steam- or water-coil air heaters to preheat inlet air, 2) cold air bypass, in which a portion of the inlet air is ducted around the air heater, and 3) hot air recirculation, in which a portion of the hot outlet air is ducted to combustion air fan inlets.

Fig. 22 Recuperative air heater cold end MMT limits when burning sulfur-bearing fuels.

Fig. 23 Regenerative air heater cold end MMT limits when burning sulfur-bearing fuels.

Passive corrosion control methods incorporated in air heater design include: 1) thicker cold end materials, such as 11 or 14 gauge (3 or 2 mm) tubes and 18 gauge (1 mm) regenerative surface elements, 2) low or high alloy cold end surface materials which have at least twice the corrosion life of carbon steel, 3) nonmetallic coating, such as porcelain enamel, Teflon, or epoxies on cold elements, 4) nonmetallic cold end surface materials such as extruded ceramic in regeneratives and borosilicate glass tubes in tubulars, and 5) tubular air heater cold end tube arrangements which maximize MMT by providing higher gas flow and lower air flow velocities.

Plugging and cleaning

Plugging is the fouling and eventual closing of heat transfer flow passages by gas-entrained ash and corrosion products. It can occur at the air heater hot end but is most common at the cold end where ash particles adhere to acid moistened surfaces. Plugging increases air heater pressure drop and can limit unit load when fan capacity is reached at less than full load.

Air heater deposits are controlled and removed by periodic on-line sootblowing, and by various methods of cold end temperature control as described above to control corrosion. Deposits may also be controlled by employing regenerative heating surface designs with easier-to-clean, less tortuous flow paths, and by using smooth enamel coated regenerative surface elements that resist particle adherence.

When on-line cleaning methods are no longer able to stop or reverse fouling, off-line cleaning is necessary. Regenerative and recuperative air heater surface is normally washed off-line with permanent, low pressure wash piping. The surface is deluged (washed)

continuously until the surface is deemed clean. Cleanliness may be proven by observed clarity of wash outlet water or by the ability to see light directed through the surface bank.

In cases where low pressure washing is not effective, high pressure washing is done. Power plant operators employ air heater washing specialists and equipment with water jets at nozzle pressure above 5000 psi (34.5 MPa). Special care must be taken to avoid breaking and/or flattening regenerative element plates.

Erosion

Heat transfer surfaces and other air heater parts can suffer erosion damage through impact of high velocity, gas-entrained ash particles. Erosion usually occurs near gas inlets where velocities are highest. However, areas near seals in regenerative air heaters can also be damaged as ash is accelerated through seal gaps. The undesirable effects of erosion are structural weakening, loss of heat transfer surface area and perforation of components which can cause air to gas or infiltration leakage. Erosion rate is a function of velocity, gas stream ash loading, physical nature of ash particles and angle of particle impact. It is controlled by reducing velocities, removing erosive elements from the gas stream, or using sacrificial material.

In the design stage, air heaters used with fuels containing highly erosive ash can be sized to limit gas inlet velocities to 50 ft/s (15 m/s). Inlet flues can also be designed to evenly distribute gas over the air heater inlet to eliminate local high velocity areas. Dust collectors, or strategically located screens and hoppers, may be used ahead of air heaters to remove some of the ash. In existing problem air heaters, flow distribution baffles may be installed to eliminate local high velocities, sacrificial materials such as abrasion resistant steel or ceramics may be placed over critical areas, or parts can be replaced with thicker materials for longer life.

Erosion in tubular air heaters frequently occurs within about 1 ft (0.3 m) of the gas inlet end due to turbulence as gas enters the tubes. Replaceable sacrificial sleeves may be installed in tube ends or egg crate-type flow straightening grids can be installed at tubular air heater inlets to reduce erosion.

Fires

Air heater fires are rare but do occur, particularly in regenerative units, and may be severe enough to completely destroy an air heater. Fires are detected by thermocouples in gas and air outlet ducts as well as with special early warning systems. Fires usually start near the cold end, which can be fouled with unburned combustible materials. Most fires occur during startup as unburned fuel oil deposited on ash fouled heating surfaces is ignited. Leaking bearing lubrication equipment and heavy accumulations of flyash are also fire hazards. Fires can be avoided by maintaining a clean air heater and proper tuning of boiler firing equipment. Frequent sootblowing during startup and just before shutdown is a strongly recommended fire prevention practice.

After a fire is confirmed, typical practice is to trip the boiler to stop air flow through the heater, to keep

the air heater rotating, and to introduce as much water as possible through the permanent water wash system. Drains in air- and gas-side duct hoppers below the air heater must be opened to remove water and ash.

Utility applications

Gas to air recuperative and regenerative air heaters are usually used in utility units, primarily to enhance unit efficiency. Small increments of increased efficiency in large units amount to substantial fuel savings. Utility units generally use multiple air heaters for plant arrangement convenience, type of firing and maximum unit availability.

Pulverized coal-fired units require two streams of hot combustion air, i.e., primary air supplied at high pressure to pulverizers and secondary air supplied at lower pressure directly to burners. Two basic air flow systems are used, hot primary air and cold primary air. Each system uses air heaters. In the hot primary air scheme, used for smaller units, about one third of the combustion air heated in a secondary heater is ducted to hot primary air fans, where it is boosted in pressure and passed to the pulverizers; the remaining two thirds is ducted to the burners. The cold primary air system uses separate air heaters supplied by separate primary and secondary (forced draft) fans. In some units, both primary and secondary air are heated in a single regenerative unit which is more cost effective than separate air heaters. Fig. 24 shows a schematic Ljungström-type air heater for primary and secondary air, referred to as a tri-sector.

If separate regenerative primary and secondary air heaters are used, the primary air heaters, which operate at high air to gas pressure differentials, exhibit twice as much leakage as the secondary units. For this reason, low leakage recuperative air heaters may be used for primary air heating and regeneratives may be used for secondary air heating.

Recuperative and regenerative air heaters are used on oil- and gas-fired units. In general, regardless of fuel type, larger units use regenerative air heaters because of their smaller size and lower initial cost. However, for air to gas pressure differentials above 40 in. wg (10 kPa), in fluidized-bed applications for example, recuperative air heaters are usually preferred.

Industrial applications

Industrial units fire a variety of fuels such as wood, municipal refuse, sewage sludge and industrial waste gases as well as coal, oil and natural gas. As a result, many air heater types are used. In the small units, tubular, plate and cast iron heaters are widely used. Fuels fired on stoker grates, such as bituminous coal, wood and refuse, do not require high air temperatures, therefore water- or steam-coil air heaters can be used.

Environmental air heater application

For environmental reasons, emission of certain fossil-fired combustion products may be limited by law. (See Chapter 32.) Systems developed to limit emissions of two

Fig. 24 Ljungström-type tri-sector air heater.

objectionable flue gas constituents, NO_x and SO_2 , may require the use of specially modified heat exchangers.

NO_x removal

When selective catalytic reduction (SCR) technology is used on a boiler to control NO_x emissions, air heaters operating downstream of the SCR require special consideration. A typical, popular arrangement is to place the SCR reactor in the boiler flue gas stream between the economizer outlet and air heater inlet (high dust arrangement).

The SCR reduces NO_x by injecting ammonia (NH_3) into the flue gas just upstream of a catalyst which converts the NO_x to water and elemental nitrogen (N_2). However, the catalyst also converts some of the sulfur dioxide (SO_2) in the flue gas to sulfur trioxide (SO_3) which combines with unreacted NH_3 to form ammonium bisulfate (NH_4HSO_4). This condenses on air heater surface elements in the 510 to 340F (266 to 171C) temperature range. The objectionable NH_4HSO_4 fouling and corrosion in regenerative air heaters can be controlled to manageable levels by design features including:

1. Arranging heating surface basket layers so that NH_4HSO_4 deposition occurs within a layer rather than between layers. Deposition in the space between basket layers is more difficult to remove and keep clean. It is typical to provide two rather than three air heater basket layers.
2. Employing a closed profile heating element which allows deeper and more effective sootblower cleaning. Closed profile elements are designs in which

individual flow passages are closed through the depth of the element layer and do not allow sootblowing media to quickly dissipate.

3. Using porcelain enamel coated bottom layer heating surface which resists corrosion and deposition, and is easier to clean because of the smooth surface.
4. Fitting the heater with hot and cold end sootblowers which can be used to water wash heating surface off-line.

Heat exchangers with these features can typically operate reliably without off-line water washing for a year or more. As discussed in Chapter 34, some regenerative air heaters have been modified to simultaneously serve as selective catalytic NO_x reduction systems.

SO₂ reduction

When sulfur emission reduction is required, flue gas desulfurization (FGD) systems are frequently used. These systems remove SO₂ from the flue gas by reaction with injected compounds such as limestone. In most cases, the scrubbed flue gas exits the FGD system at a saturation temperature of 120 to 130F (49 to 54C) before entering the stack. In cases where acid dew point corrosion of flues and stack liners is a concern or increased gas buoyancy is needed to improve stack plume dispersal, gas exiting the FGD system is reheated to 180F (82C) or higher.

Regenerative heat exchangers similar to those for combustion air heating are used in FGD systems. The heat exchangers, referred to as gas-to-gas heaters (GGH), extract heat from untreated warm flue gas to heat treated (scrubbed) flue gas leaving an FGD tower before it enters the stack. A typical arrangement with gas temperatures is shown in Fig. 25.

Several necessary GGH design features distinguish them from air heaters and permit them to operate in a very corrosive environment without compromising FGD system SO₂ removal performance. Measures taken to protect a GGH from the corrosive flue gas include:

1. Fabricating rotors of low alloy corrosion-resistant steel and adding a corrosion margin to all rotor plate thicknesses.
2. Using porcelain enamel coated heating surface element plates.
3. Using stainless and/or non-metallic circumferential, radial and axial leaf seal materials.
4. Applying a layer of vinyl ester flake glass on internal surfaces of the untreated gas outlet duct, treated gas inlet duct, treated gas outlet duct, and rotor housing.
5. Employing hot and cold end air sootblowers for on-line cleaning, fitted with water wash nozzles for off-line washing.

Leakage of the untreated gas into the treated gas reduces FGD SO₂ reduction performance and must be

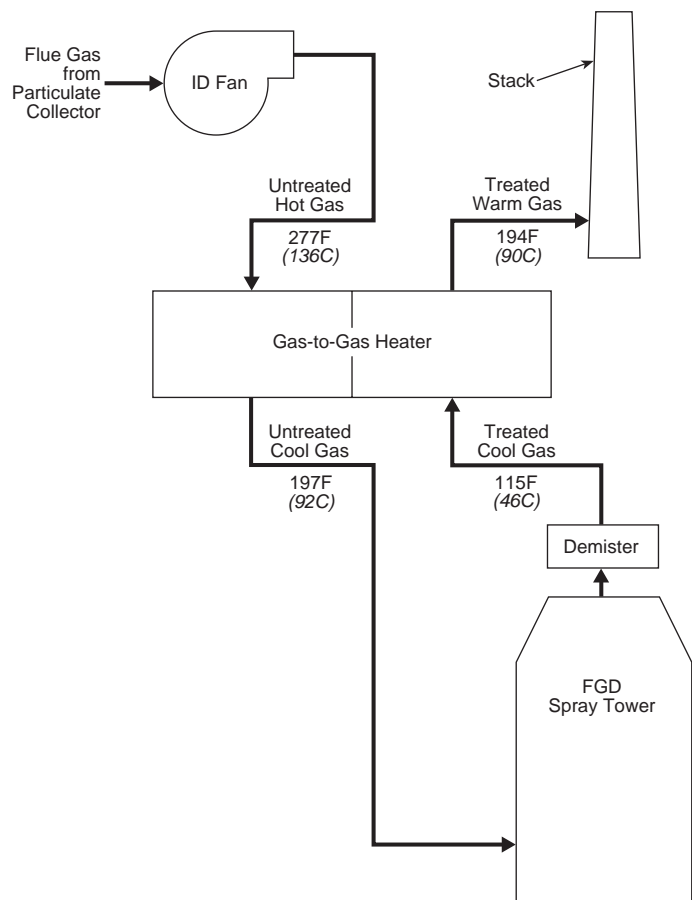

Fig. 25 Gas-to-gas heater in an FGD system.

controlled to low levels. The following features incorporated into GGH design can reduce the leakage to less than 1% of the untreated inlet gas flow:

1. Designing the rotor with radial heating surface division plates so that, during operation, there are always two under the radial and axial seal plates. Leakage flow, in this case, is forced to pass two seals rather than one seal producing a labyrinth effect which lowers leakage flow.
2. Employing an automatic sealing system to hot end radial seal plates that follows stator distortion to minimize seal leakage at all loads.
3. Purging stator compartments of untreated gas with treated gas just before they pass under radial seals and into the treated gas stream. Purging minimizes carryover leakage which is a component of total leakage. A purge system consists of a dedicated purge fan and associated ducting and controls.
4. Reducing rotor speed to the lowest possible level without significantly compromising thermal performance. Operation at low speed reduces carryover leakage.

Chapter 21

Fuel Ash Effects on Boiler Design and Operation

The effective utilization of fossil fuels for power generation depends to a great extent on the capability of the steam generating equipment to accommodate the inert residuals of combustion, commonly known as *ash*. The quantity and characteristics of the ash inherent to a particular fuel are major concerns to both the designer and the operator of the equipment.

With few exceptions, most commercial fuels contain sufficient ash to warrant specific design and operating considerations. The following focuses on these design and operating considerations, primarily as they relate to pulverized coal firing. Fuel ash characteristics relating to petroleum fuels are also discussed.

Ash dilutes the heating value of fuel, placing additional burdens on fuel storage, handling and preparation equipment. Extensive facilities are also needed to collect, remove and dispose of the ash. These material handling requirements represent significant costs in terms of equipment and real estate which are directly proportional to the amount of ash in the fuel. In the case of coal, ash quantities can be substantial. Consider, for example, a 650 MW utility steam generator firing a coal with a heating value of 10,000 Btu/lb (23,250 kJ/kg) containing 10% ash by weight. The unit would burn approximately 300 tons per hour (272 t_m/h) of coal, generating more than 700 tons per day (635 t_m/d) of ash.

In pulverized coal-fired boilers, most of this ash is carried out of the furnace by the gaseous products of combustion (flue gas). Abrasive ash particles suspended in the gas stream can cause erosion problems on convection pass heating surfaces. However, the most significant ash-related problem is deposition. During the combustion process, the mineral matter that forms ash is released from the coal at temperatures in the range of 3000F (1649C), well above the melting temperature of most mineral matter compounds. Ash can be released in a molten fluid or sticky plastic state. A portion of the ash, which is not cooled quickly to a dry solid state, impacts on and adheres to the furnace walls and other heating surfaces. Because such large total quantities of ash are involved, even a small fraction of the total can seriously interfere with boiler operation. Accumulation of ash deposits on furnace walls impedes heat transfer, delaying cooling of the flue gas and increasing the flue gas temperature leaving the furnace. Elevated temperatures at the furnace exit raise steam temperature and can extend deposition problems to pendant superheaters and

other heat absorbing surfaces in the convection pass. In extreme cases, uncontrolled ash deposits can develop to the point where flow passages in tube banks are blocked, impeding gas flow and ultimately requiring the unit to be shut down for manual removal. Large deposits in the upper furnace or radiant superheater can become dislodged and fall, damaging pressure parts in the lower furnace. Under certain conditions, ash deposits can also cause fireside corrosion on tube surfaces.

Minimizing the potential for these ash-related problems is a primary goal of both the designers and operators of coal-fired boilers. The extent to which coal ash characteristics affect boiler design is illustrated in Fig. 1 which compares the relative size of a gas-fired and coal-fired boiler. Both are sized for the same steam generating capacity and similar steam conditions. While the combustion characteristics of coal play a role in sizing the furnace, the deposition and erosion potential of the ash are the primary design considerations driving the overall size and arrangement.

The variability of ash behavior is one of the biggest problems for boiler designers and operators. Although boilers are often designed to burn a wide range of coals satisfactorily, no unit can perform equally well with all types of coal.

Ash content of coal

The ash content of coal varies over a wide range. This variation occurs not only in coals from different geographical areas or from different seams in the same region, but also from different parts of the same mine. These variations result primarily from the wide range of conditions that introduced foreign material during or following the formation of the coal. (See Chapter 9.) Ash content can also be influenced by extraneous mineral matter introduced during the mining operation. Before being sold, some commercial coals are cleaned or washed to remove a portion of what would be labeled ash in the laboratory. However, the ash content of significance to the user is the content at the point of use. The values noted below are on that basis.

Most of the coal used for power generation in the United States (U.S.) has an ash content between 6 and 20%. Low values of 3 to 4% in bituminous coals are rare and these coals find other commercial uses, particularly in the metallurgical field. On the other hand,

Fig. 1 Size comparison of gas-fired and coal-fired utility boilers.

some coals may have ash contents as high as 40%. Many high ash fuels can be successfully burned in utility (electric power generation) boilers. Their use has increased in areas where they offer an economic advantage.

Evaluation of ash content on a weight percentage basis alone does not take into account the heat input associated with the coal, which is also related to moisture content. It is common, for design and fuel evaluation purposes, to consider ash content on the basis of weight per unit of heat input, generally expressed as pounds of ash per million Btu. This factor is calculated as follows:

$$\frac{\text{Ash (\% by weight)}}{\text{HHV (Btu/lb)}} \times 10^4 = \text{lb ash}/10^6 \text{ Btu}$$

or

$$\frac{\text{Ash (\% by weight)}}{\text{HHV (kJ/kg)}} \times 10^3 = \text{kg ash}/\text{MJ}$$

where HHV is the higher heating value of the fuel.

The relevance of this factor is illustrated in Table 1, which provides proximate analyses for three selected coals. Each coal has a moderate ash content of 9 to 10% by weight. However, on a heat input basis, ash quantities vary significantly. The lignite in this example would introduce almost three times as much ash as the high volatile bituminous coal at an equivalent heat input.

Furnace design for ash removal

Historically, two distinctly different types of furnace design were used to handle the ash from coal firing in large utility boilers. These are commonly referred to as the *dry-ash* or *dry-bottom* furnace and the *slag-tap* or *wet-bottom* furnace.

All modern pulverized coal-fired boilers use the dry-

bottom arrangement. The coal-fired boiler in Fig. 1 is typical of this design. In a dry-bottom unit most of the ash, typically 70 to 80%, is entrained in the flue gas and carried out of the furnace. This portion of the ash is commonly known as *flyash*. Some of the flyash is collected in hoppers arranged under the economizer and air heaters, where coarse particles drop out of suspension when gas flow direction changes. The finer ash particles remain in suspension and are carried out of the unit for collection by particulate control equipment. (See Chapter 33.) The remaining 20 to 30% of the ash that settles in the furnace, or is dislodged from the furnace walls, is collected in a hopper formed by the frontwall and rearwall tube panels at the bottom of the furnace. This *bottom ash* is discharged through a 3 to 4 ft (0.9 to 1.2 m) wide opening that spans the entire width of the hopper.

Slag-tap furnaces were originally developed to resolve ash deposition and removal problems when firing coals with low ash fusion temperatures in dry-bottom furnaces. These units are intentionally de-

Table 1
Proximate Analyses of Three Selected Coals —
Ash Content as Weight Per Unit of Heat Input

Rank	High Volatile Bituminous	Subbituminous	Lignite
Moisture, %	3.1	23.8	45.9

Heating value, Btu/lb	12,770	8683	4469
lb Ash/10 ⁶ Btu	7.4	11.3	21.5

signed to maintain ash in a fluid state in the lower furnace. Molten ash is collected on the furnace walls and other surfaces in the lower furnace and drained continuously to openings called *slag-taps* in the furnace floor. Water tanks positioned beneath the slag-taps solidify the liquid ash for disposal.

Slag-tap furnaces have been used with both pulverized coal and Cyclone™ furnace firing systems. (See Chapter 15.) Application is limited to coals having ash viscosity characteristics which would ensure that ash fluidity could be maintained over a reasonable boiler load range. Much of the coal ash research conducted by The Babcock & Wilcox Company (B&W) concerning the viscosity-temperature relationship of coal ash was initially directed at defining coal ash suitability limits for wet-bottom and Cyclone furnace applications. A minimum coal ash content was also specified to ensure sufficient ash quantities to maintain the required slag coating. One benefit of wet-bottom firing was a significant reduction in flyash quantity. In pulverized coal wet-bottom applications, as much as 50% of the total ash was collected in the furnace. Units equipped with Cyclone furnaces could retain up to 80% of the ash in the furnace.

The application of slag-tap units for pulverized coal firing began to decline in the late 1940s, primarily due to design improvements in dry-bottom units that minimized ash deposition problems. Slag-tap units equipped with Cyclone furnaces continued to be applied until the early 1970s when the federal Clean Air Act mandated control of nitrogen oxides (NO_x) emissions. The high furnace temperatures required for wet-bottom operation were highly conducive to NO_x formation.

Ash deposition

Regardless of the firing method, when coal is burned, a relatively small portion of the ash will cause deposition problems. Ash passing through the boiler is subject to various chemical reactions and physical forces which lead to deposition on heat absorbing surface. The process of deposition and the structure of deposits are variable due to a number of factors. Particle composition, particle size and shape, particle and surface temperatures, gas velocity, flow pattern and other factors influence the extent and nature of ash deposition.

Due primarily to the differences in deposition mechanisms involved, two general types of high temperature ash deposition have been defined as *slagging* and *fouling*.

Slagging is the formation of molten, partially fused or resolidified deposits on furnace walls and other surfaces exposed to radiant heat. Slagging can also extend into convective surface if gas temperatures are not sufficiently reduced.

Most ash particles melt or soften at combustion temperatures. The time-temperature history or cooling rate of the particle determines its physical state (solid, plastic or liquid) at a given location in the furnace. Generally, in order to adhere to a clean surface and form a deposit, the particle must have a viscosity low enough to wet the surface.

Slag deposits seldom form on clean tube surfaces.

A conditioning period is required before significant deposition occurs. Assuming there is no direct flame impingement, as ash particles approach a clean tube, most tend to be resolidified due to the relatively lower temperature at the tube surface. The particles fracture on impact and partially disperse back into the flue gas stream. Over a period of time, however, a base deposit begins to form on the tube. The base deposit may be initiated by the settling of fine ash particles or the gradual accumulation of particles with very low melting point constituents. As the base deposit thickens, the temperature at its outside face increases significantly above the tube surface temperature. Eventually, the melting point of more of the ash constituents is exceeded and the deposit surface becomes molten. The process then becomes self-accelerating with the plastic slag trapping essentially all of the impinging ash particles. Ultimately, the deposit thickness reaches an equilibrium state as the slag begins to flow, or the deposit becomes so heavy that it falls away from the tubes. Depending on the strength and physical characteristics of the deposit, sootblowers using steam, compressed air or water as cleaning media (see Chapter 24) may be able to control or remove most of the deposit. However, the base deposit can remain attached to the tube, allowing subsequent deposits to accumulate much more rapidly.

Fouling is defined as the formation of high temperature bonded deposits on convection heat absorbing surfaces, such as superheaters and reheaters, that are not exposed to radiant heat. In general, fouling is caused by the vaporization of volatile inorganic elements in the coal during combustion. As heat is absorbed and temperatures are lowered in the convective section of the boiler, compounds formed by these elements condense on ash particles and heating surface, forming a glue which initiates deposition.

Areas where slagging and fouling can occur are shown in Fig. 2. Figs. 3 and 4 show heavily slagged and fouled surfaces. The characteristics of coal ash and their influence on slagging and fouling are discussed in the following sections.

Characteristics of coal ash

Sources of coal ash

Mineral matter is always present in coal and forms ash when the coal is burned. This mineral matter is usually classified as either inherent or extraneous. (See Chapter 9.) Inherent mineral matter is organically combined with the coal. This portion came from the chemical elements existing in the vegetation from which the coal was formed and from elements chemically bonded to the coal during its formation. Extraneous mineral matter is material that is foreign to the organic structure of the coal. This includes airborne and waterborne material that settled into the coal deposit during or after formation. It usually consists of mineral forms associated with clay, slate, shale, sandstone or limestone and includes pieces ranging from microscopic size to thick layers. Other extraneous material may be introduced through the mining process.

Fig. 2 Deposition zones in a coal-fired boiler.

Mineralogical composition

There are no standardized methods that are used routinely for determining the specific mineral constituents of coal. Mineralogical analysis requires the use of a low temperature ashing technique to separate the mineral matter from the organic portion of the coal. Standard high temperature ashing procedures would significantly alter the mineral forms. However, a number of researchers, using a variety of low temperature ashing methods and sophisticated analytical tech-

niques, have identified an enormous variety of mineral species in coal, encompassing the entire spectrum of major mineral forms found in the earth's crust. Most of these minerals fall into one of several groups: clay minerals (aluminosilicates), sulfides/sulfates, carbonates, chlorides, silica/silicates and oxides. Some of the more common minerals in these groups are shown in Table 2.

Chemical composition

Because both quantitative and qualitative evaluation of mineral matter forms are extremely difficult, relatively simple chemical analyses are commonly used to determine the percentages of the major elements in the ash. Elemental ash analysis is performed on a coal ash sample produced in accordance with the American Society for Testing and Materials (ASTM) D 3174 ashing procedure. Pulverized coal is burned in a furnace with an oxidizing atmosphere at 1292 to 1382F (700 to 750C). The elements present in the ash are quantitatively measured using a combination of emission spectroscopy and flame photometry and are reported as weight percents of their oxides. Coal ash is consistently found to be composed mainly of silicon, aluminum, iron and calcium with smaller amounts of magnesium, titanium, sodium and potassium. The elemental analysis also identifies phosphorus as P_2O_5 and sulfur as sulfur trioxide (SO_3). Phosphorus is usually present in very small quantities and is sometimes omitted. Sulfur is reported as SO_3 because it is normally present as the sulfate form of one of the metals.

Percentages of the individual elements vary over a wide range for different coals; however, characteristic differences are evident between the older, high rank coals common in the Eastern U.S. and the younger, low rank Western coals. Bituminous coals typically have higher levels of silica, aluminum and iron, while the lower rank subbituminous coals and lignites generally have higher levels of the alkaline earth metals, calcium and magnesium, and the alkali metal sodium. These trends are evident in the ash analyses shown in Table 3.

Although the ash constituents are reported as oxides, they actually occur in the ash predominately as

Fig. 3 Heavily slagged surface.

Fig. 4 Heavily fouled surface.

Table 2
Common Minerals Found in Coal

Clay minerals:	
Montmorillonite	$\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2 \cdot \text{H}_2\text{O}$
Illite	$\text{KAl}_2(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$
Kaolinite	$\text{Al}_4\text{Si}_4\text{O}_{10}(\text{OH})_8$
Sulfide minerals:	
Pyrite	FeS_2
Marcasite	FeS_2
Sulfate minerals:	
Gypsum	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$
Anhydrite	CaSO_4
Jarosite	$(\text{Na,K})\text{Fe}_3(\text{SO}_4)_2(\text{OH})_6$
Carbonate minerals:	
Calcite	CaCO_3
Dolomite	$(\text{Ca,Mg})\text{CO}_3$

Albite	$\text{NaAlSi}_3\text{O}_8$
Orthoclase	KAlSi_3O_8
Oxide minerals:	
Hematite	Fe_2O_3
Magnetite	Fe_3O_4
Rutile	TiO_2

a mixture of silicates, oxides and sulfates, with smaller quantities of other compounds. The silicates originate mainly from quartz and the clay minerals which contribute silicon, aluminum, sodium and much of the potassium. A principal source of iron oxide is pyrite (FeS_2) which is oxidized to form Fe_2O_3 and sulfur oxides. Part of the organic and pyritic sulfur that is oxidized combines with calcium and magnesium to form sulfates. Calcium and magnesium oxides result from the loss of carbon dioxide from carbonate minerals such as calcite (CaCO_3) and dolomite $[(\text{Ca, Mg})(\text{CO}_3)]$. In low rank coals, a major portion of the sodium, calcium and magnesium oxides can originate from organically bound elements in the coal.

Laboratory ash is prepared from a coal sample in a controlled atmosphere at controlled temperatures to provide a reproducible and uniform ash. The actual ashing process during combustion in a pulverized coal-fired furnace is a much more complex process. In a boiler furnace, pulverized coal is burned in suspension as discrete particles. If all of the mineral matter were evenly distributed through the coal, the composition of each resulting ash particle would be the same as the bulk ash composition determined by the analysis of ASTM ash. A coal with no extraneous mineral matter might approach this hypothetical case, because organically combined inherent material would be expected to be evenly distributed. In reality, however, all coals contain non-uniformly distributed extrane-

ous mineral matter in some of the wide variety of mineral forms shown on Table 2. When the coal is pulverized, some of the particles will be mostly coal with only inherent mineral matter, some will be pure mineral matter, and others will be combinations of both. Because the coal particles are burned discretely in suspension, the composition of an individual ash particle will depend on the specific mineral form or forms that were included in the coal particle. As a result, individual particle composition can vary significantly from the bulk ash composition.

During combustion, ash particles are exposed to temperatures as high as 3000F (1649C) and a variety of heating and cooling rates. The atmosphere in the burner zone can range from highly oxidizing to highly reducing. Depending on the composition of the specific particle, mineral forms in the ash can react with each other, with the organic and inorganic constituents of the coal, and with gaseous elements, such as sulfur dioxide (SO_2), in the flue gas. The compounds that are ultimately formed by these interactions are the materials that cause deposition problems. The compounds can have a wide variety of melting temperatures and viscosity-temperature characteristics. Some compounds combine to form eutectic mixtures that have melting temperatures lower than either of the original compounds. Particles that melt at lower temperatures and stay sticky long enough to reach a furnace wall become slag deposits. Volatile compounds that vaporize in the furnace tend to condense on and foul cooler convective heating surfaces.

Elemental ash analyses do not directly identify the compounds that cause deposition, or directly identify the mechanisms of deposit formation. Despite these limitations, no other data pertaining to coal ash composition are as widely available as the chemical analyses of ASTM ash. A large part of the coal ash research that has been conducted over the last sixty years has been directed at correlating analysis data and other characteristics of ASTM ash to observed ash behavior both in full scale boilers and in test facilities that closely simulate full scale conditions. Various evaluation methods have been developed based on these correlations to characterize ash behavior and predict deposition potential.

Ash fusibility

The measurement of ash fusibility temperatures is by far the most widely used method for predicting ash behavior at elevated temperatures. The preferred procedure in the U.S. is outlined in ASTM Standard D 1857, *Fusibility of Coal and Coke Ash*. An ash sample is prepared by burning coal under oxidizing conditions at temperatures of 1470 to 1650F (799 to 899C). The ash is pressed in a mold to form a triangular pyramid (cone) 0.75 in. (19 mm) in height with a 0.25 in. (6.35 mm) triangular base. The cone is heated in a furnace at a controlled rate to provide a temperature increase of 15F (8C) per minute. The atmosphere in the furnace is regulated to provide either oxidizing or reducing conditions. As the sample is heated, the temperatures at which the cone fuses and deforms to specific

Reducing		2620	2320	2370	2330	2315	2240
Oxidizing		2670	2610	2540	2410	2300	2290

shapes, as shown in Fig. 5, are recorded. Four deformation temperatures are reported as follows:

1. *Initial deformation temperature* (IT or ID) – the temperature at which the tip of the pyramid begins to fuse or show signs of deformation.
2. *Softening temperature* (ST) – the temperature at which the sample has deformed to a spherical shape where the height of the cone is equal to the width at the base ($H = W$). The softening temperature is commonly referred to as the fusion temperature.
3. *Hemispherical temperature* (HT) – the temperature at which the cone has fused down to a hemispherical lump and the height equals one half the width of the base ($H = 1/2 W$).
4. *Fluid temperature* (FT) – the temperature at which the ash cone has melted to a nearly flat layer with a maximum height of 0.0625 in. (1.59 mm).

The determination of ash fusion temperatures is strictly an empirical procedure, developed in standardized form, which can be duplicated with some degree of accuracy. Strict observance of test conditions is required to assure reproducible results. ASTM specified tolerances on reproducibility of the individual temperature measurements range from 100 to 150F (56 to 83C) when the test is performed by different operators and apparatus.

An earlier version of the ASTM D 1857 procedure

specified the use of only a reducing atmosphere and had loosely defined criteria for identifying the softening and fluid points. When the atmosphere is not specified, it is generally assumed to be reducing. Reported softening temperatures are assumed to be the ST ($H = W$) point unless otherwise specified. Methods for determining fusibility of ash used by other countries are similar to the ASTM procedure but results may vary considerably due to differences in procedures or the definition of terms.

The gradual deformation of the ash cone is generally considered to result from differences in melting characteristics of the various ash constituents. As the temperature of the sample is increased, compounds with the lowest melting temperatures begin to melt, causing the initial deformation. As the temperature continues to increase, more of the compounds melt and the degree of deformation proceeds to the softening and hemispherical stages. The process continues until the

Fig. 5 Specific shapes as ash fuses and deforms with temperature.

temperature is higher than the melting point of most of the ash constituents and the fluid stage is reached.

Fusibility testing was originally developed to evaluate the clinkering (agglomerating) tendency of coal ash produced by combustion on a grate. In several respects, the test method is a somewhat better simulation of stoker firing than suspension burning of pulverized coal. During the fusion test, at a heating rate of 15F (8C) per minute, the transition from the IT to the FT stage may take up to two hours or more for a high fusion ash. Rather than slow heating and gradual melting of the ash, the process in a pulverized coal furnace is essentially reversed. Ash particles are rapidly heated, and then cooled at a relatively slow rate, as they pass through the furnace. During combustion, coal particles are heated almost instantaneously to temperatures ranging up to 3000F (1649C). As heat is removed from the flue gas, the ash is cooled over a period of less than two seconds to temperatures around 1900 to 2200F (1038 to 1204C) at the furnace exit.

In practical terms, for dry-bottom furnaces, fusion temperatures provide an indication of the temperature range over which portions of the ash will be in a molten fluid or semi-molten, plastic state. High fusion temperatures indicate that ash released in the furnace will cool quickly to a nonsticky state resulting in minimal potential for slagging. Conversely, low fusion temperatures indicate that ash will remain in a molten or plastic state longer, exposing more of the furnace surface or convective surface to potential deposition.

When temperatures in the furnace are below the measured initial deformation temperature, the majority of the ash particles are expected to be in a dry solid state. In this form, particles impacting on heating surface will bounce off and be re-entrained in the gas stream, or, at worst, settle on the surface as a dusty deposit which can be readily removed by sootblowers. At temperatures above the IT, the ash becomes increasingly more plastic in nature and impacting particles have a greater potential to stick to heating surfaces.

Fusibility temperatures also provide an indication of deposit characteristics as they relate to control and cleanability. When the temperature at a deposit surface is at or above the fluid temperature of the ash, slag will tend to flow or drip from the surface. While fluid slag can not be controlled with sootblowers, the deposits tend to be self-limiting in thickness and do not interfere significantly with heat transfer effectiveness. However, if the deposit surface temperature is in the plastic range, between the initial deformation and hemispherical temperatures, the slag will be too viscous to flow and will continue to build in thickness. Wide IT to HT differentials can result in deposits that build quickly to large proportions and are difficult to control, because sootblowers can be ineffective in penetrating the plastic shell that forms on the deposit surface.

In practice, very high and very low fusion values are relatively easy to interpret as being troublesome or non-troublesome with respect to slagging. Unfortunately, however, most coals fall in an intermediate range where evaluations can be much more difficult. Fusion temperatures have their most valid significance when used on a comparative basis against cor-

responding data from other fuels of known full-scale performance. Even comparisons can be misleading, however, when differences in data are within the range of reproducibility of the test. Actual ash viscosity measurements (described later) provide a much more accurate and less subjective definition of the viscosity/temperature relationship and are considered by B&W to provide a better assessment of slagging potential.

Influence of ash elements

Ash classification

Coal ash is classified into two categories based on its chemical composition. *Lignitic* ash is defined as having more (CaO + MgO) than Fe_2O_3 . *Bituminous* ash is defined as having more Fe_2O_3 than the sum of CaO and MgO. Bituminous ash is generally characteristic of higher rank coals from the eastern U.S. Lower rank western coals typically have lignitic ash. As a result, bituminous ash is sometimes referred to as eastern ash and lignitic ash is sometimes referred to as western ash. However, ash classification is not specific to ASTM rank or geographical origin. In rare cases, lignites and subbituminous coals can have bituminous ash and bituminous coals can have lignitic ash. For example, the Utah coal shown in Table 3 is classified a bituminous, but has lignitic ash.

Effect of iron

Iron has a dominating influence on the slagging characteristics of coals with bituminous type ash. As shown in Table 2, iron can be present in coal in several mineral forms. These include pyrite (FeS_2), siderite (FeCO_3), hematite (Fe_2O_3), magnetite (Fe_3O_4) and ankerite $[(\text{Ca}, \text{Fe}, \text{Mg})\text{CO}_3]$. Pyrite is the major form of iron in most Eastern coals. In areas of the furnace where there is sufficient oxygen, pyrite is converted to Fe_2O_3 and SO_2 . If the local atmosphere is reducing, however, pyrrhotite (FeS) is formed along with the lesser-oxidized iron forms such as FeO and metallic iron, Fe. The reduced forms have significantly lower melting temperatures than the oxidized forms. When completely oxidized to Fe_2O_3 iron tends to raise all four values of ash fusion temperatures: initial deformation, softening, hemispherical and fluid. In the lesser oxidized form (FeO) it tends to lower all of these values. The effect of iron in each of these forms is indicated in Fig. 6, plotted for a large number of ash samples from U.S. coals. The data show that as the amount of iron in the ash increases, there is a greater difference in ash fusibility between oxidizing and reducing conditions.

These effects may be negligible with coal ash containing small amounts of iron. Coals with lignitic ash generally have small amounts of iron and the ash fusion temperatures are affected very little by the state of iron oxidation. In fact, lignitic ash containing high levels of calcium and magnesium may have ash fusion temperatures that are lower on an oxidizing basis than on a reducing basis. The ash analysis and fusion temperatures shown for the subbituminous coal in Table 3 illustrate this effect.

Fig. 6 Influence of iron on coal ash fusion temperatures.

Base to acid ratio

The constituents of coal ash can be classified as either basic or acidic. The basic constituents are iron, the alkaline earth metals calcium and magnesium, and the alkali metals sodium and potassium. Acidic constituents are silicon, aluminum and titanium. Bases and acids tend to combine to form compounds with lower melting temperatures. Experience has shown that the relative proportions of basic and acidic constituents provide an indication of the melting behavior and viscosity characteristics of coal ash.

The elemental analysis is used to calculate the percent base, percent acid and the base to acid ratio as follows:

$$\text{Percent base} = \frac{(\text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{Na}_2\text{O} + \text{K}_2\text{O}) \times 100}{\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2 + \text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{Na}_2\text{O} + \text{K}_2\text{O}} \quad (2)$$

$$\text{Percent acid} = \frac{(\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2) \times 100}{\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2 + \text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{Na}_2\text{O} + \text{K}_2\text{O}} \quad (3)$$

$$\text{Base/acid ratio} = \frac{\text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{Na}_2\text{O} + \text{K}_2\text{O}}{\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2} \quad (4)$$

The range of base to acid ratio extends from approximately 0.1 for highly acidic ash to 9.0 for ash that is high in base content.

Ash that is either highly acidic or highly basic generally has high ash fusion and melting temperatures.

However, the presence of basic constituents in an acidic ash tends to flux or reduce the melting temperature and viscosity of the mixture. Conversely, the melting temperature and viscosity of a basic ash are reduced by relative proportions of acidic constituents. When the percent base and percent acid are nearly equal, fusion temperatures and ash viscosity tend to be reduced to minimum levels. The general trend is shown in Fig. 7. Minimum fusion temperatures typically occur at approximately 40 to 45% base which equates to base to acid ratios in the range of 0.7 to 0.8. Ratios in the range of 0.5 to 1.2 are generally considered to indicate high slagging potential.

The base to acid ratio considers all of the basic and acidic constituents to have equal effects on ash melting characteristics. However, research has shown that the various acids and bases have different fluxing strengths which must also be considered.

Studies conducted by B&W on the relationship of ash composition to ash viscosity have provided additional factors which improve the simple base to acid relationship. Ash viscosity is an important criterion for determining the suitability of a coal ash for use in a slag-tap furnace. Experience has shown that slag will flow readily at or below a viscosity of 250 poise. The temperature at which this viscosity occurs is called the T_{250} temperature of the ash. The preferred maximum T_{250} for wet-bottom applications is 2450F (1343C). Trends in T_{250} temperatures have been shown to correlate with ash fusion temperatures. Low T_{250} temperatures indicate low fusion temperatures and increased slagging potential.

Ash viscosity can be measured directly in a high temperature viscometer. Because viscosity measurements

Fig. 7 Fusion temperatures and viscosities versus acidic constituents.

require a considerable amount of coal ash that may not be readily available and are costly and time consuming, methods were developed to determine viscosity from chemical analysis of the coal ash. Based on a large number of direct viscosity measurements of bituminous and lignitic ash samples, T_{250} temperatures were related to ash composition as shown in Figs. 8 and 9. Fig. 8 is for bituminous ash and lignitic ash with an acidic content above 60%. At base to acid ratios less than 0.3, the silicon (SiO_2)/aluminum (Al_2O_3) ratio is taken into account. Silicon and aluminum are both acidic constituents; however, higher percentages of silicon tend to raise the T_{250} and the melting temperature.

Fig. 9 is for lignitic ash with an acidic content less than 60%. T_{250} is a function of both the percent base and the dolomite percentage which is defined as:

$$\text{Dolomite percentage} = \frac{(\text{CaO} + \text{MgO}) \times 100}{\text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{Na}_2\text{O} + \text{K}_2\text{O}} \quad (5)$$

At a given percent base, higher dolomite percentages increase the T_{250} temperature, indicating that calcium and magnesium tend to raise ash viscosity and fusion temperature. Increasing amounts of the other base constituents (iron, sodium and potassium) tend to lower the T_{250} temperature.

Taken together, these trends indicate higher melting temperatures and higher viscosities at a given temperature for ash that is predominately composed of either silicon and aluminum or calcium and magnesium. Lower melting temperatures result from intermediate mixtures of these elements. However, in all combinations, iron, sodium and potassium act to flux the ash and increase the slagging potential.

As previously noted, the fluxing strength of iron is related to its state of oxidation. Metallic iron (Fe) and ferrous iron (FeO) are stronger fluxes than Fe_2O_3 and

Fig. 8 Plot of temperature for 250 poise viscosity versus base to acid ratio – based on ferric percentage of 20.

tend to reduce fusion temperatures and slag viscosity at a given temperature. The degree of iron oxidation is normally expressed as the ferric percentage where:

$$\text{Ferric percentage} = \frac{\text{Fe}_2\text{O}_3 \times 100}{\text{Fe}_2\text{O}_3 + 1.11\text{FeO} + 1.43\text{Fe}} \quad (6)$$

Fig. 9 Basic content and dolomite percentage of ash versus temperature for 250 poise viscosity.

The effect of ferric percentage on slag viscosity for a typical bituminous ash is shown in Fig. 10. Note that the T_{250} temperature can vary over a wide range depending on the degree of iron oxidation. Experience has shown that slag from boiler furnaces operating under normal conditions with 15 to 20% excess air has a ferric percentage of approximately 20%. The curves in Fig. 8 are based on this value.

Influence of alkalis on fouling

The alkali metals, sodium and potassium, have long been associated with the fouling tendencies of coal ash. Volatile forms of these elements are vaporized in the furnace at combustion temperatures. Subsequent reactions with sulfur in the flue gas and other elements in the ash form compounds that contribute to the formation of bonded deposits on convection heating surface.

Research conducted by B&W dating back to the 1950s identified a relationship between the total alkali content in bituminous coals and fouling potential. The specific laboratory procedure developed to establish this relationship, called the sintering strength test, is described in detail later in this chapter. Basically, the test involves measuring the compressive strength of flyash pellets heated in air for a period of time at temperatures of 1500 to 1800F (816 to 982C). The application of this method, combined with observations of fouling conditions in operating boilers, showed that high fouling coals produced flyash with high sintered strength. Conversely, low strength flyash was associated with low fouling coals. Correlation of standard ASTM ash analysis data with the sintering test results indicated a significant relationship (Fig. 11) between total alkali content (Na_2O and K_2O , expressed as equivalent total Na_2O) and flyash sintered strength. These correlations formed the basis for the first *foul-*

ing index for bituminous coals which used the total alkali content in the coal to predict fouling potential.

Because ASTM ash produced in the laboratory could not be expected to represent the physical and chemical properties of flyash produced by full scale combustion, sintering strength testing required actual flyash samples aspirated from the flue gas in operating boilers. This meant full scale tests under steady-state conditions with a consistent coal supply, which became increasingly more difficult as unit size increased. To improve the efficiency and accuracy of obtaining data, a small laboratory ashing furnace (LAF) was constructed to burn pulverized coal at controlled conditions similar to those in a commercial boiler.

Subsequent tests on flyash produced in the LAF from a wide variety of bituminous coals demonstrated that sodium was the most important single factor affecting ash fouling. Potassium, which had been included in the previous alkali fouling indices, was found to make no significant contribution to sintering strength. Additionally, it was found that water soluble sodium, which was related to the more readily vaporized forms of sodium, had a major effect on sintered strength. This result was obtained by washing coals with hot condensate in the laboratory to remove the water soluble sodium. The washed coals were ashed in the LAF and sintered at various temperatures. Results for a high fouling Illinois coal are shown in Table 4. Water washing decreased the sodium content in the ash by approximately 70%, while the potassium content, which was initially higher than the sodium content, decreased by only 4%. Removing the soluble sodium resulted in a reduction in sintering strength at 1700F (927C) from 17,300 psi (119.3 MPa) for the raw coal to 550 psi (3.8 MPa) for the washed coal. Because the coal had a high chlorine content, it was concluded that most of the volatile sodium was probably in the form of NaCl . The insoluble potassium was likely associated with clay minerals or feldspar which would not readily decompose and vaporize during combustion.

The relationship of sintering strength to the percentage of soluble sodium in the ash was also found to be a function of the base to acid ratio, as shown in

Fig. 10 Viscosity-temperature plots of a typical slag showing effect of ferric percentage.

Fig. 11 Effect of alkali content in coal.

Table 4
Effect of Soluble Sodium on Sintered Strength

Ash Analysis	Raw Coal	Washed Coal
SiO ₂	45.0	49.8
Al ₂ O ₃	18.0	20.9
Fe ₂ O ₃	21.0	22.9
TiO ₂	0.8	1.0
CaO	8.8	1.6
MgO	0.9	1.0
Na ₂ O	1.6	0.5
K ₂ O	2.4	2.3
Ash sintered strength, psi (MPa)	17,300 (119.3)	550 (3.8)

Fig. 12. The combination of high sodium and high base to acid ratios resulted in the highest sintering strengths. Low ratios and sodium contents resulted in reduced flyash strength at the same sintering temperature. Similar trends were noted for variations in sintering strength as a function of base to acid ratio and total Na₂O in the ash. Statistical evaluations of these relationships were used to develop the fouling index currently used for coals with bituminous ash.

Similar tests on the sintering characteristics of lignitic ash indicated that the sintering criteria associated with fouling for bituminous ash did not apply to lignitic ash with high alkaline (CaO, MgO) contents. However, sintering strength was found to be directly proportional to the total sodium content in the ash shown in Fig. 13. Full scale and pilot scale tests conducted by the U.S. Bureau of Mines at the Grand Forks Coal Research Laboratory in North Dakota also established a correlation between fouling rate and sodium content for coals with lignitic ash. As shown in Fig. 14, deposition rates were found to increase sharply as the Na₂O content increased up to approximately 6% and then level off at higher percentages of sodium.

Fig. 12 Bituminous (Eastern) ash fouling effect of base to acid ratio and soluble sodium on sintered strength.

As previously noted, in low rank coals, a major portion of the alkali and alkaline earth metals can be organically bound in the coal. Because they are intimately mixed with the coal, it is believed that alkalis in this form are readily vaporized during combustion and play a dominating role in fouling. The organically associated elements occur in the form of cations chemically bonded to the organic structure of the coal. Ion exchange techniques have been developed to remove the cations from the coal for measurement. The method employed by B&W uses an ammonium acetate solution to provide a source of NH₄⁺ ions which extract the ion-exchangeable cations. The laboratory procedure is described later in this chapter. Ion exchange data for a high fouling North Dakota lignite and a severe fouling Montana subbituminous coal are shown in Table 5. The data show that essentially all of the sodium in both coals is organically bound. In the lignite, the ion-exchangeable sodium actually exceeded the total sodium measured in ASTM ash. The difference most likely results from a loss of sodium due to vaporization during the high temperature ashing procedure. The relatively low percentages of ion-exchangeable K₂O indicate that most of the potassium exists in stable mineral forms.

Viscosity-temperature relationship of coal ash

The characteristics of slag deposits which form on furnace walls and other radiant surface are a function of deposit temperature and deposit composition.

Fig. 13 Effect of Na₂O on sintering strength (North Dakota lignite ash).

Fig. 14 Effect of Na_2O on deposition rate.

Deposit composition, in turn, is a function of the local atmosphere, particularly for ash with a significant iron content. Relationships between these factors determine the physical state of the deposit, which can range from a dry solid to plastic or even a viscous liquid if temperatures are sufficiently high. Dry deposits are usually not troublesome; they tend to be loosely bonded to the tube surface and relatively easy to remove by sootblowing. If deposits are allowed to build in thickness, the temperature increases and the surface of the deposit can become semi-molten or plastic. The plastic slag traps other transient ash particles and continues to build more and more rapidly as the surface temperature continues to increase. Ultimately, the deposit reaches an equilibrium state as the slag begins to flow.

Field experience has shown that plastic slag tends to form large deposits that are highly resistant to removal by conventional ash cleaning equipment. This

observation led to an extensive study of the relationship between ash viscosity and potential slagging tendency. Viscosity measurements that had previously been used to determine flow characteristics for wet-bottom furnace applications were extended to higher viscosity ranges to define the temperature range where a given ash would exhibit plastic characteristics.

As liquid ash is cooled, the logarithm of its viscosity increases linearly with decreasing temperature as shown in Fig. 15. At some point, the progression deviates from the linear relationship, and viscosity begins to increase more rapidly as the temperature continues to decrease. This transition into the plastic region is caused by the selective separation of solid material from the liquid, resulting from crystallization of the higher melting point constituents of the ash. The temperature at which this deviation takes place is called the temperature of critical viscosity (T_{cv}). T_{cv} varies depending on ash composition but normally occurs in a range between 100 and 500 poise. The end of the plastic region is the point of solidification, or freeze point, of the slag. The freeze point typically occurs at a viscosity of approximately 10,000 poise. For convenience in comparing the viscosity-temperature relationship of various ashes, the viscosity range of 250 to 10,000 poise has been defined as the plastic region.

The temperature at which the plastic region begins and the range of temperature over which the ash is plastic provide an indication of the slagging tendency. The lower the temperature within this range and the wider the range, the greater the potential for slagging. Viscosity-temperature curves for a high slagging Illinois coal and a low slagging east Kentucky coal, shown in Fig. 16, illustrate this effect. The plastic range for the Illinois coal begins at a relatively low temperature and extends over a wide temperature range. In contrast, the east Kentucky coal has a very narrow plastic range which begins at a much higher temperature. In comparison to the Illinois coal, the Kentucky coal ash would be expected to cool quickly below the temperature where the ash is plastic, exposing much less of the furnace to potential deposition.

As previously noted, the iron content of coal ash and its degree of oxidation have a significant influence on

Table 5 Ion Exchange Data — High and Severe Fouling Coals			
Source:		North Dakota	Montana
Rank:		Lignite	Subbituminous

Fig. 15 Viscosity increase with decreasing temperature.

the viscosity of the ash. This effect is illustrated in Fig. 17 which shows the viscosity-temperature relationship for the high iron Illinois coal under both oxidizing and reducing conditions. Under reducing conditions, the viscosity at a given temperature is significantly lower and the ash remains plastic over a much wider temperature range.

Ash reflectivity

Ash from certain coals produces furnace deposits that have reflective rather than insulating properties. This is particularly true of low sulfur, low sodium coals found in the western U.S., from the Powder River Basin in Wyoming and Montana. Reflective deposits can significantly reduce furnace heat absorption and increase furnace exit gas temperature even when only a very thin deposit is present. This can result in excessive radiant superheater slagging and fouling of convection surfaces. Experience has shown that reflective ash deposits can be difficult to remove and require special considerations in selection of ash cleaning equipment and media. (See Chapter 24.) Proprietary methods based upon field experience and laboratory studies are used to evaluate the potential for reflective ash formation, and to address the impact on furnace design and boiler performance.

Ash characterization methods

Several slagging and fouling indices have been developed by B&W to provide criteria for various aspects of boiler design. Slagging indices establish design criteria for the furnace and other radiant surface while fouling indices establish design criteria for convective

Fig. 16 Ash viscosity comparison for a high slagging and low slagging coal (oxidizing atmosphere).

Fig. 17 Ash viscosity comparison – oxidizing and reducing conditions.

surface. Deposition characteristics are generally classified into four categories: low, medium, high and severe.

For the most part, the indices described below are based on readily available ASTM ash analysis and fusibility data. In actual practice, when evaluating coals, designers take into account full scale experience on similar fuels and results of non-routine testing which can, in some cases, modify the classification. These indices can also be used on a comparative basis to rank coals with respect to their slagging and fouling potential when evaluating a new coal supply for an existing unit.

Ash classification

Because the characteristics of bituminous and lignitic ash vary significantly, the first step in calculating slagging and fouling indices is the determination of ash type. In accordance with the criteria previously described, ash is classified as bituminous when:

$$\text{Fe}_2\text{O}_3 > \text{CaO} + \text{MgO} \quad (7)$$

Ash is classified as lignitic when:

$$\text{Fe}_2\text{O}_3 < \text{CaO} + \text{MgO} \quad (8)$$

Slagging index – bituminous ash (R_s) Calculation of the slagging index (R_s) for bituminous ash takes into account the base to acid ratio and the weight percent, on a dry basis, of the sulfur in the coal. The base to acid ratio indicates the tendency of the ash to form compounds with low melting temperatures. The sulfur content provides an indication of the amount of iron that is present as pyrite. The calculation is as follows:

$$R_s = \frac{B}{A} \times S \quad (9)$$

where

$$\begin{aligned} B &= \text{CaO} + \text{MgO} + \text{Fe}_2\text{O}_3 + \text{Na}_2\text{O} + \text{K}_2\text{O} \\ A &= \text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2 \\ S &= \text{weight \% sulfur, on a dry coal basis} \end{aligned}$$

Classification of slagging potential using R_s is as follows:

$$\begin{aligned} R_s &< 0.6 &= \text{low} \\ 0.6 &< R_s &< 2.0 &= \text{medium} \\ 2.0 &< R_s &< 2.6 &= \text{high} \\ 2.6 &< R_s &&= \text{severe} \end{aligned}$$

Slagging index – lignitic ash (R_s^*) The slagging index for lignitic ash (R_s^*) is based on ASTM ash fusibility temperatures. As previously noted, fusibility temperatures indicate the temperature range where plastic slag is likely to exist. The index is a weighted average of the maximum hemispherical temperature (HT) and the minimum initial deformation temperature (IT) as follows:

$$R_s^* = \frac{(\text{Max HT}) + 4 (\text{Min IT})}{5} \quad (10)$$

where

$$\begin{aligned} \text{Max HT} &= \text{higher of the reducing or oxidizing hemispherical softening temperatures, F} \\ \text{Min IT} &= \text{lower of the reducing or oxidizing initial deformation temperatures, F} \end{aligned}$$

Classification of slagging potential using R_s^* is as follows:

$$\begin{aligned} 2450 &< R_s^* &= \text{low} \\ 2250 &< R_s^* &< 2450 &= \text{medium} \\ 2100 &< R_s^* &< 2250 &= \text{high} \\ R_s^* &< 2100 &= \text{severe} \end{aligned}$$

Slagging index – viscosity (R_{vs}) As previously noted, B&W's most accurate method for predicting slagging potential is based on the viscosity-temperature relationship of the coal ash. This index (R_{vs}) is applicable to both bituminous and lignitic ash coals; however, measured ash viscosities are required.

$$R_{vs} = \frac{(T_{250\text{oxid}}) - (T_{10,000\text{red}})}{97.5(fs)} \quad (11)$$

where

$$\begin{aligned} T_{250\text{oxid}} &= \text{temperature, F, corresponding to a viscosity of 250 poise in an oxidizing atmosphere} \\ T_{10,000\text{red}} &= \text{temperature, F, corresponding to a viscosity of 10,000 poise in a reducing atmosphere} \end{aligned}$$

and fs is a correlation factor based on the average of the oxidizing and reducing temperatures (T_{fs}) corresponding to a viscosity of 2000 poise. Values for fs as a function of T_{fs} are provided in Fig. 18.

Classification of slagging potential using R_{vs} is as follows:

$$\begin{aligned} R_{vs} &< 0.5 &= \text{low} \\ 0.5 &< R_{vs} &< 1.0 &= \text{medium} \\ 1.0 &< R_{vs} &< 2.0 &= \text{high} \\ 2.0 &< R_{vs} &&= \text{severe} \end{aligned}$$

Fouling index – bituminous ash (R_f) The fouling index for bituminous ash is derived from sintering strength characteristics using the sodium content of the coal ash and the base to acid ratio as follows:

$$R_f = \frac{B}{A} \times \text{Na}_2\text{O} \quad (12)$$

where

$$\begin{aligned} B &= \text{CaO} + \text{MgO} + \text{Fe}_2\text{O}_3 + \text{Na}_2\text{O} + \text{K}_2\text{O} \\ A &= \text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{TiO}_2 \\ \text{Na}_2\text{O} &= \text{weight \% from analysis of coal ash} \end{aligned}$$

Classification of fouling potential using R_f is as follows:

$$\begin{aligned} R_f &< 0.2 &= \text{low} \\ 0.2 &< R_f &< 0.5 &= \text{medium} \\ 0.5 &< R_f &< 1.0 &= \text{high} \\ 1.0 &< R_f &&= \text{severe} \end{aligned}$$

Fouling index – lignitic ash The fouling classification for lignitic ash coals is based on the sodium content in the ash as follows:

When $\text{CaO} + \text{MgO} + \text{Fe}_2\text{O}_3 > 20\%$ by weight of coal ash

$$\begin{aligned} \text{Na}_2\text{O} &< 3 &= \text{low to medium} \\ 3.0 &< \text{Na}_2\text{O} &< 6 &= \text{high} \\ \text{Na}_2\text{O} &> 6 &= \text{severe} \end{aligned}$$

When $\text{CaO} + \text{MgO} + \text{Fe}_2\text{O}_3 < 20\%$ by weight of coal ash

$$\begin{aligned} \text{Na}_2\text{O} &< 1.2 &= \text{low to medium} \\ 1.2 &< \text{Na}_2\text{O} &< 3 &= \text{high} \\ \text{Na}_2\text{O} &> 3 &= \text{severe} \end{aligned}$$

Coal ash effects on boiler design

Furnace design

The key to a successful overall gas-side design is proper sizing and arrangement of the furnace. As a first priority, the furnace must be designed to minimize slagging and to provide effective control of slag where and when it does form.

Ash deposition in the furnace can cause a number of problems. Slag deposits reduce furnace heat absorption and raise gas temperature levels at the furnace exit. This, in turn, can cause slagging and can aggravate fouling in the convection banks where ash deposits become increasingly more difficult to control as gas temperatures increase. The shift in heat absorption from the furnace to the superheater and reheater results in increased attemperator spray flow for control of steam temperatures, reducing cycle efficiency. Slag buildup at the top of a tall furnace is dangerous. Large deposits can become dislodged and fall, causing failures of furnace hopper tubes and loss of availability. Excessive slagging in the lower furnace can interfere with ash removal.

Experience has shown that several interrelated furnace design parameters are critical for slagging control. These parameters focus on keeping ash particles in suspension and away from furnace surfaces, distributing heat evenly to avoid high localized temperatures, and removing enough heat to achieve tempera-

Fig. 18 Slagging index correction factor fs.

tures at the furnace exit that will minimize deposition on convection surface.

In the context of gas-side design, the furnace basically serves three functions. It must provide sufficient volume to completely burn the fuel, provide sufficient heat transfer surface to cool the flue gas and ash particles to a temperature suitable for admission to the convection surface, and minimize the formation of NO_x emissions (see Chapter 34). In general, for a coal-fired unit, it is the second criterion that determines the minimum furnace size.

The slagging classification of the coal establishes the upper limit on furnace exit gas temperature (FEGT) required to minimize the potential for slagging both in the radiant superheater and the close-spaced convection surface. As described in Chapter 22, furnace exit gas temperature is a function of furnace heat release rate. Limiting the FEGT, therefore, limits the heat release rate, resulting in lower average temperatures in the furnace. FEGT limits and corresponding heat release rates have been established by experience for different types of coal. In general, units using coals with low or medium slagging tendencies can have higher heat release rates and higher FEGTs. Units firing coals with high or severe slagging potential require lower heat release rates and lower FEGTs.

Ideally, the furnace would be an open box, sized with sufficient wall surface to cool the furnace gas and ash particles to the desired temperature before they reached any superheater surface. However, thermodynamic considerations in modern high pressure and high temperature cycles require that a significant portion of the total heat absorption be accomplished in the superheater and reheater. This requirement places a practical limit on the amount of furnace wall surface which, in a drum boiler, is dedicated to generating saturated steam. In order to achieve the required FEGT it becomes necessary to replace water-cooled furnace wall surface with steam-cooled superheater surface. These surfaces are generally in the form of widely spaced platens (see Chapter 19) located in the upper radiant zone of the furnace. Because platen

surface is located in a relatively high gas temperature zone and subject to ash particle impaction, the side spacing must be sufficient to limit the potential for bridging and provide a degree of self-cleaning. Typical side spacing between platen sections is 4 to 5 ft (1.2 to 1.5 m). When platen superheater surface is used, the slagging classification of the coal establishes the upper limit on platen inlet gas temperature, in addition to limiting the FEGT.

An alternate method of controlling furnace exit gas temperature that has been widely used is gas tempering by flue gas recirculation. In this method, relatively cool gas from the economizer outlet is mixed with hot furnace gas near the furnace exit. Gas tempering offers a number of advantages. The FEGT can be limited with less furnace surface while the increased gas weight improves the thermal head for heat transfer, reducing the surface requirements in the convection pass. Proper introduction of the tempering flue gas provides a flat temperature profile at the furnace exit, reducing the possibility of localized slagging and fouling. Once the choice of gas recirculation is made, the system can also be used to control reheat steam temperature at partial loads. For this purpose, flue gas from the economizer outlet is introduced into the furnace through the furnace hopper opening. The cool gas reduces furnace heat absorption and makes more heat available to the reheater which offsets its natural characteristic of decreasing outlet steam temperature at partial loads.

The major disadvantages of gas recirculation are fan maintenance and power requirements. Fan erosion can be minimized to some extent by proper design and operation of a mechanical dust collector ahead of the fan. Extracting the recirculated gas after a hot precipitator offers the best potential for a relatively clean recirculated gas source.

In addition to having sufficient volume and heating surface, the furnace also must be correctly proportioned with respect to width, depth and height to minimize slagging. A significant design parameter in this regard is heat input from fuel to the furnace per unit of furnace plan area at the burners. Maximum limits on plan area heat release rate are a function of the slagging potential of the coal. Limits typically range from 1.5 to 1.8×10^6 Btu/h ft² (4.7 to 5.7 MW/m²) for severe slagging and low slagging coals respectively.

The furnace must also be designed to limit the potential for ash particle impaction on furnace surfaces. Ample clearance must be provided between the burners and furnace walls as well as the furnace hopper and arch. These critical dimensions have been established by operating experience and keyed to the slagging classification of the coal.

The slagging classification also determines the locations, quantity and spacing of furnace wall blowers and long retractable sootblowers in the pendant radiant surface. (See Chapter 24.) These allow control of the deposition that inevitably occurs and are essential for maintaining furnace surface effectiveness and furnace exit gas temperature within the range provided for in the design. Some degree of slagging may be permitted above the burner zone but only to

the extent that it can be controlled by selective operation of the wall blowers. The control of these deposits can help maintain steam temperature at reduced loads. Slag deposits on furnace walls must be avoided below and between burners, however, where they can not be controlled by sootblowers.

Effect of slagging potential on furnace sizing

Referring to Fig. 19, three large utility boilers are shown sized for 660 MW at maximum continuous load. The boilers are assumed to have the same width for purposes of illustration, with the boiler setting height and furnace depth varied to accommodate the slagging characteristics of the different fuels. Boiler (a) is designed to fire a bituminous coal having a low to medium slagging potential. The slightly larger boiler (b) is designed to fire a subbituminous coal classified as having a high slagging potential. The difference in size can be attributed primarily to the difference in slagging potential. The furnace (b) depth has been increased to control slagging by reducing the input per plan area. The input and gas weight are higher for the subbituminous coal due to its higher moisture content and resulting lower boiler efficiency. This increases the required furnace surface and the furnace exit area to maintain acceptable gas velocities entering the convection pass. Comparing boiler (c), firing a severe slagging lignite, to boiler (b), the furnace depth has again been increased due to the increased slagging potential. The furnace surface has also been increased to reduce the gas temperature leaving the furnace. The size differential of the three units is quantified in Table 6. This table shows the proportionate differences or increases using boiler (a) as a base. Boiler (a) is assigned a size factor of 1.0 for the various parameters shown.

Convection pass design

The key to successfully preparing a design that will control convection pass fouling reverts back to a furnace design that will maintain the furnace exit gas temperature at predicted levels. Temperature excursions at the furnace exit result in corresponding higher temperature levels throughout the convection pass which can cause deposition problems even with coals which normally would be considered to have a low or moderate fouling tendency.

In general, convective heating surface, both pendant and horizontal, is arranged to minimize the potential for bridging and obstruction of the gas lanes between adjacent sections. The minimum clear side spacing (measured perpendicular to the gas flow) between sections in a bank varies as a function of the average flue gas temperature entering the bank. The widest spacing is required in the superheater banks which are in close proximity to the furnace exit, where the gas temperature and fouling potential are high. As the flue gas temperature is reduced, the side spacing in succeeding banks can also be reduced. The specific side space dimensions at a given temperature entering the bank depend on the fouling classification of the coal. Severe fouling coals require the widest spacing. Adequate side spacing must be maintained even in low temperature horizontal banks such as economizers. While these surfaces are not normally subject to bonded deposits, sufficient clear space must be maintained between sections to ensure that accumulations of ash dislodged from upstream surfaces will not bridge and plug the gas lanes. (See Chapter 20.)

Bank depths (measured parallel to the direction of gas flow) are established as a function of fouling potential, clear side spacing and the temperature enter-

Fig. 19 Influence of slagging potential on furnace size. (See Table 6.)

Table 6
Boiler Size Versus Slagging Classification

	Boiler		
	(a)	(b)	(c)
Coal Rank	Bituminous	Subbituminous	Lignite
Slagging	Low/Med	High	Severe
Furnace plan area	1.0	1.11	1.24
Furnace surface	1.0	1.18	1.50
No. of furnace wall blowers	30	36	70

ing the bank. Cavities between the banks provide locations for long retractable sootblowers. At high gas temperatures, shallow bank depths are required to ensure adequate sootblower effectiveness. Sootblower jet penetration increases as temperatures are reduced and bank depths can be increased incrementally in cooler areas.

Flyash erosion

The metal loss on convection pass tubes due to flyash erosion is proportional to the total ash quantity passing through the boiler and is an exponential function of flue gas velocity. While with a given fuel there is no control of the ash quantity, erosion problems can be eased by reducing flue gas velocities. Velocity limits are determined based on the ash quantity on a pounds per million Btu (kg/MW_t) basis and the relative proportion of abrasive constituents in the ash. Typical limits range from 65 ft/s (19.8 m/s) for relatively non-abrasive low ash coals to 45 ft/s (13.7 m/s) or less for coals with high ash quantities and/or abrasive ash.

Effect of operating variables

Although the predominant factors affecting deposition are ash characteristics and boiler design, operating variables can also have a significant impact on slagging and fouling.

In general, operating variables associated with combustion optimization (see Chapter 14) tend to reduce the potential for deposition problems. These variables include air distribution, fuel distribution, coal fineness and excess air.

Air and fuel imbalances can result in high excess air at some burners while others operate with less than theoretical air. This, in turn, results in localized reducing conditions in the burner zone which can aggravate slagging, especially with coals having high iron content. High coal/air ratios can also delay combustion and upset heat distribution, resulting in elevated temperatures in the upper furnace and at the furnace exit. Long burnout times also increase the potential for burning particles to contact furnace walls and other heat transfer surfaces.

Secondary air imbalances can be minimized by adjusting individual burner flows to provide a flat O₂ profile at the economizer outlet. Care must be exercised to avoid burner adjustments that cause flame impingement on furnace walls. On the fuel side, burner line resistances should be balanced to maintain uniform coal flow to each burner. Coal feeders should be calibrated and adjusted to provide uniform coal flow to each pulverizer.

Low pulverizer fineness (see Chapter 13) can also cause problems associated with delayed combustion. Coarse particles require longer residence times for burnout and can cause slagging in the lower furnace.

Excess air has a tempering effect on average temperatures within the furnace and on furnace exit temperature. Excess air also reduces the potential for localized reducing conditions in the furnace when it is introduced through the burners. Air infiltration into the furnace or convection pass is far less beneficial and should be corrected or taken into account when establishing excess air requirements. While there is an associated efficiency loss, raising excess air above normal design levels is usually an effective tool for controlling deposition problems. In some cases, high excess air may also upset superheater/reheater absorption and steam temperatures.

Sootblowers (see Chapter 24) are the primary means of dealing directly with furnace wall slagging and convection pass fouling. The most important fundamental requirement is to use this equipment in a preventive, rather than corrective, manner. Sootblowers are most effective in controlling dry, loosely bonded deposits which typically occur in the early stages of deposition. If furnace slag is allowed to accumulate to the point that it becomes plastic or wet, or if convection pass deposits are allowed to build and sinter for long periods of time, removal becomes much more difficult. Sootblower sequencing requirements must be established by initial operating experience and updated when required, especially when fuel characteristics change. Boiler diagnostic systems, which are discussed in the following section, can assist in optimizing sootblower operation.

The least desirable operating technique for controlling deposition problems is load reduction. The most severe situations may require a permanent derate. However, in many marginal situations, temporary load reductions during off peak periods may provide sufficient cooling to shed slag and allow sootblowers to regain effectiveness.

Application of advanced diagnostic and control systems

Awareness of slagging and fouling conditions is critical to achieving reliability and availability on a coal-fired utility boiler. However, boiler surface cleanliness has been, traditionally, one of the most difficult operating variables to quantify. Typical indications of surface fouling appear to the operator indirectly in the form of steam temperatures, spray attemperation flows and draft losses (gas resistance). In some cases, experienced operators who are familiar with the op-

erating characteristics of a unit can make judgments on slagging and fouling conditions based on operating conditions, but these secondary indications can be misleading. For example, the furnace can be slagged, causing undesirably high gas temperatures entering the convection surface. However, the steam temperatures and spray attemperation may be normal if the convection surfaces are also fouled.

Another indication of surface cleanliness is draft loss. By watching draft loss across a bank, an alert operator can determine that sootblowing is probably required. Usually, however, by the time a change in draft loss is detected across widely spaced pendant sections, the banks are already bridged and it may be too late for removal by the sootblowers.

Visual observation is frequently used to further quantify cleanliness conditions. In many instances, however, access is limited and subjective evaluations can leave considerable room for error. Advanced methods have been developed to overcome these shortcomings and to improve upon traditional time-based sootblowing control.

Computer based performance monitoring systems can provide a direct and quantitative assessment of furnace and convective surface cleanliness. B&W's Heat Transfer Manager™ (HTM) program is based on the heat transfer analysis program developed over many years for boiler design and validated by extensive empirical data. The HTM program is configured on a boiler-specific basis, taking into account the arrangement of the furnace and all convective surface. Measurements of temperatures, pressures, flows, and gas analysis data are used to perform heat transfer analysis in the furnace and convective section on a bank by bank basis.

Advanced intelligent sootblowing systems have also been developed to combine this real time assessment of furnace and convective surface cleanliness with closed loop control of the cleaning equipment. B&W's Powerclean™ system automatically determines where and when sootblowing should occur in the furnace and convection pass. Powerclean uses cleanliness data from the HTM program in an expert decision making structure that dictates when blowers should be cycled.

Intelligent systems such as Powerclean recognize problem areas early in their development, so that selective sootblowing can be directed at a specific problem area and ash cleaning equipment is operated based on need. Intelligent sootblowing systems can optimize blowing medium use and improve performance while reducing tube damage and providing consistency to boiler operations.

Slagging can be particularly troublesome in localized areas of the furnace. To help optimize wall cleaning, heat flux sensors can be used. These sensors are installed in the waterwalls of the furnace and provide a differential temperature across the wall which changes in proportion to the amount of deposition. Sensor data is integrated into the overall intelligent sootblowing system so that cleanliness can be optimized in the furnace region. If an array of sensors is installed, the furnace can be broken into regions for better control of wall cleaning equipment and to optimize operation.

Additional discussion of the application of control systems to local sootblower cleaning requirements is provided in Chapter 24.

Non-routine ash evaluation methods

The following describes the laboratory equipment and test procedures, referenced earlier, that are used to supplement the standard ASTM coal ash characterization methods.

Laboratory ashing furnace

As noted, the ASTM ashing procedure does not duplicate the ashing process that actually occurs in a boiler. A laboratory ashing furnace (LAF) provides a means to obtain flyash and deposit samples that are comparable to those obtained from full scale installations operating under similar conditions.

B&W's LAF, shown in Fig. 20, is designed to fire pulverized coal at rates typically between 5 and 10 lb/h (2.3 and 4.5 kg/h). The facility consists of a fuel feed system, pulverized coal burner and a refractory lined chamber. The combustion chamber is surrounded by an electrically heated guard furnace which controls the rate of heat removal from the chamber to simulate full scale furnace temperatures. The firing rate is established to approximate full scale furnace residence time. A deposition section located at the furnace exit contains air- or water-cooled probes. The surface temperature of the probes can be adjusted to simulate furnace and superheater tube operating temperatures.

Fig. 20 Schematic of laboratory ashing furnace (LAF).

The probes are instrumented to allow measurement of metal temperatures, cooling fluid flow rates, and cooling fluid inlet and outlet temperatures. These data permit calculation of the total heat flux from the flue gas through the deposit and into the probe. The deposition section is also fitted with sootblowers to evaluate the effectiveness of ash removal equipment. Fig. 21 shows ash particles impacting a simulated superheater tube during a deposition test. The B&W LAF was used to develop extensive data which has now been correlated to the ash characteristics. These correlations have largely replaced the need for routine laboratory testing.

Measurement of ash viscosity

Viscosity of coal ash is measured in a high temperature rotating-bob viscometer (Fig. 22). The ash under study is contained in a cylindrical platinum-rhodium crucible, and a cylindrical bob is rotated in the liquid at a constant speed through a calibrated suspension wire. The torque or amount of twist produced in the suspension wire is proportional to the viscosity. The amount of twist is measured and recorded as the interval between impulses from light beams reflected from mirrors attached to the ends of the wire. The suspension wires are calibrated against viscosity standard oils obtained from the Bureau of Standards.

The electrically heated furnace is of the Globar tube type with temperature regulation provided through a controlling type potentiometer actuated by a thermocouple located in the furnace adjacent to the sample crucible. A thermocouple imbedded in the ash crucible support indicates sample temperature. Provision is made for controlling the atmosphere within the furnace. Ash is introduced into the crucible at an elevated temperature [2600 to 2800F (1427 to 1538C)] and held at that temperature until it becomes uniformly fluid. The temperature is then decreased in predeter-

Fig. 21 Deposit formation on simulated superheater tube.

Fig. 22 Section through furnace of high temperature viscometer.

mined steps and the viscosity of the ash is measured at each temperature.

Ash sintering strength

The sintering strength test is performed on a flyash sample prepared in the LAF under a standard set of firing conditions. The flyash is passed through a 60 mesh (U.S. standard) (250 micron) screen to remove any particles of slag and then ignited to constant weight at 900F (482C) to remove any carbon that might be present. The ignited ash is then reduced to a minus 100 mesh size and at least 24 cylindrical specimens [0.6 in. (15.2 mm) diameter by 0.85 in. (21.6 mm) long] are formed in a hand press at a pressure of 150 psi (1034 kPa). At least six specimens are heated in air, usually at each of four temperature levels [1500, 1600, 1700 and 1800F (816, 871, 927 and 982C)] for 15 hours.

After the specimens have cooled slowly in the furnace, they are removed, measured and then crushed in a standard metallurgical testing machine. The sintered or compression strength is then computed from the applied force and the cross-sectional area of the sintered specimen. The average strength of six specimens is used as the strength of the sintered flyash at a particular sintering temperature.

Measurement of ion exchangeable cations in coal

Twenty grams of an air-dried minus 60 mesh coal sample are mixed with 100 ml of 1 N ammonium acetate in a 300 ml three-neck round bottom flask. A thermometer is inserted into the slurry. The slurry is stirred constantly and heated to $60 \pm 5^\circ\text{C}$. The coal slurry sample is refluxed for 18 hours. The sample is filtered through a cellulosic filter media with 0.45 μ

average pore size and washed twice with 25 ml of 1 N ammonium acetate solution.

The above procedure is repeated on the filtered coal except that the time is shortened to three hours. The combined filtrates are acidified by adding 2% by volume of glacial acetic acid and stored for inductive coupled plasma atomic emission spectrometric (ICPAES) analysis of Na, K, Ca and Mg.

Coal ash corrosion

Serious external wastage or corrosion of high temperature superheater and reheater tubes was first encountered in coal-fired boilers in 1955. Tube failures resulting from excessive thinning of the tube walls, as shown in Fig. 23, occurred almost simultaneously in the reheater of a dry ash furnace boiler and the secondary superheater of a slag-tap furnace unit. Corrosion was confined to the outlet tube sections of the reheater and the secondary superheater, which were made from chromium ferritic and stainless steel alloys, respectively.

Significantly, these boilers were among the first to be designed for 1050F (566C) main and reheat steam temperatures; also, both units burned high sulfur, high alkali Central and Southern Illinois coals, which were causing chronic ash fouling problems at the time.

Early investigations showed that corrosion occurred where complex alkali sulfates concentrated on tube surfaces beneath bulky layers of ash and slag. When dry, the complex sulfates were relatively innocuous; but when semi-molten [1100 to 1350F (593 to 732C)], they corroded the alloy steels used in superheater construction, and also other normally corrosion resistant alloys.

At first, it appeared that coal ash corrosion might be confined to boilers burning high alkali coals, but complex sulfate corrosion was soon found on super-

heaters and reheaters of several boilers burning low to medium alkali coals. Where there was no corrosion, the complex sulfates were either absent or the tube metal temperatures were moderate [less than 1100F (593C)]. The general conclusions drawn from this survey of corrosion were:

1. All bituminous coals contain enough sulfur and alkali metals to produce corrosive ash deposits on superheaters and reheaters, and those containing more than 3.5% sulfur and 0.25% chlorine may be particularly troublesome.
2. Experience has shown that corrosion rate is affected by both tube metal temperature and gas temperature. Fig. 24, which is used as a guide in design, indicates stable and corrosive zones of fuel ash corrosion as a function of gas and metal temperatures.

Based on this information, B&W modified the design of its boilers to greatly reduce the corrosion of superheaters and reheaters. These modifications included changes in furnace geometry, burner configuration, superheater arrangement and the use of gas tempering, all of which reduced metal and gas temperatures and reduced temperature imbalances. Experience from these installations has shown that it is possible to operate boilers with main and reheat steam temperatures up to 1050F (566C) with little, if any, corrosion from most coals.

Meanwhile, there was a gradual return to the 1000F (538C) steam conditions, due primarily to economic factors and secondarily to coal ash corrosion. This temperature level has permitted the use of lower cost alloys in the boiler, steam piping and turbine, with substantial savings in investment costs; it also has provided a greater margin of safety to avoid corrosion. Steam temperatures remained on the 1000F (538C) plateau for several decades. However, improved alloy creep and corrosion resistance and the potential for

Fig. 23 Typical corroded 18Cr-8Ni tube from secondary superheater.

Fig. 24 Coal ash corrosion – stable and corrosive zones.

cycle efficiency improvement have led to increased steam temperatures in the newest generation of utility boilers. Some recent boilers have been designed with main and reheat steam temperatures at and above 1100F (593C), and temperatures of 1200F (640C) and above are envisioned.

General characteristics of corrosion

External corrosion of superheaters and reheaters is concentrated on the upstream side of the tube, as shown in Fig. 25. The greatest metal loss usually occurs on the 10 and 2 o'clock sectors of the tubes, and it tapers off to little or none on the back side of the tubes. The corroded surface of the tube is highly sculptured by a shallow macropitting type of attack. The amount of corrosion, as measured by reduction in tube wall thickness, varies considerably along the length of the tube, depending on local conditions, i.e., the position of the tube in the bank or platen, the proximity of sootblowers, the composition of ash deposits and, most importantly, the gas and metal temperatures.

The corrosion rate is a nonlinear function of metal temperature (Fig. 26). Typically, the corrosion of both chromium ferritic and 18Cr-8Ni stainless steels increases sharply above a temperature of 1150F (621C), passes through a broad maximum between 1250 and 1350F (677 and 732C) and then decreases rapidly at still higher temperatures. However, the corrosion behavior varies depending on gas and ash chemistries and other factors, as well as temperatures.

The highest corrosion rates are generally found on the outlet tubes of radiant superheater or reheater platens opposite retractable sootblowers. Values ranging from 50 to 250 mils/yr (1.27 to 6.35 mm/yr) have been observed on 18Cr-8Ni stainless steel tubes under these adverse conditions. When similar high temperature surfaces [1100 to 1175F (593 to 635C)] are arranged in convection tube banks so they are shielded from direct furnace radiation and sootblower action, corrosion rates are much lower, ranging between 5 and 20 mils/yr (0.13 to 0.51 mm/yr).

Corrosive ash deposits

Corrosion is rarely found on superheater or reheater tubes having only dusty deposits. It is nearly always associated with sintered or slag type deposits that are strongly bonded to the tubes. Such deposits consist of at least three distinct layers. The outer layer, shown diagrammatically in Fig. 27, constitutes the bulk of the deposit and has an elemental composition similar

Fig. 25 Transverse sections of corroded tubes from secondary superheater platens.

Fig. 26 Effect of temperature on corrosion rate.

to that of flyash. Though often hard and brittle, this layer is a porous structure through which gases may diffuse. Innocuous by itself, it plays an important part in the formation of an intermediate layer that contains the corrosive agents.

The intermediate layer, frequently called the white layer, is a white to yellow colored material which varies in thickness from 0.03 to 0.25 in. (0.76 to 6.35 mm). It usually has a chalky texture where corrosion is mild or nonexistent, but is fused and semi-glossy where corrosion is severe. In the latter condition this layer is difficult to remove as it is so firmly bonded to the corroded surface beneath.

Fig. 27 Analyses of typical ash deposit from 18Cr-8Ni superheater tube.

Upon heating in the air, the intermediate layer melts around 1000F (538C) and slowly discolors and hardens into a hard mass resembling rust. Chemical analyses of this layer show that it contains higher concentrations of potassium, sodium and sulfur than does the parent coal ash. A large part of this deposit is water soluble and the water soluble fraction is always acidic. The most common compounds found are $\text{Na}_3\text{Fe}(\text{SO}_4)_3$ and $\text{KAl}(\text{SO}_4)_2$.

Complex alkali sulfates, when molten, rapidly corrode most, if not all, superheater alloys. Corrosion begins between 1000 and 1150F (538 and 621C), depending on the relative amounts of complex sodium and potassium sulfates present and whether these are predominantly iron or aluminum base compounds. Corrosion usually begins at the lower temperature where the sodium-iron-sulfate system is the major part of the intermediate layer, but corrosion is more severe and persists into a higher temperature range when the potassium-aluminum-sulfate system dominates.

If the intermediate layer is carefully removed, a black, glassy inner layer is revealed, which appears to have replaced the normally protective oxide on the tube. This layer is composed primarily of corrosion products, i.e., oxides, sulfides, and sulfates of iron and other alloying constituents in the tube metal. It seldom exceeds 0.063 in. (1.59 mm) thickness on corroded 18Cr-8Ni stainless steel tubes, probably because of its strong tendency to spall when the tubes cool. The layer containing corrosion products from chromium ferritic steels often reaches 0.125 in. (3.18 mm) thickness and exhibits little tendency to spall as the tube cools.

Corrosion mechanisms

The elements in coal ash corrosion (sodium, potassium, aluminum, sulfur and iron) are derived from the mineral matter in coal. The minerals supplying these elements include shales, clays and pyrites which are commonly found in all coals.

During the combustion of coal, these minerals are exposed to high temperatures and strongly reducing effects of carbon for very short periods of time. Although comparatively stable, the mineral matter undergoes rapid decomposition under these conditions. Some of the alkalis are released or volatilized as relatively simple compounds, which have dew points in the 1000 to 1300F (538 to 704C) range. Furthermore, sulfur in the coal is oxidized, releasing SO_2 with the formation of a small amount of SO_3 , leaving a residue of iron oxide (Fe_2O_3).

By far the largest portion of the mineral matter or its derived species react to form the glassy particulates of flyash. The flyash and volatile species in the flue gases deposit on the tube surfaces. Slowly, over a period of weeks, the alkalis and the sulfur oxides diffuse through the layer of flyash toward the tube surface. In the lower temperature zone of the ash deposit, chemical reactions between the alkalis, the sulfur oxides, and the iron and aluminum components of the flyash form complex alkali sulfates as follows:

and

Similar reactions occur with sodium sulfate (Na_2SO_4), although the complex sodium sulfates are less apt to form at high temperatures because of their lower stability.

Work at B&W has shown that SO_3 concentrations in ash deposits must be very high (1000 to 1500 ppm) compared to the level in the flue gas (10 to 25 ppm) in order to form the complex alkali sulfates in the intermediate layer. Therefore, the bulk of the SO_3 must come from the catalytic oxidation of SO_2 in the outer layer of the deposit.

When the SO_3 produced in the outer deposit exceeds the partial pressure of SO_3 necessary for stability, the complex sulfates form through the above reactions. When the opposite is true, the complex sulfates begin to decompose according to the reverse of these reactions until a new equilibrium is reached. Because the formation of SO_3 is temperature dependent, the reversibility of these reactions is also temperature dependent. As shown in Fig. 26 the corrosion rate increases with temperature, passes through a maximum between 1250 and 1350F (677 and 732C), and then falls to a comparatively low level at higher temperatures.

The temperature range of this rapid liquid-phase attack is bracketed by: 1) the melting temperature of the mixture of complex alkali sulfates present, and 2) their thermal stability limits. The extreme width of this temperature band is approximately 400F (222C); corrosion due to the complex alkali sulfates may range from as low as 1000F (538C) to a maximum of 1400F (760C), depending on the species present in the intermediate layer.

Corrective measures

Various methods of combating corrosion of superheater and reheater tubes have been used or suggested, including the following:

1. the use of stainless steel shields to protect the most vulnerable tubes,
2. coal selection,
3. improvement of combustion conditions, i.e., providing proper coal fineness, fast ignition, good mixing and proper excess air, and
4. the use of more corrosion resistant alloys and alloy cladding on the most vulnerable superheater and reheater tubes. (See Chapter 19.)

New high chromium content stainless steels are generally more resistant to coal ash corrosion, but added chromium tends to degrade other metallurgical properties. New modified 25% chromium 20% nickel stainless steels offer improved performance for moderate conditions. Higher chromium nickel-based alloys and cladding offer maximum resistance for the most severe conditions.

Fuel oil ash

The ash content of residual fuel oil seldom exceeds 0.2%, an exceedingly small amount compared to that in coal. Nevertheless, even this small quantity of ash

is capable of causing severe problems of deposition and corrosion in boilers. Of the many elements that may appear in oil ash deposits, the most important are vanadium, sodium and sulfur. Compounds of these elements are found in almost every deposit in boilers fired by residual fuel oil and often constitute the major portion of these deposits.

Origin of ash

As with coal, some of the ash-forming constituents in the crude oil had their origin in animal and vegetable matter from which the oil was derived. The remainder is extraneous material, resulting from contact of the crude oil with rock structures and salt brines, or is picked up during refining processes, storage and transportation. (See Chapter 9.)

In general, the ash content increases with increasing asphaltic constituents in which the sulfur acts largely as a bridge between aromatic rings. Elemental sulfur and hydrogen sulfide have been identified in crude oil, and simpler sulfur compounds are found in the distillates of crude oil including thioesters, disulfides, thiophenes and mercaptans.

Vanadium, iron, sodium, nickel and calcium in the fuel oil were probably derived from the rock strata but some elements, such as vanadium, nickel, zinc and copper, probably came from organic matter from which the petroleum was derived. Vanadium and nickel especially are known to be present in organo-metallic compounds known as porphyrins which are characteristic of certain forms of animal life. Table 7 indicates the amounts of vanadium, nickel and sodium present in residual fuel oils from various crudes.

Crude oil as such is not normally used as a fuel but is further processed to yield a wide range of more valuable products. For example, in a modern U.S. refinery, 92.4% of the crude is converted to lighter fraction fuels and products such as gasoline, leaving 7.6% of

residual fuel oil or distillate residue. Virtually all metallic compounds and a large part of the sulfur compounds are concentrated in the distillation residue. Where low sulfur residual fuel oils are required, they are obtained by blending with suitable stocks, including both heavy distillates and distillation from low sulfur crudes. This procedure is also used occasionally if a residual fuel oil must meet specifications such as vanadium or ash content.

Release of ash during combustion

Residual fuel oil is preheated and atomized to provide enough reactive surface so that it will burn completely within the boiler furnace. (See Chapter 11.) The atomized fuel oil burns in two stages. In the first stage the volatile portion burns and leaves a porous coke residue and in the second stage the coke residue burns. In general, the rate of combustion of the coke residue is inversely proportional to the square of its diameter, which in turn is related to the droplet diameter. Therefore, small fuel droplets give rise to coke residues that burn very rapidly, and the ash forming constituents are exposed to the highest temperatures in the flame envelope. The ash forming constituents in the larger coke residues from the larger fuel droplets are heated more slowly, partly in association with carbon. Release of the ash from these residues is determined by the rate of oxidation of the carbon.

During combustion, the organic vanadium compounds in the residual fuel oil thermally decompose and oxidize in the gas stream to V_2O_3 , V_2O_4 and finally V_2O_5 . Although complete oxidation may not occur and there may be some dissociation, a large part of the vanadium originally present in the oil exists as vapor phase V_2O_5 in the flue gas. The sodium, usually present as chloride in the oil, vaporizes and reacts with sulfur oxides either in the gas stream or after deposition on tube surfaces.

Subsequently, reactions take place between the vanadium and sodium compounds, with the formation of complex vanadates having melting points lower than those of the parent compounds; for example:

Melting points: 1625F 1275F 1165F

Excess sodium or vanadium in the ash deposit, above that necessary for the formation of the sodium vanadates (or vanadylvanadates), may be present as Na_2SO_4 and V_2O_5 , respectively.

The sulfur in residual fuel oil is progressively released during combustion and is promptly oxidized to SO_2 . A small amount of SO_2 is further oxidized to SO_3 by a small amount of atomic oxygen present in the hottest part of the flame. Also, catalytic oxidation of SO_2 to SO_3 may occur as the flue gases pass over vanadium rich ash deposits on high temperature superheater tubes and refractories. (See Chapter 35.)

Oil slag formation and deposits

The deposition of oil ash constituents on the furnace walls and superheater surfaces can be a serious problem. This deposition, coupled with corrosion of super-

heater and reheater tubes by deposits, was largely responsible for the break in the trend towards higher steam temperatures that occurred in the early 1960s.

Practically all boiler installations are typically designed for steam temperatures in the 1000 to 1015F (538 to 546C) range to minimize those problems and to avoid the higher capital costs of the more expensive alloys required in the tubes, steam piping and turbine for 1050 to 1100F (566 to 593C) steam conditions.

There are many factors affecting oil ash deposition on boiler heat absorbing surfaces. These factors may be grouped into the following interrelated categories: characteristics of the fuel oil, design of the boiler, and operation of the boiler.

Characteristics of fuel oil ash

Sodium, sulfur and vanadium are the most significant elements in the fuel oil because they can form complex compounds having low melting temperatures, 480 to 1250F (249 to 677C), as shown in Table 8. Such temperatures fall within the range of tube metal temperatures generally encountered in furnace and superheater tube banks of many oil-fired boilers. However, because of its complex chemical composition, fuel oil ash seldom has a single sharp melting point, but rather softens and melts over a wide temperature range.

An ash particle that is in a sticky, semi-molten state at the tube surface temperature may adhere to the tube if it is brought into contact by the gas flow over the tube. Even a dry ash particle may adhere due to mutual attraction or surface roughness. Such an initial deposit layer will be at a higher temperature than that of the tube surface because of its relatively low thermal conductivity. This increased temperature promotes the formation of adherent deposits. Therefore, fouling will continue until the deposit surface temperature reaches a level at which all of the ash in the gas stream is in a molten state, so that the surface is merely washed by the liquid without freezing and continued buildup.

In experimental furnaces, it has been found that the initial rate of ash buildup was greatest when the sodium-vanadium ratio in the fuel oil was 1:6, but an equilibrium thickness of deposit [0.125 to 0.25 in. (3.175 to 6.35 mm)] was reached in approximately 100 hours of operation. When the fuel oil contained more refractory constituents, such as silica, alumina and iron oxide, in addition to sodium and vanadium, an equilibrium condition was not reached and the tube banks ultimately plugged with ash deposits. However, these ash deposits were less dense, i.e., more friable, than the glassy slags encountered with a 1:6 sodium-vanadium fuel oil. Both the rate of ash buildup and the ultimate thickness of the deposits are also influenced by physical factors such as the velocity and temperature of the flue gases and particularly the tube metal temperature.

In predicting the behavior of a residual oil insofar as slagging and tube bank fouling are concerned, several fuel variables are considered including: 1) ash content, 2) ash analysis, particularly the sodium and vanadium levels and the concentration of major con-

stituents, 3) melting and freezing temperatures of the ash, and 4) the total sulfur content of the oil. Applying this information in boiler design is largely a matter of experience.

Boiler design

Generally speaking, progressive fouling of furnaces and superheaters should not occur as long as the ash characteristics are not severe compared to the tube metal temperatures. If such trouble is encountered, the solution can usually be found in improving combustion conditions in the furnace and/or modifying the sootblowing procedures.

Studies on both laboratory and field installations have shown that the rate of ash deposition is a function of the velocity and temperature of the flue gases and the concentration of oil ash constituents in the flue gases. The geometry of the furnace and the spacing of tubes in the convection banks are selected in the design of a boiler to minimize the rate of deposition. It is common practice to use in-line tube arrangements with wider lateral spacings for tubes located in higher gas temperature zones. This makes bridging of ash deposits between tubes less likely and facilitates cleaning of tube banks by the sootblowers.

Boiler operation

Poor atomization of the fuel oil results in longer flames and frequently increases the rate of slag buildup on furnace walls which, in turn, makes it more difficult to keep the convection sections of the boiler clean. Completing combustion before the gases pass over the first row of tubes is especially important.

* Decomposes at a temperature around the melting point.

Relatively large carbonaceous particles have a far greater tendency to impinge on the tubes than do the smaller ash particles. If these larger particles are in a sticky state, they will adhere to the tubes where oxidation will proceed at a slow rate with consequent formation of ash. Fouling from this cause is difficult to detect by inspection during boiler outages because the carbonaceous material has usually disappeared completely. It can generally be detected during operation because flames are usually long and smoky, and *sparklers* may be carried along in the flue gases.

Regular and thorough sootblowing can have a decisive effect on superheater and reheater fouling. (See Chapter 24.) To be fully effective, however, sootblowing cycles should be frequent enough so that ash deposits can not build to a thickness where their surfaces become semi-molten and difficult to remove. In instances of extreme slagging, it is sometimes necessary to relocate sootblowers, to install additional sootblowers to control deposition in a critical zone, or to use additives.

The boiler load cycle can also have a significant effect on the severity of slagging and superheater fouling. A unit that is base loaded for long periods is more apt to have fouling problems on a borderline fuel oil than a unit that takes daily swings in load. In the latter instance, the furnace generally remains cleaner due to periodic shedding of slag, with the result that the gas temperatures through the superheaters are appreciably lower. This eases the burden on the sootblowers and substantially controls ash deposit formation in the superheater-reheater tube banks. Overloading the boiler, even for an hour or two a day, should be avoided, especially if excess air has to be lowered to the point where some of the burners are starved of air. The furnace is apt to become slagged and ash deposition can creep into the superheater and reheater tube banks.

Oil ash corrosion

High temperature corrosion

The sodium-vanadium complexes, usually found in oil ash deposits, are corrosive when molten. A measurable corrosion rate can be observed over a wide range of metal and gas temperatures, depending on the amount and composition of the oil ash deposit. Fig. 28 shows the combined gas and metal temperature effects on corrosion for a specific fuel oil composition of 150 ppm vanadium, 70 ppm sodium and 2.5% sulfur. As the vanadium concentration of the fuel oil varies, the amount of corrosion, compared to a 150 ppm vanadium fuel, will increase or decrease according to the curve shown in Fig. 29. The effect of the sodium level in the fuel oil is not as clear. The sodium content does, however, definitely affect the minimum metal temperature at which corrosion will be significant.

At the present time there appears to be no alloy that is immune to oil ash corrosion. In general, the higher the chromium content of the alloy, the more resistant it is to attack. This is the main reason for the use of 18Cr-8Ni alloys for high temperature superheater

tubes. High chromium contents, greater than 30%, give added corrosion resistance but at the expense of physical properties; 25Cr-20Ni has been used as a tube cladding but even this alloy has not provided complete protection. High-nickel high-chromium alloys may be more resistant to oil ash attack under oxidizing conditions, but the higher material cost must be justified by longer life, which is not always predictable.

Low temperature corrosion

In oil-fired boilers, the problem of low temperature corrosion resulting from the formation and condensation of sulfuric acid from the flue gases is similar to that previously described for coal firing.

Oil-fired boilers are more susceptible to low temperature corrosion than are most coal-fired units for two reasons: 1) the vanadium in the oil ash deposits is a good catalyst for the conversion of SO_2 to SO_3 , and 2) there is a smaller quantity of ash in the flue gases. Ash particles in the flue gas react with and reduce the amount of SO_3 vapor in the gas, and oil has considerably less ash than coal. Furthermore, coal ash is more basic than oil ash and more effectively neutralizes acid.

Methods of control

The methods of control that have been used or proposed to control fouling and corrosion in oil-fired boilers are summarized in Table 9, but in every instance economics govern their applicability. There is no doubt that reducing the amount of ash and sulfur entering

Fig. 28 Effect of gas and metal temperatures on corrosion of 304, 316 and 321 alloys in a unit fired with oil containing 150 ppm vanadium, 70 ppm sodium and 2.5% sulfur. Test duration 100 hours.

Fig. 29 Effect of vanadium concentration on oil ash corrosion.

the furnace is the surest means of control and that minimizing the effects of the ash constituents, once they have deposited on the tubes, is the least reliable. Because the severity of fouling and corrosion depends not only on the fuel oil characteristics but also on boiler design and operating variables, a generalized solution to these problems can not be prescribed.

Fuel oil supply

Although fuel selection and blending are practiced to some extent in the U.S., the common purpose is to provide safe and reliable handling and storage at the power plant rather than to avoid fouling difficulties. Because the threshold limits of sodium, sulfur and vanadium are not well defined for either fouling or corrosion, use of these means of control can not be fully exploited.

Fuel oil additives

An approach that is effective where the fuel oil ash is most troublesome involves adding, to the fuel or furnace, small amounts of materials that change the character of the ash sufficiently to permit its removal by steam or air sootblowers or air lances.

Additives are effective in reducing the problems associated with superheater fouling, high temperature ash corrosion and low temperature sulfuric acid corrosion. Most effective are alumina, dolomite and magnesia. Kaolin is also a source of alumina. Analyses of typical superheater deposits from a troublesome fuel oil, before and after treating it with alumina or dolomite, are shown in three bar graphs on the left of Fig. 30. The results for a different oil treated with magnesia are shown in the bar graph on the right.

The reduction of fouling and high temperature corrosion is accomplished basically by producing a high melting point ash deposit that is powdery or friable and easily removed by sootblowers or lances. When the ash is dry, corrosion is considerably reduced.

Low temperature sulfuric acid corrosion is reduced by the formation of refractory sulfates by reaction with the SO_3 gas in the flue gas stream. By removing the SO_3 gas, the dew point of the flue gases is sufficiently reduced to protect the metal surfaces. The sulfate compounds formed are relatively dry and easily removed by the normal cleaning equipment.

In general, the amount of additive used should be about equal to the ash content of the fuel oil. In some instances, slightly different proportions may be required for best results, especially for a high temperature corrosion reduction, in which it is generally accepted that the additive should be used in weight ratios of 2:1 or 3:1 (additive/ash), based on the vanadium content of the oil.

Several methods have been successfully used to introduce the additive materials into the furnace. The one in general use consists of metering a controlled amount of an additive oil slurry in the burner supply line. The additive material should be pulverized to 100% through a 325 mesh (44 micron) screen for good dispersion and minimum atomizer wear.

For a boiler fired by a high pressure return flow oil system (Chapter 11), it has been found advantageous to introduce the additive powders by blowing them into the furnace at the desired locations. The powder has to be reduced in size to 100% through a 325 mesh (44 micron) screen for good dispersion.

The choice of a particular additive depends on its availability and cost to the individual plant and the method of application chosen. For example, alumina causes greater sprayer plate wear than the other materials when used in an oil slurry.

The quantity of deposit formed is, of course, an important consideration for each unit from the aspect of cleaning. A comparison of the amounts of deposit

Table 9

Fig. 30 Effect of fuel oil additives on composition of oil ash deposit.

formed with different additives shows that dolomite produces the greatest quantity because of its sulfating ability, magnesia is intermediate, and alumina and kaolin form the least. However, when adequate cleaning facilities are available, the deposits are easily removed and the quantities formed should not be a problem.

Excess air control

As mentioned previously the problems encountered in the combustion of residual fuel oils – high temperature deposits (fouling), high temperature corrosion and low temperature sulfuric acid corrosion – all arise from the presence of vanadium and sulfur in their highest states of oxidation. By reducing the excess air from 7% to 1 or 2%, it is possible to avoid the formation of fully oxidized vanadium and sulfur compounds and, thereby, reduce boiler fouling and corrosion problems.

In a series of tests on an experimental boiler, it was found that the maximum corrosion rate of type 304 stainless steel superheater alloy held at 1250F (677C) in 2100F (1149C) flue gas was reduced more than 75% (Fig. 31) when the excess air was reduced from an average of 7% to a level of 1 to 2%. Moreover, the ash deposits that formed on the superheater bank were soft and powdery, in contrast to hard, dense deposits that adhered tenaciously to the tubes when the excess air was around 7%. Also, the rate of ash buildup was only half as great. Operation at the 1 to 2% excess air level practically eliminated low temperature corrosion of carbon steel at all metal temperatures above the dew point of the flue gases (Fig. 32). However, much of the beneficial effects of low excess air combustion are lost if the excess air at the burner fluctuates even for short periods of time to a level of about 5%. Carbon loss values for low excess air were ap-

Fig. 31 Effect of low excess air combustion on high temperature oil ash corrosion.

proximately 0.5%, which is generally acceptable for electric utility and industrial practice.

A number of large industrial boilers both in the U.S. and in Europe have been operating with low excess air for several years. As a result, the benefits of reducing low temperature corrosion are well established. However, the benefits on high temperature slagging and corrosion are not wholly conclusive. In any event, great care must be exercised to distribute the air and fuel oil equally to the burners, and combustion conditions must be continuously monitored to assure that combustion of the fuel is complete before the combustion gases enter the convection tube banks.

Fig. 32 Effect of excess air on low temperature corrosion of carbon steel.

Two coal-fired boilers: one 685 MW pulverized coal unit and one 844 MW unit with Cyclone™ furnaces.

Chapter 22

Performance Calculations

The evaluation of boiler performance involves many complex factors as indicated in preceding chapters. Only a few of these factors are subject to precise analysis; many others are the result of data taken from operating units. Ash in the fuel has perhaps the most dramatic impact on boiler performance as discussed in Chapter 21. In spite of the large number of variables, boilers are designed, built and operated in conformance with design specifications.

A well-designed and operated boiler completes combustion within the furnace. Flue gas temperatures leaving the furnace can be predicted by the methods presented in Chapter 4. Beyond the furnace, heat transfer surface arrangements represent a balance of temperature difference, space, pressure drop and draft losses. The final selection of these surface arrangements represents a compromise on the designer's part in meeting performance requirements while controlling ash deposition, corrosion, and erosion.

This chapter introduces the basic principles of boiler performance calculations. It illustrates the use of heat transfer, thermodynamics and fluid mechanics to determine heat and material balances for given boiler heat transfer components through practical application. These principles, as well as fundamental relationships, experimental data, operational experience and designer knowledge, are being incorporated into advanced numerical computational models for boiler evaluation. As discussed in Chapter 6 and elsewhere in *Steam*, these models are becoming increasingly useful in the design of boilers.

For the fossil fuel-fired steam generators being considered, the hotter heat transfer medium consists of the products of combustion, or flue gases. The cooler me-

dium is superheated steam, steam-water mixtures at saturation, water or air depending upon the heat transfer component under consideration. Heat transfer surfaces can be categorized into one of four cases according to relative hot and cold medium flow direction and temperature as shown in Fig. 1. Typically, boiler banks or screens are Case I, superheaters and reheaters are either Case II or III, economizers are Case II or III, and air heaters are generally Case IV.

Performance calculations are typically used to establish one of three parameters: temperature, heat transfer surface area, or surface cleanliness. As in most thermal analysis problems, the evaluation of boiler performance is an iterative process. To evaluate flue gas and steam temperatures for a known boiler design arrangement, the surface area and surface cleanliness are normally known while the temperatures are assumed. The outlet temperature calculation updates subsequent iterations until convergence between assumed and calculated temperatures is achieved.

Heat transfer surface area or sizing can be determined for given fluid temperatures and surface cleanliness by assuming an initial surface arrangement and then confirming the desired thermal performance by calculation. High calculated outlet flue gas temperatures indicate the need for additional surface whereas low calculated outlet flue gas temperatures indicate the need to remove surface. Surface area is adjusted until calculated and specified temperatures converge.

Finally, for a given boiler configuration, measured temperatures can be used to assess surface cleanliness. An initially assumed cleanliness is used with the measured temperatures and known surface to verify the temperature data. The cleanliness factors are varied until temperature convergence is achieved.

When calculating the thermal performance of heat transfer equipment, initial temperatures are selected in part based upon past experience. These are used to establish the thermophysical properties, calculate mean temperature differences and solve the problem.

Note: To avoid the confusion of dual units, this chapter is provided in English units only. See Appendix 1 for SI conversion factors.

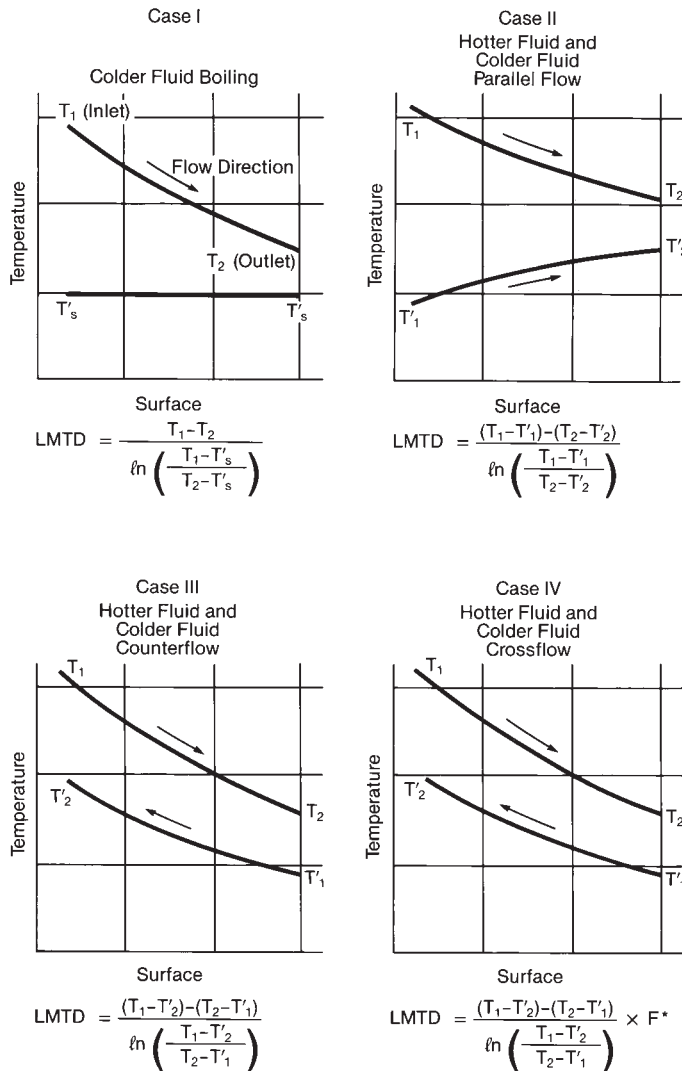

Fig. 1 Log mean temperature difference (LMTD) for selected heat exchanger configurations – single phase except for Case I colder fluid. (*As discussed in Chapter 4, a configuration factor F is needed for the case of crossflow.)

The resulting final temperatures are compared to the original assumptions. Generally, if an error of 5F or less is observed between iteration steps, the solution is considered complete. Otherwise, the new temperature is used to repeat the analysis.

To illustrate performance calculations, a small boiler (Fig. 2) with a simplified furnace and heating surface arrangement will serve as an example. The objective is to evaluate the outlet flue gas temperatures for the given surface area and cleanliness. The procedures developed here are fundamental and as such can be used on a wide range of boiler applications.

Operating conditions

Boiler performance specifications are defined by the customer. These specifications normally include: steam output conditions – pressure, temperature and flow; feedwater conditions; fuel and ash analysis; load range; capability; and efficiency. The final boiler design efficiently meets the specifications with a minimum of surface, materials and flow losses.

The specific analysis procedure is started at slightly different steps depending upon whether an existing piece of equipment is being analyzed or a new plant is being designed. For an existing installation, boiler performance calculations begin by confirming heat transfer equipment geometry and by defining the required operating conditions. Heat and material balances, including combustion calculations for the steam generator as a whole, are then determined. These calculations provide the information required to analyze each heat recovery component. The performance of each component is often intimately tied to other components within the boiler. As discussed in Chapter 1, the calculation process normally follows the direction of flue gas flow from furnace to stack and that is the approach used in the following example. Predictions of boiler performance are only complete when the performance of all devices within the boiler envelope agrees with the overall unit heat and material balances.

If a new plant is being analyzed, the process begins with the heat and material balances to establish air, fuel, feedwater and flue gas handling requirements. The process then continues with the iterative determination of heat transfer surface and equipment sizing as discussed above.

Because air resistance and draft loss calculations, including stack effects, are dependent on established air and gas temperature profiles through the boiler and accessories, they are determined after any thermal analysis. Pressure drop calculations are included in each component's evaluation. Flue and duct resistance calculations and the evaluation of stack effects are the final steps in the performance calculations.

For the example considered here, dimensional pa-

Fig. 2 Example of a coal-fired industrial boiler, sectional side view.

rameters are contained in Table 1, while Table 2 contains the specified operating conditions. The remainder of this chapter focuses on predicting performance for the hypothetical boiler.

Heat and material balances

Heat and material balances begin with combustion calculations. For this example, combustion calculations are determined by the *Btu method* as presented in Chapter 10. For the fuel analysis and losses specified in Table 2, the combustion calculations are summarized in Table 3.

The unit is expected to produce 250,000 lb/h superheated steam at 450 psig and 650F with feedwater conditions of 470 psig and 220F entering the economizer. The energy output, or heat in steam, is calculated to be 285.6×10^6 Btu/h (See Table 3, line 10).

The combustion calculations of Table 3 also define key parameters which guide much of the subsequent equipment design – heat input (328.6×10^6 Btu/h, Table 3, line 54), gas weight (324,100 lb/h, Table 3, line 56), air weight (302,500 lb/h, Table 3, line 58) and heat available (1034 Btu/lb Table 3, line 60). These values are noted for future reference.

This completes the heat and material balances and combustion calculations for the defined boiler envelope. As shown in Fig. 3, all pressures, temperatures and flows crossing the unit boundaries are established and calculations can now proceed on each component. A more detailed analysis would also account for items such as air infiltration, continuous boiler water dis-

charge (blowdown), saturated steam extractions and steam reheaters, if applicable.

Component performance calculations

Furnace

Furnace exit gas temperatures must be determined to design downstream heat transfer components. Through testing and correlation of gas temperature data, furnace exit gas temperature has been found to have a relationship to the heat input of the fuel and to the effectiveness of the furnace walls. In Chapter 4, furnace exit gas temperature curves for various fuels are approximated. This extended family of curves represents the accumulation of extensive field experience and analytical evaluation. They are dependent on fuel and furnace geometry.

The heat which can be absorbed by the furnace was determined from the combustion calculations to be 1034 Btu/lb of flue gas. The layout of the furnace (Table 1) provides a flat projected surface of 4100 ft². For 2.5 in. outside diameter (OD) furnace tubes on 3 in. centers, Chapter 4, Fig. 33 indicates an effectiveness factor of 1.0. The heat release rate to the furnace is then:

Heat release rate =

$$\frac{\text{Heat available} \times \text{Gas mass flow rate}}{\text{Flat projected area} \times \text{Effectiveness factor}} \quad (1)$$

$$= 81.7 \times 10^3 \text{ Btu/h ft}^2$$

Table 1
Physical Arrangement - Furnace

Construction: 2.5 in. outside diameter (OD) tubes on 3 in. centers with membrane construction. (See Chapter 23 for description.)

Notes:

1. The superheater is a counterflow configuration; however, the steam flows in two parallel paths from steam drum to superheater outlet header. This is also called a two-flow arrangement.
2. Boiler bank tubes vary in length; the value listed represents an average length.
3. Heating surface is the external surface area of the tubes exposed to the flue gas except for the air heater where the flue gas flows through rather than over the tubes.
4. Free flow area is the minimum clear area between tubes, perpendicular to the direction of gas or air flow except for air heaters. The gas side free flow area for air heaters is the area defined by the inside diameter (ID) of the air heater tubes.

Flat projected area	= 4100 ft ²
Effectiveness factor	= 1.0

Furnace exit gas temperature is 2000F from Chapter 4, Fig. 34. Sufficient information is now known to begin analysis of the convection pass, i.e., screen, superheater, boiler bank, economizer and air heater.

The performance of the convection pass, however, is a function of the cleanliness, or effectiveness, of the heat transfer surfaces. The values of the heat transfer coefficient, as described in Chapter 4, apply to heat transfer surfaces free from ash and slag deposits. For calculation purposes, the effect of ash or other deposits on the heat transfer surfaces can be accounted for with a cleanliness factor:

$$\text{Cleanliness factor} = \frac{\text{Actual heat transfer rate}}{\text{Clean surface heat transfer rate}} \quad (2)$$

where gas side heat transfer coefficients are multiplied by the cleanliness factor to reproduce a given fuel's fouling characteristics. Unless specifically noted, the

calculations that follow account for bituminous coal ash deposition and cleanliness factors have been omitted for simplicity. If the calculation procedures developed here are used with other dirty fuels, then commensurate cleanliness factors are required to accurately predict thermal performance.

Screen

Heat transfer

In this boiler design, the gases leaving the furnace first pass across the screen tubes. In this case, the tubes contain boiling water. These tubes control the amount of furnace radiation reaching the superheater surface. The heat transfer relationship for this surface is as follows:

$$q = U A (LMTD) = \dot{m}_g c_p \Delta T_g = \dot{m}_g c_p (T_1 - T_2) \quad (3)$$

where

q	= heat transfer rate, Btu/h
U	= h_g = combined heat transfer coefficient or overall heat transfer coefficient, Btu/h ft ² F where the boiling water film and tube wall resistances are assumed negligible
h_g	= $h_{rg} + h_{cg}$ = overall gas side heat transfer coefficient, Btu/h ft ² F
h_{rg}	= radiation heat transfer coefficient (gas side), Btu/h ft ² F
h_{cg}	= convection heat transfer coefficient (gas side), Btu/h ft ² F
A	= total surface area, ft ²
$LMTD$	= log mean temperature difference, gas and saturated water (T'_s), F
\dot{m}_g	= gas mass flow rate, lb/h
c_p	= mean specific heat of gas, Btu/lb F
ΔT_g	= $T_1 - T_2$
T_1	= gas temperature entering tube bank, F
T_2	= gas temperature leaving tube bank, F
T'_s	= saturation temperature of boiler water, F

Using the nomenclature listed above, the log mean temperature difference for Case I of Fig. 1 is defined by:

$$LMTD = \frac{(T_1 - T_2)}{\ln \frac{T_1 - T'_s}{T_2 - T'_s}} \quad (4)$$

Heat is transferred to the screen by direct furnace radiation, intertube radiation and convection. Furnace radiation to the screen is considered first. Radiation from the furnace to the screen is calculated from relationships developed in Chapter 4 using an effectiveness of 0.3 which approximates flue gas and screen surface emissivities. The temperature differential ($T_1^4 - T_2^4$) is defined by the furnace exit gas temperature and the screen tube temperature. Due to the large difference between gas and screen tube temperatures and the exponents in the formulation, it is sufficiently accurate to assume that the screen tube temperature is equal to the saturation temperature.

Fig. 3 Example of boiler fuel, air, gas, water and steam flow streams.

$$q'' = \sigma F_e (T_1^4 - T_2^4) = 18,420 \text{ Btu/h ft}^2 \quad (5)$$

where

$$\begin{aligned} q'' &= \text{heat flux, Btu/h ft}^2 \\ \sigma &= \text{Stefan-Boltzmann constant} \\ &= 1.71 \times 10^{-9} \text{ Btu/h ft}^2 \text{ R}^4 \\ F_e &= \text{effectiveness factor} = 0.3 \\ T_1 &= \text{furnace exit gas temperature} \\ &= 2000\text{F} = 2460\text{R} \\ T_2 &= \text{saturation temperature} \\ &= 462\text{F} = 922\text{R} \end{aligned}$$

The entrance to the screen is 18 ft high and 12 ft wide for a flat projected area of 216 ft². The heat transferred to the screen by furnace radiation is 216 ft² × 18,420 Btu/h ft² or 3.98 × 10⁶ Btu/h.

Based on the configuration of the screen (two rows deep on 6 in. side- and back-spacing), some of the radiant heat is absorbed by the screen and the remainder is absorbed by the superheater. From Chapter 4, Fig. 33, Curve 1, an effectiveness factor of 0.55 (i.e., 55% of the radiant energy entering any row is absorbed) is used to determine radiant screen absorption. On a row by row basis, the radiation from the furnace is distributed as follows:

Furnace radiation to first screen row:	3.98 × 10 ⁶ Btu/h
First screen row absorption:	0.55 × 3.98 × 10 ⁶ Btu/h = 2.19 × 10 ⁶ Btu/h
Furnace radiation to second screen row:	1.79 × 10 ⁶ Btu/h

Second screen row absorption:

$$0.55 \times 1.79 \times 10^6 \text{ Btu/h} = 0.99 \times 10^6 \text{ Btu/h}$$

Furnace radiation to superheater:

$$0.81 \times 10^6 \text{ Btu/h}$$

Furnace radiation does not affect the flue gas temperature drop across the screen; however, the furnace radiation absorbed by the screen is taken into account when determining screen steam generation rate. Furnace radiation passing through the screen will be absorbed by the superheater. The evaluation of furnace radiation on superheater performance will be addressed in the superheater section.

The heat transfer to the screen tubes is by convection and intertube radiation, and is calculated from the formulas provided below. Calculations start by assuming a gas temperature leaving the screen. This assumption is verified later. In this case, 1920F is assumed. Log mean temperature difference:

$$LMTD = \frac{(T_1 - T_2)}{\ln \frac{T_1 - T'_s}{T_2 - T'_s}} = 1498\text{F} \quad (6)$$

where

$$\begin{aligned} T_1 &= \text{furnace exit gas temperature} = 2000\text{F} \\ T_2 &= \text{gas temperature leaving screen} = 1920\text{F} \\ T'_s &= \text{saturation temperature} = 462\text{F} \end{aligned}$$

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 2498 \text{ lb/h ft}^2 \quad (7)$$

where

$$\begin{aligned} \dot{m}_g &= \text{gas mass flow rate} = 324,100 \text{ lb/h} \quad \text{Table 3} \\ A_g &= \text{minimum gas free flow area} \quad \text{Table 1} \\ &= 130 \text{ ft}^2 \end{aligned}$$

Gas film temperature:

$$T_f = T'_s + (LMTD/2) = 1211\text{F} \quad (8)$$

where

$$\begin{aligned} T'_s &= 462\text{F} \\ LMTD &= 1498\text{F} \end{aligned}$$

Gas Reynolds number:

$$Re = K_{Re} G_g = 5745 \quad (9)$$

where

$$\begin{aligned} K_{Re} &= \text{gas properties factor} = 2.3 \text{ h ft}^2/\text{lb} \quad \text{Fig. 4} \\ G_g &= 2498 \text{ lb/h ft}^2 \end{aligned}$$

Gas film convection heat transfer coefficient from Chapter 4, Equation 61:

$$h_{cg} = h'_c F_{pp} F_a F_d = 7.53 \text{ Btu/h ft}^2 \text{ F} \quad (10)$$

where

$$\begin{aligned} h'_c &= \text{basic convection crossflow} \quad \text{Ch. 4, Fig. 18} \\ &\quad \text{geometry and velocity factor} \\ &= 69.9 \text{ Btu/h ft}^2 \text{ F} \end{aligned}$$

Fig. 4 Determination of Reynolds number, Re.

- F_{pp} = physical properties factor Ch. 4, Fig. 19
 $= 0.133$
 F_a = arrangement factor = 0.81 Ch. 4, Fig. 22
 F_d = heat transfer depth factor Ch. 4, Fig. 23
 $= 1.0$

In this calculation, F_d is 1.0 because the furnace flue gases turn prior to entering the screen.

The total radiation absorption in the screen is comprised of direct furnace radiation and intertube radiation. Direct furnace radiation affects screen steam generation rate, but does not affect the gas temperature leaving the screen. The intertube radiation, however, is a direct function of flue gas temperature leaving the bank. Also, direct furnace radiation is proportional to the planar area it crosses while intertube radiation is proportional to the total bank heating surface.

To determine intertube radiation, the radiation heat transfer coefficient must be adjusted to eliminate direct furnace radiation through the use of an effectiveness factor based on areas.

$$F_s = \frac{\text{Effective surface}}{\text{Total surface}} = \frac{A - A_p}{A} = 0.681 \quad (11)$$

where

- A = total bank heating surface = 542 ft² Table 1
 A_p = planar area of the bank credited with radiation absorption. In this example, 80% of the direct furnace radiation was absorbed by the screen.
 $= 0.8 \times 12 \times 18 = 172.8 \text{ ft}^2$

Because this calculation subtracts the effect of direct furnace radiation, it will be added back in when the total screen absorption is finally determined.

Gas side radiation heat transfer coefficient adjusting for effective surface:

$$h_{rg} = h'_r K F_s = 2.35 \text{ Btu/h ft}^2 \text{ F} \quad (12)$$

where

- $h'_r = 8.2 \text{ Btu/h ft}^2 \text{ F}$ Fig. 5
 p_r = partial pressure = 0.19 atm Fig. 6
 L = mean radiating length = 1.42 ft Fig. 7
 K = fuel factor = 0.42 Fig. 8
 $F_s = 0.681$

Combined heat transfer coefficient:

$$h_g = h_{cg} + h_{rg} = 9.88 \text{ Btu/h ft}^2 \text{ F} \quad (13)$$

where

- $h_{cg} = 7.53 \text{ Btu/h ft}^2 \text{ F}$
 $h_{rg} = 2.35 \text{ Btu/h ft}^2 \text{ F}$

Overall heat transfer rate:

$$q = U A (LMTD) = 8.02 \times 10^6 \text{ Btu/h} \quad (14)$$

where

- $U = h_g = 9.88 \text{ Btu/h ft}^2 \text{ F}$
 $A = 542 \text{ ft}^2$
 $LMTD = 1498\text{F}$

To verify the flue gas exit temperature assumption of $T_2 = 1920\text{F}$ for the screen tubes, the gas temperature leaving the screen can be calculated by an en-

Fig. 5 Basic radiation heat transfer coefficient, h'_r , for Equations 12, 32, and 44.

Fig. 6 Partial pressure, p_r , of principal radiating constituents ($\text{CO}_2 + \text{H}_2\text{O}$) of combustion gases in atmosphere for various fuels, heat values and excess air.

ergy balance between the energy absorbed by the screen tubes (excluding furnace radiation) and the energy lost by the flue gas.

$$T_2 = T_1 - q / \dot{m}_g c_p = 1920\text{F} \quad (15)$$

where

$$\begin{aligned} T_1 &= 2000\text{F} \\ q &= 8.02 \times 10^6 \text{ Btu/h} \\ \dot{m}_g &= 324,100 \text{ lb/h} \\ c_p &= 0.31 \text{ Btu/lb F} \end{aligned} \quad \begin{array}{l} \text{Eq. 3} \\ \text{Fig. 9} \end{array}$$

Solving the heat balance for T_2 indicates agreement with the earlier assumption of 1920F, and no recalculation is required. Otherwise, T_2 from Equation 15 would be used in Equation 6 and the calculation repeated.

To complete the screen heat transfer analysis, the total screen absorption is determined. Screen absorption is the sum of the convection and intertube radiation heat transfer rates ($8.02 \times 10^6 \text{ Btu/h}$) and direct furnace radiation rate ($3.18 \times 10^6 \text{ Btu/h}$) for a total

screen absorption of $11.20 \times 10^6 \text{ Btu/h}$.

Draft loss

Screen gas side draft loss is calculated from Chapter 3, Equations 52 and 56:

$$\begin{aligned} \Delta P &= (f N F_d) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G}{10^3} \right)^2 \\ &= 0.04 \text{ in. wg} \end{aligned} \quad (16)$$

where

$$\begin{aligned} f &= \text{friction factor} = 0.23 && \text{Ch. 3, Fig. 15} \\ N &= \text{number of tube rows} = 2 && \text{Table 1} \\ F_d &= \text{tube bundle correction factor} \\ &= 1.12 && \text{Ch. 3, Fig. 14} \\ B &= \text{barometric pressure} \\ &= 30 \text{ in. Hg} && \text{Table 2} \\ T &= 0.95 (T_1 + T_2)/2 = 1862\text{F} && (\text{Note 1 below}) \\ G &= 2498 \text{ lb/h ft}^2 && \text{Eq. 7} \end{aligned}$$

Pressure drop

The screen tubes are part of the furnace circuitry and tube side pressure drop calculations for this surface are included in a circulation analysis. Refer to Chapter 5 for circulation information.

Superheater

Heat transfer

The next component in the direction of flue gas flow is the superheater. Saturated steam from the steam drum is heated to the outlet conditions shown in Table 2.

Fig. 7 Mean radiating length, L , for various tube diameters and arrangements or pitches – in-line tubes.

Note 1: Under most conditions, this equation is a good approximation of effective flue gas temperature.

The governing heat transfer equations for superheater surfaces are:

$$q = U A (LMTD) \quad (17)$$

$$LMTD = \frac{(T_1 - T'_2) - (T_2 - T'_1)}{\ln \frac{(T_1 - T'_2)}{(T_2 - T'_1)}} \quad (18)$$

Fig. 1, Case III

$$q = \dot{m}_g c_p \Delta T_g = \dot{m}_g c_p (T_1 - T_2) \quad (19)$$

$$q = \dot{m}_s \Delta H \quad (20)$$

where

- q = heat transfer rate, Btu/h
- U = $(h_g h_s)/(h_g + h_s)$ = combined heat transfer coefficient, Btu/h ft² F (assuming negligible wall resistance)
- h_g = $h_{rg} + h_{cg}$ = overall gas side heat transfer coefficient, Btu/h ft² F
- h_{rg} = radiation heat transfer coefficient (gas side), Btu/h ft² F
- h_{cg} = convection heat transfer coefficient (gas side), Btu/h ft² F
- h_s = convection heat transfer coefficient (steam side), Btu/h ft² F
- A = total surface area, ft²
- $LMTD$ = counterflow log mean temperature difference, gas and steam, F
- T_1 = gas temperature entering superheater, F
- T_2 = gas temperature leaving superheater, F
- T'_1 = steam temperature entering superheater, F
- T'_2 = steam temperature leaving superheater, F
- \dot{m}_g = mass flow of gas, lb/h
- c_p = mean specific heat of gas, Btu/lb F
- ΔT_g = $T_1 - T_2$, gas temperature differential, F
- \dot{m}_s = mass flow of steam, lb/h
- ΔH = steam enthalpy difference, Btu/lb

Superheater steam side design conditions are:

Outlet:

$$T'_2 = 650\text{F}, P'_2 = 450 \text{ psig}, H'_2 = 1331 \text{ Btu/lb}$$

Fig. 8 Effect of fuel, partial pressure (H_2O and CO_2) and mean radiating length on radiation heat transfer coefficient.

Fig. 9 Approximate mean specific heat, c_p , of flue gas.

Inlet:

$$T'_1 = 462\text{F}, P'_1 = 460 \text{ psig}, H'_1 = 1205 \text{ Btu/lb}$$

$$\Delta H = 126 \text{ Btu/lb}$$

The outlet conditions are specified in Table 2 while the inlet conditions are assumed to be saturated steam at the drum pressure. Drum pressure is determined by superheater pressure drop and is assumed here based upon experience and verified later.

The heat transfer rate to the superheater is calculated as follows:

$$q = \dot{m}_s \Delta H = 31.50 \times 10^6 \text{ Btu/h} \quad (21)$$

where

$$\dot{m}_s = 250,000 \text{ lb/h}$$

Table 2

$$\Delta H = 126 \text{ Btu/lb}$$

Previous calculations determined that the superheater will receive 0.81×10^6 Btu/h furnace radiation. Therefore, the heat transferred by convection and intertube radiation is:

$$q_{ci} = q - q_r = 30.69 \times 10^6 \text{ Btu/h} \quad (22)$$

where

$$q = 31.50 \times 10^6 \text{ Btu/h}$$

$$q_r = 0.81 \times 10^6 \text{ Btu/h}$$

By rearranging Equation 19, the gas temperature leaving the superheater can be determined:

$$T_2 = T_1 - q_{ci} / (\dot{m}_g c_p) = 1608 \text{ F} \quad (23)$$

where

$$q_{ci} = 30.69 \times 10^6 \text{ Btu/h}$$

$$T_1 = \text{gas temperature entering superheater} \\ = \text{gas temperature leaving screen} = 1920\text{F}$$

$$\dot{m}_g = 324,100 \text{ lb/h}$$

$$c_p = 0.303 \text{ Btu/lb F}$$

Fig. 9

Superheater log mean temperature difference is:

$$LMTD = \frac{(T_1 - T'_2) - (T_2 - T'_1)}{\ln \frac{(T_1 - T'_2)}{(T_2 - T'_1)}} = 1207\text{F} \quad (24)$$

where

$$\begin{aligned} T_1 &= 1920\text{F} \\ T_2 &= 1608\text{F} \\ T'_1 &= 462\text{F} \\ T'_2 &= 650\text{F} \end{aligned}$$

The average gas side film temperature is approximated by (see Note 2 below):

$$T_f = (T'_1 + T'_2)/2 + LMTD/2 = 1160\text{F} \quad (25)$$

where

$$\begin{aligned} T'_1 &= 462\text{F} \\ T'_2 &= 650\text{F} \\ LMTD &= 1207\text{F} \end{aligned}$$

Superheater tube material and thickness are selected according to the American Society of Mechanical Engineers (ASME) Code and manufacturing capabilities which are discussed in Chapters 7 and 8. For this example, a 2.50 in. OD carbon steel seamless tube with 0.220 in. wall thickness has been selected. Thickness is set by tube bending limitations and is normally greater than that required by Code. Allowing for manufacturing tolerances (+15% for pressure tubing), the average inside diameter (ID) of the tube is calculated to be 1.99 in. The flow area corresponding to this diameter is 3.12 in.². The total steam flow area is 1.0 ft² (2 flow × 23 rows × 3.12 in.² × ft²/144 in.²).

Steam mass flux:

$$G_s = \dot{m}_s / A_s = 250,600 \text{ lb/h ft}^2 \quad (26)$$

where

$$\begin{aligned} \dot{m}_s &= 250,000 \text{ lb/h} \\ A_s &= 0.998 \text{ ft}^2 \end{aligned}$$

Steam Reynolds number:

$$\text{Re} = \frac{G_s D_e}{\mu} = 867,600 \quad (27)$$

where

$$\begin{aligned} D_e &= 1.99 \text{ in.} = 0.166 \text{ ft} \\ \mu &= \text{steam absolute viscosity} \\ &= 0.048 \text{ lb/h ft} \\ G_s &= 250,600 \text{ lb/h ft}^2 \end{aligned} \quad \text{Ch. 3, Fig. 5}$$

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 2498 \text{ lb/h ft}^2 \quad (28)$$

where

$$\begin{aligned} \dot{m}_g &= 324,100 \text{ lb/h} \\ A_g &= 130 \text{ ft}^2 \end{aligned}$$

Table 1

Gas side Reynolds number:

$$\text{Re} = K_{\text{Re}} G_g = 6495 \quad (29)$$

where

$$\begin{aligned} K_{\text{Re}} &= 2.6 \text{ h ft}^2/\text{lb} \\ G_g &= 2498 \text{ lb/h ft}^2 \end{aligned} \quad \text{Fig. 4}$$

Gas film convection heat transfer coefficient from Equation 61 in Chapter 4:

$$h_{cg} = h'_c F_{pp} F_a F_d = 5.91 \text{ Btu/h ft}^2 \text{ F} \quad (30)$$

where

$$\begin{aligned} h'_c &= 69.9 \text{ Btu/h ft}^2 \text{ F} & \text{Ch. 4, Fig. 18} \\ F_{pp} &= 0.133 & \text{Ch. 4, Fig. 19} \\ F_a &= 0.635 & \text{Ch. 4, Fig. 22} \\ F_d &= 1.0 & \text{Ch. 4, Fig. 23} \end{aligned}$$

To obtain the gas side radiation heat transfer coefficient (h_{rg}), a factor, F_s , must be included to account for the furnace radiation absorbed in the superheater. In the screen calculations, it was shown that 80% of the furnace radiation was absorbed in the screen while 20% passed through the screen and was absorbed by the superheater. Similar to the screen calculations, superheater intertube radiation will be determined by eliminating direct furnace radiation from the radiation heat transfer coefficient through the use of an effectiveness factor:

$$F_s = \frac{A - A_p}{A} = 0.986 \quad (31)$$

where

$$\begin{aligned} A &= 3169 \text{ ft}^2 \\ A_p &= 0.2 (12 \times 18) = 43.2 \text{ ft}^2 \end{aligned} \quad \text{Fig. 2}$$

Gas side radiation heat transfer coefficient:

$$h_{rg} = h'_r K F_s = 2.81 \text{ Btu/h ft}^2 \text{ F} \quad (32)$$

where

$$\begin{aligned} h'_r &= 9.5 \text{ Btu/h ft}^2 \text{ F} & \text{Fig. 5} \\ p_r &= 0.19 \text{ atm} & \text{Fig. 6} \\ L &= 0.85 \text{ ft} & \text{Fig. 7} \\ K &= 0.30 & \text{Fig. 8} \\ F_s &= 0.986 \end{aligned}$$

In a superheater, the resistance to heat transfer through the steam film inside the tubes can not be assumed to be negligible as was done with the screen. Steam film convection heat transfer coefficient from Chapter 4, Equation 58, corrected to the OD surface area:

$$h_s = h'_l F_{pp} F_T D_i / D_o = 148 \text{ Btu/h ft}^2 \text{ F} \quad (33)$$

Note 2: This approximation applies when one working fluid controls the overall heat transfer coefficient.

where

$$\begin{aligned} h'_l &= 687 \text{ Btu/h ft}^2 \text{ F} && \text{Ch. 4, Fig. 13} \\ F_{pp} &= 0.33 && \text{Ch. 4, Fig. 16} \\ F_T &= \text{temperature factor} = 0.82 && \text{Ch. 4, Fig. 17} \\ D_i &= 1.99 \text{ in.} \\ D_o &= 2.50 \text{ in.} \end{aligned}$$

Overall heat transfer coefficient:

$$\begin{aligned} U &= \frac{h_g h_s}{h_g + h_s} = \frac{(h_{rg} + h_{cg}) h_s}{h_{rg} + h_{cg} + h_s} \\ &= 8.23 \text{ Btu/h ft}^2 \text{ F} \end{aligned} \quad (34)$$

where

$$\begin{aligned} h_{rg} &= 2.81 \text{ Btu/h ft}^2 \text{ F} \\ h_{cg} &= 5.91 \text{ Btu/h ft}^2 \text{ F} \\ h_s &= 148 \text{ Btu/h ft}^2 \text{ F} \end{aligned}$$

Overall heat transfer rate:

$$q = U A (LMTD) = 31.48 \times 10^6 \text{ Btu/h} \quad (35)$$

where

$$\begin{aligned} U &= 8.23 \text{ Btu/h ft}^2 \text{ F} \\ A &= 3169 \text{ ft}^2 \\ LMTD &= 1207 \text{ F} \end{aligned} \quad \text{Table 1}$$

Because this agrees with 31.50×10^6 Btu/h from Equation 21, no iteration is required. If these heat transfer rate calculations do not agree, then the steam outlet temperature or the superheater surface must be re-estimated and the calculations repeated until agreement is achieved.

Draft loss

Superheater gas side draft loss is determined by combining Equations 52 and 56 in Chapter 3.

$$\begin{aligned} \Delta P &= (f N F_d) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G}{10^3} \right)^2 \\ &= 0.06 \text{ in. wg} \end{aligned} \quad (36)$$

where

$$\begin{aligned} f &= 0.06 && \text{Ch. 3, Fig. 15} \\ N &= 12 && \text{Table 1} \\ F_d &= 1.0 && \text{Ch. 3, Fig. 14} \\ B &= 30 \text{ in. Hg} \\ T &= 0.95 (T_1 + T_2)/2 = 1676 \text{ F} \\ G &= 2498 \text{ lb/h ft}^2 \end{aligned}$$

Steam pressure drop

Superheater steam side pressure drop is the sum of friction or straight-flow losses, entrance and exit losses, and bend losses. Equations 47 and 51 in Chapter 3 can be combined as follows:

$$\begin{aligned} \Delta P &= \Delta P_f + \Delta P_{e+e} + \Delta P_b \\ &= \left(\frac{fL}{D_i} + \frac{1.5}{12} + \frac{N_b}{12} \right) v \left(\frac{G}{10^5} \right)^2 = 8.24 \text{ psi} \end{aligned} \quad (37)$$

where

$$\begin{aligned} \Delta P_f &= \text{frictional pressure drop } (fL/D_i) \\ \Delta P_{e+e} &= \text{entrance } (1/12) \text{ and exit } (0.5/12) \\ &\quad \text{pressure drop} \\ \Delta P_b &= \text{bend loss } (N_b/12) \\ G &= \text{steam mass flux} \\ &= 250,600 \text{ lb/h ft}^2 \\ f &= 0.012 && \text{Ch. 3, Fig. 1} \\ L &= \text{length of one continuous} \\ &\quad \text{superheater tube from steam} \\ &\quad \text{drum to superheater outlet} \\ &\quad \text{header} = 130 \text{ ft} \\ D_i &= 1.99 \text{ in.} \\ v &= \text{average steam specific volume} \\ &= 1.15 \text{ ft}^3/\text{lb} \\ N_b &= \text{bend loss factor} = 2.8 \end{aligned}$$

The superheater is a two-flow design. Steam side pressure drop will be determined for the steam path with the highest bend loss factors which, in this example, is the path with three short radius 180 degree bends. A composite bend loss factor for this path is determined as follows:

$$\begin{aligned} N_b: \text{ Three 180 degree bends,} \\ &\quad R/D = 0.81, 3 \times 0.6 = 1.80 && \text{Ch. 3, Fig. 9} \\ \text{Two 180 degree bends,} \\ &\quad R/D = 2.44, 2 \times 0.28 = 0.56 && \text{Ch. 3, Fig. 9} \\ \text{Two 90 degree bends,} \\ &\quad R/D = 2.44, 2 \times 0.22 = 0.44 && \text{Ch. 3, Fig. 9} \\ \text{Composite } N_b &= 2.80 \end{aligned}$$

Drum pressure and saturation temperature can now be determined and verified. The steam drum pressure is equal to the outlet steam pressure plus the superheater pressure loss calculated above, plus the steam separation equipment loss. Note, the steam separation equipment loss is manufacturer specific.

Superheater outlet pressure	450 psig	Table 2
Superheater-to-terminal	+ 0 psi	(assumed)
pipe loss		
Superheater pressure drop	+ 8 psi	
Steam separation equipment	+ 2 psi	(assumed)
Drum pressure	460 psig	
Sat. temperature (at 460 psig)	462 F	

This saturation pressure is in agreement with that originally assumed.

Boiler bank

Heat transfer

The function of the boiler bank, like the screen tubes, is to boil water, and the governing heat transfer equations defined for the screen are also applicable. Heat is transferred by convection, intertube radiation, and radiation from the rear cavity. In this example there are no cavities in the screen or superheater; however, in many applications cavities exist to accommodate sootblowers. Whenever cavities surround a bank of tubes, whether front or rear, the impact of the cavities on heat transfer must be considered (see discussion on cavity heat transfer).

Calculations begin by assuming the gas temperature leaving the boiler bank to be 818F based upon prior experience. The log mean temperature difference is calculated from Fig. 1, Case I:

$$LMTD = \frac{(T_1 - T_2)}{\ln \frac{T_1 - T'_s}{T_2 - T'_s}} = 676F \quad (38)$$

where

$$\begin{aligned} T_1 &= \text{gas temperature entering the boiler bank} \\ &= \text{gas temperature leaving the superheater} \\ &= 1608F \\ T_2 &= \text{assumed bank exit temperature} = 818F \\ T'_s &= \text{saturation temperature} = 462F \end{aligned}$$

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 3813 \text{ lb/h ft}^2 \quad (39)$$

where

$$\begin{aligned} \dot{m}_g &= 324,100 \text{ lb/h} \\ A_g &= 85 \text{ ft}^2 \end{aligned} \quad \text{Table 1}$$

Gas film temperature:

$$T_f = T'_s + LMTD/2 = 800F \quad (40)$$

where

$$\begin{aligned} T'_s &= 462F \\ LMTD &= 676F \end{aligned}$$

Gas Reynolds number:

$$Re = K_{Re} G_g = 10,700 \quad (41)$$

where

$$\begin{aligned} K_{Re} &= 2.8 \text{ h ft}^2/\text{lb} \\ G_g &= 3813 \text{ lb/h ft}^2 \end{aligned} \quad \text{Fig. 4}$$

Gas film heat transfer coefficient:

$$h_{cg} = h'_c F_{pp} F_a F_d = 8.45 \text{ Btu/h ft}^2 \text{ F} \quad (42)$$

where

$$\begin{aligned} h'_c &= 90.7 \text{ Btu/h ft}^2 \text{ F} & \text{Ch. 4, Fig. 18} \\ F_{pp} &= 0.118 & \text{Ch. 4, Fig. 19} \\ F_a &= 0.79 & \text{Ch. 4, Fig. 22} \\ F_d &= 1.0 & \text{Ch. 4, Fig. 23} \end{aligned}$$

For the screen, it was determined that 80% of the direct furnace radiation is absorbed in a two-row bank. It can be shown that all rear cavity radiation is absorbed in the boiler bank because it is 28 rows deep. To calculate intertube radiation, an effectiveness factor must again be determined:

$$F_s = \frac{A - A_p}{A} = 0.98 \quad (43)$$

where

$$\begin{aligned} A &= 11,545 \text{ ft}^2 & \text{Table 1} \\ A_p \text{ at } 100\% &= 12 \times 18 = 216 \text{ ft}^2 & \text{Fig. 2} \end{aligned}$$

Gas side radiation heat transfer coefficient:

$$h_{rg} = h'_r K F_s = 0.83 \text{ Btu/h ft}^2 \text{ F} \quad (44)$$

where

$$\begin{aligned} h'_r &= 4.0 \text{ Btu/h ft}^2 \text{ F} & \text{Fig. 5} \\ p_r &= 0.19 & \text{Fig. 6} \\ L &= 0.47 \text{ ft} & \text{Fig. 7} \\ K &= 0.212 & \text{Fig. 8} \\ F_s &= 0.98 \end{aligned}$$

Combined heat transfer coefficient:

$$h_g = h_{cg} + h_{rg} = 9.29 \text{ Btu/h ft}^2 \text{ F} \quad (45)$$

where

$$\begin{aligned} h_{cg} &= 8.45 \text{ Btu/h ft}^2 \text{ F} \\ h_{rg} &= 0.83 \text{ Btu/h ft}^2 \text{ F} \end{aligned}$$

Overall heat transfer rate assuming negligible wall and boiling resistances:

$$q = U A (LMTD) = 72.4 \times 10^6 \text{ Btu/h} \quad (46)$$

where

$$\begin{aligned} U &= h_g = 9.29 \text{ Btu/h ft}^2 \text{ F} \\ A &= 11,545 \text{ ft}^2 \\ LMTD &= 676F \end{aligned} \quad \text{Table 1}$$

Checking the gas temperature leaving the boiler bank:

$$T_2 = T_1 - q / (\dot{m}_g c_p) = 818F \quad (47)$$

where

$$\begin{aligned} T_1 &= 1608F \\ q &= 72.4 \times 10^6 \text{ Btu/h} \\ \dot{m}_g &= 324,100 \text{ lb/h} \\ c_p &= 0.283 \text{ Btu/lb F} \end{aligned} \quad \text{Fig. 9}$$

This agrees with the original outlet temperature assumption and therefore no recalculation is required. Otherwise, T_2 would be used in Equation 38 and the calculations repeated.

Draft loss

The governing equation for the gas side draft loss in the boiler bank is:

$$\begin{aligned} \Delta P &= (f N F_d) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G}{10^3} \right)^2 \\ &= 1.03 \text{ in. wg} \end{aligned} \quad (48)$$

where

$$\begin{aligned} f &= 0.27 & \text{Ch. 3, Fig. 15} \\ N &= 28 & \text{Table 1} \\ F_d &= 1.0 & \text{Ch. 3, Fig. 14} \\ B &= 30 \text{ in. Hg} & \text{Table 2} \\ T &= 0.95 (T_1 + T_2)/2 = 1152F \\ G &= 3813 \text{ lb/h ft}^2 \end{aligned}$$

Pressure drop

As with the screen tubes, the boiler bank is integral to the furnace circuitry. Pressure loss to the steam-water flow is discussed in Chapter 5.

Cavity between boiler bank and economizer

Heat transfer

Heat is transferred from each cavity to the cooler banks which form its boundaries. Cavity radiation is most significant at higher gas temperatures. In this example, cavity radiation has little impact on the overall results, but is included to illustrate the procedure for evaluating other configurations.

Assume the gas temperature leaving the cavity, entering the economizer to be 815F and the water temperature leaving the economizer to be 280F. Both assumptions are verified later. Consider cavity radiation to the boiler bank first.

Log mean temperature difference is approximated by:

$$LMTD = (T_1 + T_2)/2 - T'_s = 355F \quad (49)$$

where

$$\begin{aligned} T_1 &= \text{gas temperature entering the cavity} \\ &= \text{gas temperature leaving the boiler bank} \\ &= 818F \\ T_2 &= 815F \text{ (assumed)} \\ T'_s &= \text{saturation temperature} = 462F \end{aligned}$$

By definition, mean radiating length:

$$L = 3.4 \frac{V_L}{A} = 7.1 \text{ ft} \quad (50)$$

where

$$\begin{aligned} V_L &= \text{volume of the cavity} \\ &= 12 \text{ ft} \times 18 \text{ ft} \times 10 \text{ ft} = 2160 \text{ ft}^3 \quad \text{Fig. 2} \\ A &= \text{area} = 2 (12 \times 18 + 12 \times 10 + 10 \times 18) \\ &= 1032 \text{ ft}^2 \quad \text{Fig. 2} \end{aligned}$$

Gas side radiation heat transfer coefficient:

$$h_{rg} = h'_r K = 2.28 \text{ Btu/h ft}^2 \text{ F} \quad (51)$$

where

$$\begin{aligned} h'_r &= 2.4 \text{ Btu/h ft}^2 \text{ F} \quad \text{Fig. 5} \\ p_r &= 0.19 \text{ atm} \quad \text{Fig. 6} \\ L &= 7.1 \text{ ft} \\ K &= 0.95 \quad \text{Fig. 8 (Extrapolated)} \end{aligned}$$

Because radiation is the only significant mode of heat transfer in the cavity, the overall heat transfer coefficient $U = h_{rg}$. The overall heat transfer rate to the boiler bank is then:

$$q = U A (LMTD) = 174,600 \text{ Btu/h} \quad (52)$$

where

$$\begin{aligned} U &= h_{rg} = 2.28 \text{ Btu/h ft}^2 \text{ F} \\ A &= 12 \times 18 = 216 \text{ ft}^2 \\ LMTD &= 355F \end{aligned} \quad \text{Fig. 2}$$

Radiation to the economizer follows the same logic.

$$LMTD = (T_1 + T_2)/2 - T'_2 = 535F \quad (53)$$

where

$$\begin{aligned} T_1 &= \text{gas temperature entering the cavity} \\ &= 818F \\ T_2 &= \text{gas temperature leaving the cavity} \\ &= 815F \\ T'_2 &= \text{assumed economizer water outlet temperature} \\ &= 282F \end{aligned}$$

$$h_{rg} = h'_r K = 1.90 \text{ Btu/h ft}^2 \text{ F} \quad (54)$$

where

$$\begin{aligned} h'_r &= 2.0 \text{ Btu/h ft}^2 \text{ F} \quad \text{Fig. 5} \\ p_r &= 0.19 \text{ atm} \quad \text{Fig. 6} \\ L &= 7.1 \text{ ft} \\ K &= 0.95 \quad \text{Fig. 8} \end{aligned}$$

$$q = U A (LMTD) = 121,900 \text{ Btu/h} \quad (55)$$

where

$$\begin{aligned} U &= h_{rg} = 1.90 \text{ Btu/h ft}^2 \text{ F} \\ A &= 12 \times 10 = 120 \text{ ft}^2 \\ LMTD &= 535F \end{aligned} \quad \text{Fig. 2}$$

Total heat transfer is the sum of the rates to the boiler bank and economizer, or 296,500 Btu/h. Check the gas temperature leaving the cavity:

$$T_2 = T_1 - q/(\dot{m}_g c_p) = 815F \quad (56)$$

where

$$\begin{aligned} T_1 &= 818F \\ q &= 296,500 \text{ Btu/h} \\ \dot{m}_g &= 324,100 \text{ lb/h} \\ c_p &= 0.27 \text{ Btu/lb F} \end{aligned} \quad \text{Fig. 9}$$

This is the same as the assumed value and further iteration is not needed. Otherwise, T_2 from Equation 56 would be used in Equation 49 and the calculations repeated. Verification of the economizer water outlet temperature is shown in the next section.

The total boiler bank absorption can now be determined. Absorption due to convection and intertube radiation is 72.4×10^6 Btu/h (Equation 46) while that from cavity radiation is 0.17×10^6 Btu/h (Equation 52) for a total boiler bank absorption of 72.6×10^6 Btu/h.

Economizer

The next component in the direction of flue gas flow is the economizer. The economizer heats the feedwater before it enters the steam drum.

Heat transfer

Economizer heat transfer follows the same formulations established for the superheater:

$$q = U A (LMTD) \quad (57)$$

$$q = \dot{m}_g c_p \Delta T_g = \dot{m}_g c_p (T_2 - T_1) \quad (58)$$

$$q = \dot{m} \Delta H \quad (59)$$

where the terms are generally defined after Equations 17 to 20 except the tube side fluid is water instead of steam.

Economizer outlet water temperature was previously assumed to be 282F. It was also established that 121,900 Btu/h is transferred from the cavity preceding the economizer. The total heat transfer rate to the economizer is calculated to be:

$$q = \dot{m} \Delta H = 15.70 \times 10^6 \text{ Btu/h} \quad (60)$$

where

\dot{m}	= 250,000 lb/h	Table 2
T'_2	= 282F	
H_2	= 252 Btu/lb	Ch. 2, Table 3
T'_1	= 220F	Table 2
H_1	= 189 Btu/lb	Table 2
ΔH	= $H_2 - H_1$ = 63.0 Btu/lb	

The heat transfer by convection and intertube radiation is:

$$q_{ci} = q - q_r = 15.58 \times 10^6 \text{ Btu/h} \quad (61)$$

where

$$q = \text{total heat transfer rate} = 15.70 \times 10^6 \text{ Btu/h}$$

$$q_r = \text{cavity radiation} = 121,900 \text{ Btu/h}$$

As can be seen from this result, cavity thermal radiation at low temperatures is not usually significant.

By rearranging Equation 58, the gas temperature leaving the economizer can be determined:

$$T_2 = T_1 - q_{ci} / (\dot{m}_g c_p) = 635\text{F} \quad (62)$$

where

q_{ci}	= 15.58×10^6 Btu/h	
\dot{m}_g	= 324,100 lb/h	Table 3
c_p	= 0.268 Btu/lb F	Fig. 9
T_1	= 815F	

From Fig. 1, Case III, for counterflow heat exchanger, the log mean temperature difference is:

$$LMTD = \frac{(T_1 - T'_2) - (T_2 - T'_1)}{\ln \frac{(T_1 - T'_2)}{(T_2 - T'_1)}} = 472\text{F} \quad (63)$$

where

$$T_1 = \text{economizer inlet gas temperature} = 815\text{F}$$

$$T_2 = \text{economizer outlet gas temperature} = 635\text{F}$$

$$T'_1 = \text{economizer water inlet temperature} = 220\text{F}$$

Table 2

$$T'_2 = \text{economizer water outlet temperature} = 282\text{F}$$

Average gas film temperature is approximated by (See previous Note 2):

$$T_f = (T'_1 + T'_2)/2 + LMTD/2 = 487\text{F} \quad (64)$$

where

$$T'_1 = 220\text{F}$$

$$T'_2 = 282\text{F}$$

$$LMTD = 472\text{F}$$

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 7780 \text{ lb/h ft}^2 \quad (65)$$

where

$$\dot{m}_g = 324,100 \text{ lb/h}$$

Table 3

$$A_g = 42 \text{ ft}^2$$

Table 1

Reynolds number:

$$\text{Re} = K_{\text{Re}} G_g = 23,300 \quad (66)$$

where

$$K_{\text{Re}} = 3.0 \text{ h ft}^2 / \text{lb}$$

Fig. 4

$$G_g = 7780 \text{ lb/h ft}^2$$

Gas film heat transfer coefficient:

$$h_{cg} = h'_c F_{pp} F_a F_d = 13.14 \text{ Btu/h ft}^2 \text{ F} \quad (67)$$

where

$$h'_c = 152.6 \text{ Btu/h ft}^2 \text{ F}$$

Ch. 4, Fig. 18

$$F_{pp} = 0.105$$

Ch. 4, Fig. 19

$$F_a = 0.82$$

Ch. 4, Fig. 22

$$F_d = 1.0$$

Ch. 4, Fig. 23

As for the preceding components, an effectiveness factor based on the total economizer surface area is determined:

$$F_s = \frac{A - A_p}{A} = 0.951 \quad (68)$$

where

$$A = 2456 \text{ ft}^2$$

Table 1

$$A_p \text{ at } 100\% = (12 \text{ ft}) (10 \text{ ft}) = 120 \text{ ft}^2$$

Fig. 2

Gas side radiation heat transfer coefficient:

$$h_{rg} = h'_r K F_s = 0.30 \text{ Btu/h ft}^2 \text{ F} \quad (69)$$

where

$$\begin{aligned} h'_r &= 1.6 \text{ Btu/h ft}^2 \text{ F} && \text{Fig. 5} \\ p_r &= 0.19 && \text{Fig. 6} \\ L &= 0.30 \text{ ft} && \text{Fig. 7} \\ K &= 0.20 && \text{Fig. 8} \\ F_s &= 0.951 \end{aligned}$$

The water film and tube wall resistances are negligible so the total heat transfer coefficient is:

$$U = h_g = h_{cg} + h_{rg} = 13.44 \text{ Btu/h ft}^2 \text{ F} \quad (70)$$

where

$$\begin{aligned} h_{cg} &= 13.14 \text{ Btu/h ft}^2 \text{ F} \\ h_{rg} &= 0.30 \text{ Btu/h ft}^2 \text{ F} \end{aligned}$$

Overall heat transfer rate:

$$q = U A (LMTD) = 15.57 \times 10^6 \text{ Btu/h} \quad (71)$$

where

$$\begin{aligned} U &= 13.44 \text{ Btu/h ft}^2 \text{ F} \\ A &= 2456 \text{ ft}^2 && \text{Table 1} \\ LMTD &= 472\text{F} \end{aligned}$$

After adding cavity radiation (121,900 Btu/h), the total heat transfer rate to the economizer is 15.69×10^6 Btu/h.

Verifying the water outlet temperature assumption, the outlet enthalpy is evaluated from:

$$H_2 = H_1 + q/\dot{m} = 252 \text{ Btu/lb or } T'_2 = 282\text{F} \quad (72)$$

where

$$\begin{aligned} q &= 15.69 \times 10^6 \text{ Btu/h} \\ \dot{m} &= 250,000 \text{ lb/h} \\ H_1 &= 189 \text{ Btu/lb} \end{aligned}$$

From steam tables at an enthalpy of 252 Btu/lb, the water temperature is verified to be 282F. Therefore, the total economizer absorption is 15.69×10^6 Btu/h.

Draft loss

Economizer gas side draft loss is calculated from Chapter 3, Equations 52 and 56.

$$\begin{aligned} \Delta P &= (f N F_d) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G}{10^3} \right)^2 \\ &= 1.57 \text{ in. wg} \end{aligned} \quad (73)$$

where

$$\begin{aligned} f &= 0.39 && \text{Ch. 3, Fig. 15} \\ N &= 10 && \text{Table 1} \\ F_d &= 1.0 && \text{Ch. 3, Fig. 14} \\ B &= 30 \text{ in. H}_2\text{O} \\ T_1 &= 815\text{F} \\ T_2 &= 635\text{F} \\ T &= 0.95 (T_1 + T_2)/2 = 689\text{F} \\ G &= 7780 \text{ lb/h ft}^2 \end{aligned}$$

Water side pressure drop

In this example, the economizer tubes are 2 in. OD with 0.148 in. wall thickness. Considering the manufacturing tolerance of plus 15% in the pressure tubing wall thickness, the tube inside diameter is 1.66 in. Water flow area is 2.16 in.²/tube and the total flow area is 0.706 ft² (2.16 in.²/tube \times 47 tubes \times 1.0 ft²/144 in.²). Water mass flux is:

$$G = \dot{m}/A = 354,100 \text{ lb/h ft}^2 \quad (74)$$

where

$$\begin{aligned} \dot{m} &= 250,000 \text{ lb/h} \\ A &= 0.706 \text{ ft}^2 \end{aligned}$$

Water side Reynolds number:

$$\text{Re} = \frac{GD_i}{\mu} = 98,000 \quad (75)$$

where

$$\begin{aligned} G &= 354,100 \text{ lb/h ft}^2 \\ D_i &= 1.66 \text{ in.} = 0.138 \text{ ft} \\ \mu &= 0.5 \text{ lb/h ft} && \text{Ch. 3, Fig. 3} \end{aligned}$$

Economizer pressure drop is the sum of friction losses, entrance and exit losses, and bend losses.

$$\Delta P = \left(\frac{fL}{D_i} + \frac{1.5}{12} + \frac{N_b}{12} \right) v \left(\frac{G}{10^5} \right)^2 = 0.36 \text{ psi} \quad (76)$$

where

$$\begin{aligned} f &= 0.018 && \text{Ch. 3, Fig. 1} \\ L &= 101 \text{ ft} \\ D_i &= 1.66 \text{ in.} \\ N_b &= \text{nine } 180 \text{ degree } 0.79 \text{ R/D bends} \\ &= 9 \times 0.61 = 5.49 && \text{Ch. 3, Fig. 9} \\ v &= \text{specific volume} = 0.017 \text{ ft}^3/\text{lb} && \text{Ch. 2, Table 3} \\ G &= 354,100 \text{ lb/h ft}^2 \end{aligned}$$

The total pressure drop (economizer inlet to the steam drum) must include the static head of water for that elevation difference (25 ft) plus fittings and friction losses. Assuming the feedwater pipe diameter is large and fitting losses are negligible ($\Delta P_{\text{piping}} = 0$), then the static head is calculated by:

$$\Delta P_{\text{static}} = \frac{\Delta Z}{144v} = 10.0 \text{ psi} \quad (77)$$

where

$$\begin{aligned} \Delta Z &= \text{elevation between drum center-} \\ &\quad \text{line and economizer inlet header} \\ &= 25 \text{ ft} \\ v &= 0.0173 \text{ ft}^3/\text{lb} && \text{Ch. 2, Table 3} \end{aligned}$$

Total pressure drop from economizer inlet to drum is:

$$\Delta P = \Delta P_{\text{economizer}} + \Delta P_{\text{static}} + \Delta P_{\text{piping}} = 10.4 \text{ psi} \quad (78)$$

where

$$\begin{aligned}\Delta P_{\text{economizer}} &= 0.36 \text{ psi} \\ \Delta P_{\text{static}} &= 10.0 \text{ psi} \\ \Delta P_{\text{piping}} &= 0 \text{ (assumed)}\end{aligned}$$

Air heater

Heat transfer

The air heater is the last heat transfer component before the stack. In the overall heat and material balances, the air heater exit gas temperature is assumed to be 390F. The air heater, when sized properly, will have sufficient surface to provide the required air temperature to the fuel equipment (burners, pulverizers, etc.) and lower the gas temperature to that assumed in the combustion calculations. For the air heater, the heat transfer rate is determined as follows:

$$q = \dot{m}_g c_p (T_1 - T_2) = 21.09 \times 10^6 \text{ Btu/h} \quad (79)$$

where

$$\begin{aligned}\dot{m}_g &= 324,100 \text{ lb/h} && \text{Table 3} \\ c_p &= 0.265 \text{ Btu/lb F} && \text{Fig. 9} \\ T_1 &= \text{gas temperature entering the air heater} \\ &= \text{gas temperature leaving the economizer} \\ &= 635\text{F} \\ T_2 &= \text{assumed air heater exit temperature} \\ &= 390\text{F}\end{aligned}$$

For the air side, the temperature rise is:

$$T'_2 = T'_1 + q / (\dot{m}_a c_p) = 366\text{F} \quad (80)$$

where

$$\begin{aligned}T'_1 &= 80\text{F} && \text{Table 2} \\ q &= 21.09 \times 10^6 \text{ Btu/h} \\ \dot{m}_a &= 302,500 \text{ lb/h} && \text{Table 3} \\ c_p &= 0.244 \text{ Btu/lb F} && \text{Fig. 10}\end{aligned}$$

The tubular air heater in this example is a crossflow design. The log mean temperature difference is determined from Fig. 1, Case IV. This requires not only the two inlet and two outlet temperatures, but also a crossflow correction factor, F :

$$LMTD = \frac{(T_1 - T'_2) - (T_2 - T'_1)}{\ln \frac{(T_1 - T'_2)}{(T_2 - T'_1)}} \times F = 260\text{F} \quad (81)$$

where

$$\begin{aligned}T_1 &= 635\text{F} \\ T_2 &= 390\text{F} \\ T'_1 &= 80\text{F} \\ T'_2 &= 366\text{F} \\ F &= \text{crossflow correction factor} \\ &= 0.90\end{aligned} \quad \text{Fig. 3} \quad \text{Ch. 4, Fig. 26}$$

In an air heater, gas and air film heat transfer coefficients are approximately equal. For this example,

film temperatures are approximated by the following calculations.

$$\text{Gas: } T_f = (T_1 + T_2) / 2 - LMTD / 4 = 448\text{F} \quad (82)$$

where

$$\begin{aligned}T_1 &= 635\text{F} \\ T_2 &= 390\text{F} \\ LMTD &= 260\text{F}\end{aligned}$$

$$\text{Air: } T_f = (T'_1 + T'_2) / 2 + LMTD / 4 = 288\text{F} \quad (83)$$

where

$$\begin{aligned}T'_1 &= 80\text{F} \\ T'_2 &= 366\text{F} \\ LMTD &= 260\text{F}\end{aligned}$$

The flue gas flows through 1363 tubes (29 rows of 47 tubes per row). The air heater tubes are electric resistance welded (ERW), 2.25 in. OD with a 0.083 in. wall thickness. Allowing for manufacturing tolerances (9% for nonpressure tubing), the average tube inside diameter is 2.07 in. Gas flow area is 3.36 in.²/tube for a total of 31.8 ft². The gas mass flux is:

$$G_g = \dot{m}_g / A_g = 10,185 \text{ lb/h ft}^2 \quad (84)$$

where

$$\begin{aligned}\dot{m}_g &= 324,100 \text{ lb/h} && \text{Table 3} \\ A_g &= 31.8 \text{ ft}^2\end{aligned}$$

Gas Reynolds number:

$$Re = K_{Re} G_g = 30,600 \quad (85)$$

where

$$\begin{aligned}K_{Re} &= 3.0 \text{ h ft}^2/\text{lb} && \text{Fig. 4} \\ G_g &= 10,185 \text{ lb/h ft}^2\end{aligned}$$

Gas film heat transfer coefficient is the sum of the convection heat transfer coefficient from the longitu-

Fig. 10 Mean specific heat, c_p , of air at one atmosphere.

dinal gas flow inside the air heater tubes and a small gaseous radiation component from within the tube. The gas convection heat transfer coefficient h_{cg} is calculated from Equation 58 in Chapter 4. However, recognize that these coefficients do not account for fouling. To properly account for the ash layer inside the tubes, the gas side heat transfer coefficients will be multiplied by a cleanliness factor in the overall heat transfer calculation, Equation 91.

$$h_{cg} = h'_l F_{pp} F_T D_i / D_o = 9.91 \text{ Btu/h ft}^2 \text{ F} \quad (86)$$

where

$$\begin{aligned} h'_l &= 52.6 \text{ Btu/h ft}^2 \text{ F} && \text{Ch. 4, Fig. 13} \\ F_{pp} &= 0.188 && \text{Ch. 4, Fig. 14} \\ F_T &= 1.09 && \text{Ch. 4, Fig. 17} \\ D_i &= 2.07 \text{ in.} \\ D_o &= 2.25 \text{ in.} && \text{Table 1} \end{aligned}$$

Gas side radiation heat transfer coefficient:

$$h_{rg} = h'_r K = 0.18 \text{ Btu/h ft}^2 \text{ F} \quad (87)$$

where

$$\begin{aligned} h'_r &= 1.0 \text{ Btu/h ft}^2 \text{ F} && \text{Fig. 5} \\ p_r &= 0.19 && \text{Fig. 6} \\ L &= 0.17 \text{ ft} && \text{Tube ID} \\ K &= 0.18 && \text{Fig. 8} \end{aligned}$$

From Table 1, the air side free flow area is 62 ft², hence the air mass flux is calculated to be:

$$G_a = \dot{m}_a / A_a = 4866 \text{ lb/h ft}^2 \quad (88)$$

where

$$\begin{aligned} \dot{m}_a &= 302,500 \text{ lb/h} \\ A_a &= 62 \text{ ft}^2 \end{aligned} \quad \text{Table 3}$$

Air Reynolds number:

$$\text{Re} = K_{\text{Re}} G_a = 17,000 \quad (89)$$

where

$$\begin{aligned} K_{\text{Re}} &= 3.5 \\ G_a &= 4866 \text{ lb/h ft}^2 \end{aligned} \quad \text{Fig. 4}$$

The crossflow convection heat transfer coefficient for air is obtained from Chapter 4, Equation 61.

$$h_{ca} = h'_c F_{pp} F_a F_d = 11.50 \text{ Btu/h ft}^2 \text{ F} \quad (90)$$

where

$$\begin{aligned} h'_c &= 109.4 \text{ Btu/h ft}^2 \text{ F} && \text{Ch. 4, Fig. 18} \\ F_{pp} &= 0.104 && \text{Ch. 4, Fig. 20} \\ F_a &= 1.01 && \text{Ch. 4, Fig. 21} \\ F_d &= 1.0 && \text{Ch. 4, Fig. 23} \end{aligned}$$

Assuming negligible wall resistance, the overall heat transfer coefficient is:

$$U = \frac{F_{FR} (h_{cg} + h_{rg}) h_{ca}}{F_{FR} (h_{cg} + h_{rg}) + h_{ca}} = 5.07 \text{ Btu/h ft}^2 \text{ F} \quad (91)$$

where

$$\begin{aligned} F_{FR} &= 0.90 \\ h_{cg} &= 9.91 \text{ Btu/h ft}^2 \text{ F} \\ h_{rg} &= 0.18 \text{ Btu/h ft}^2 \text{ F} \\ h_{ca} &= 11.50 \text{ Btu/h ft}^2 \text{ F} \end{aligned}$$

The cleanliness or fouling resistance factor, F_{FR} , is empirically derived from field test data; 0.9 is representative of bituminous coal. The total heat transfer rate for the air heater is:

$$q = U A (LMTD) = 20.69 \times 10^6 \text{ Btu/h} \quad (92)$$

where

$$\begin{aligned} U &= 5.07 \text{ Btu/h ft}^2 \text{ F} \\ A &= 15,656 \text{ ft}^2 \\ LMTD &= 260\text{F} \end{aligned} \quad \text{Table 1}$$

Air heater exit gas temperature is calculated to be:

$$T_2 = T_1 - q / (\dot{m}_g c_p) = 390\text{F} \quad (93)$$

where

$$\begin{aligned} T_1 &= 635\text{F} \\ q &= 20.69 \times 10^6 \text{ Btu/h} \\ \dot{m}_g &= 324,100 \text{ lb/h} \\ c_p &= 0.26 \text{ Btu/lb F} \end{aligned} \quad \text{Fig. 9}$$

which is in agreement with the temperature assumed. Otherwise, T_2 would be substituted into Equation 81 and the calculations repeated.

Draft loss (gas inside tubes)

Air heater draft loss is comprised of friction (ΔP_f) plus entrance and exit losses (ΔP_{e+e}). Modifying and combining Chapter 3, Equations 47 and 52 for average gas temperatures, draft loss can be expressed as follows:

$$\begin{aligned} \Delta P &= \Delta P_f + \Delta P_{e+e} = \left(12 \frac{fL}{D_i} + 1.5 \right) \left(\frac{30}{B} \right) \\ &\times \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_g}{10^3} \right)^2 = 2.35 \text{ in. wg} \end{aligned} \quad (94)$$

where

$$\begin{aligned} f &= 0.024 && \text{Ch. 3, Fig. 1} \\ L &= 19.5 \text{ ft} && \text{Table 1} \\ D_i &= 2.07 \text{ in.} \\ T_1 &= 635\text{F} \\ T_2 &= 390\text{F} \\ T &= (T_1 + 2T_2)/3 = 472\text{F} \text{ (Note 3 below)} \\ G_g &= 10,185 \text{ lb/h ft}^2 \\ B &= 30 \text{ in. Hg} \end{aligned}$$

Note 3: An approximation used for mean gas temperature.

Air resistance (air crossflow over tubes)

The draft loss due to air flow across the air heater tubes is calculated from Chapter 3, Equations 52 and 56.

$$\Delta P = (f N F_d) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_a}{10^3} \right)^2 \quad (95)$$

$$= 1.52 \text{ in. wg}$$

where

$$\begin{aligned} f &= 0.55 && \text{Ch. 3, Fig. 15} \\ N &= 29 && \text{Table 1} \\ F_d &= 1.0 && \text{Ch. 3, Fig. 14} \\ B &= 30 \text{ in. Hg} \\ T_1' &= 80\text{F} \\ T_2' &= 366\text{F} \\ T &= 1/0.95 (T_1 + T_2)/2 = 235\text{F (Note 4 below)} \\ G_a &= 4866 \text{ lb/h ft}^2 \end{aligned}$$

Boiler thermal performance summary

Fig. 11 summarizes thermal performance. This figure illustrates the relative component absorption and temperature profiles. The furnace and boiler bank absorb the most heat. The furnace, screen and boiler bank are utilizing the heat available to generate saturated steam. The superheater raises the steam temperature to the desired outlet condition. The economizer is controlling gas temperature. The air heater is providing hot air for combustion and together with the economizer, is minimizing the flue gas temperature to the stack, reducing the sensible heat loss and increasing overall boiler efficiency.

Flues, ducts and stack

Performance calculations are not yet complete. Component draft loss and air resistance calculations have been made, but air and gas side performance still requires the evaluation of flues, ducts and stack effects. Once these are established, the designer can evaluate forced draft and induced draft fan conditions.

Air side loss – forced draft fan outlet to furnace

Air resistance calculations for forced draft fan outlet to windbox inlet are considered first. Static pressure at the windbox for this example is set at 5 in. wg. Windbox pressure is normally a function of the burner or fuel equipment design and is specified to assure proper operation. Starting at the windbox and working toward the forced draft fan:

Air mass flux:

$$G_a = \dot{m}_a / A_a = 2520 \text{ lb/h ft}^2 \quad (96)$$

Note 4: Under most conditions, this equation is a good approximation for effective air temperature.

where

$$\begin{aligned} \dot{m}_a &= 302,500 \text{ lb/h} \\ A_a &= 10 \times 12 = 120 \text{ ft}^2 \end{aligned}$$

Table 3
Fig. 1

Reynolds number:

$$\text{Re} = \frac{G_a D_e}{\mu} = 4.4 \times 10^5 \quad (97)$$

where

$$\begin{aligned} G_a &= 2520 \text{ lb/h ft}^2 \\ D_e &= \text{hydraulic diameter} \\ &= 4 \times \text{area/perimeter} \\ &= 4 \times 120/44 = 10.9 \text{ ft} \\ \mu &= 0.062 \text{ lb/h ft} \end{aligned} \quad \text{Ch. 3, Fig. 4}$$

The air resistance from windbox inlet to air heater outlet is:

$$\Delta P = \left(\frac{fL}{D_e} + N \right) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_a}{10^3} \right)^2 \quad (98)$$

$$= 0.04 \text{ in. wg}$$

where

$$\begin{aligned} f &= 0.0134 && \text{Ch. 3, Fig. 1} \\ L &= 25 \text{ ft} \\ D_e &= 10.9 \text{ ft} \\ B &= 30 \text{ in. Hg} \\ T &= 366\text{F} \\ G_a &= 2520 \text{ lb/h ft}^2 \end{aligned}$$

Fig. 11 Example boiler thermal performance summary.

$$\begin{aligned} N &= N_{bend} + N_{expansion} = 1.41 \\ N_{bend} &= 1.32 && \text{Ch. 3, Fig. 10} \\ N_{expansion} &= 0.09 && \text{Ch. 3, Fig. 7} \end{aligned}$$

The frictional component of this equation (fL/D_e) is negligible. The draft loss from the air heater inlet to the forced draft fan transition outlet, neglecting friction, is:

$$\Delta P = N \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_a}{10^3} \right)^2 = 0.03 \text{ in. wg (99)}$$

where

$$\begin{aligned} N &= N_{contraction} + N_{bend} = 1.54 \\ N_{contraction} &= 0.22 && \text{Ch. 3, Fig. 6} \\ N_{bend} &= 1.32 && \text{Ch. 3, Fig. 10} \\ B &= 30 \text{ in. Hg} \\ T &= T' \text{ for the air heater} = 80\text{F} && \text{Table 2} \\ G_a &= 2520 \text{ lb/h ft}^2 \end{aligned}$$

The net static pressure at the forced draft (FD) fan outlet transition is then:

$$\begin{aligned} P_{total} &= P_{windbox} + \Delta P_{windbox \text{ to air heater}} + \Delta P_{air \text{ heater to FD fan}} \\ &\quad + \Delta P_{air \text{ heater}} = 6.59 \text{ in. wg} \end{aligned} \quad (100)$$

where

$$\begin{aligned} P_{windbox} &= 5.0 \text{ in. wg (set by burners)} \\ \Delta P_{windbox \text{ to air heater}} &= 0.04 \text{ in. wg} \\ \Delta P_{air \text{ heater to FD fan}} &= 0.03 \text{ in. wg} \\ \Delta P_{air \text{ heater}} &= 1.52 \text{ in. wg} \end{aligned}$$

Gas side loss – furnace to stack

The draft loss calculations begin at the furnace exit and work their way back to the induced draft fan. However, the net ID fan conditions must also include the draft loss for the downstream flues and the stack effect. The static pressure at the furnace exit in balanced draft boilers is controlled to be slightly negative; a value of -0.1 in. wg is used in this example.

Although it doesn't affect the ID fan size evaluation, there may be a need to determine the furnace pressure at the burner level. The calculation that follows is provided for information and illustrates stack effect. Stack effect for the furnace is determined from methods developed in Chapter 25 as follows:

$$\Delta P_{SE} = SE \times Z = -0.58 \text{ in. wg} \quad (101)$$

where

$$\begin{aligned} Z &= \text{centerline of furnace exit to} \\ &\quad \text{centerline of windbox} = -50 \text{ ft} && \text{Fig. 2} \\ SE &= \text{stack effect} \\ &= 0.0116 \text{ in. wg/ft} && \text{Ch. 25, Eq. 3} \\ &\quad \text{and Ch. 25, Table 3} \\ T_1 &= \text{adiabatic temperature} \\ &= 3560\text{F} && \text{Table 3} \\ T_2 &= \text{furnace exit gas temperature} = 2000\text{F} \end{aligned}$$

By controlling the furnace outlet to -0.1 in. wg, the net static pressure in the furnace at the burner elevation is approximately -0.68 in. wg.

From screen, superheater, and boiler bank component calculations, gas side draft losses were deter-

mined to be 0.04, 0.06 and 1.03 in. wg, respectively. The net static pressure at the boiler bank outlet is:

$$\begin{aligned} P_{\text{boiler outlet bank}} &= P_{\text{furnace}} - \Delta P_{\text{screen}} - \Delta P_{\text{superheater}} \\ &\quad - \Delta P_{\text{boiler bank}} = -1.23 \text{ in. wg} \end{aligned} \quad (102)$$

where

$$\begin{aligned} P_{\text{furnace}} &= -0.10 \text{ in. wg} \\ \Delta P_{\text{screen}} &= 0.04 \text{ in. wg} \\ \Delta P_{\text{superheater}} &= 0.06 \text{ in. wg} \\ \Delta P_{\text{boiler bank}} &= 1.03 \text{ in. wg} \end{aligned}$$

The calculations for the boiler bank outlet flue to the economizer inlet are handled the same as those for the air resistance calculations.

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 2700 \text{ lb/h ft}^2 \quad (103)$$

where

$$\begin{aligned} \dot{m}_g &= 324,100 \text{ lb/h} \\ A_g &= 120 \text{ ft}^2 && \text{Fig. 2} \end{aligned}$$

Reynolds number:

$$Re = \frac{G_g D_e}{\mu} = 368,000 \quad (104)$$

where

$$\begin{aligned} G_g &= 2700 \text{ lb/h ft}^2 \\ D_e &= \text{hydraulic diameter} \\ &= 4 \times \text{area/perimeter} \\ &= 4 \times 120/44 = 10.9 \text{ ft} \\ \mu &= 0.08 \text{ lb/h ft} && \text{Ch. 3, Fig. 4} \end{aligned}$$

Draft loss:

$$\begin{aligned} \Delta P &= \left(\frac{fL}{D_e} + N \right) \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_g}{10^3} \right)^2 \\ &= 0.07 \text{ in. wg} \end{aligned} \quad (105)$$

where

$$\begin{aligned} f &= 0.014 && \text{Ch. 3, Fig. 1} \\ L &= 15 \text{ ft} \\ D_e &= 10.9 \text{ ft} \\ N &= 1.35 && \text{Ch. 3, Fig. 10} \\ T &= 1/2 (818 + 815) = 817\text{F} \\ G_g &= 2700 \text{ lb/h ft}^2 \\ B &= 30 \text{ in. Hg} \end{aligned}$$

From the economizer component calculations, draft loss was calculated to be 1.57 in. wg. Stack effect from the boiler bank outlet to economizer outlet is:

$$\Delta P_{SE} = SE \times Z = 0.11 \text{ in. wg} \quad (106)$$

where

$$\begin{aligned} SE &= 0.0071 \text{ in. wg/ft} && \text{Ch. 25, Eq. 3} \\ &\quad \text{and Ch. 25, Table 3} \\ Z &= 15 \text{ ft} \end{aligned}$$

The net static pressure at the economizer outlet is then calculated:

$$P_{\text{economizer outlet}} = P_{\text{boiler bank outlet}} - \Delta P_{\text{boiler bank to economizer}} - \Delta P_{\text{economizer}} - \Delta P_{SE} = -2.98 \text{ in. wg} \quad (107)$$

where

$$\begin{aligned} P_{\text{boiler bank outlet}} &= -1.23 \text{ in. wg} \\ \Delta P_{\text{boiler bank to economizer}} &= 0.07 \text{ in. wg} \\ \Delta P_{\text{economizer}} &= 1.57 \text{ in. wg} \\ \Delta P_{SE} &= 0.11 \text{ in. wg} \end{aligned}$$

The flue gas resistance from the economizer outlet to the air heater is due to friction only. However (fL/D_e) for this flue run is small, hence the resistance is negligible. Air heater gas side draft loss was previously calculated to be 2.35 in. wg. Referring to Fig. 2, the flue cross-section from the air heater outlet to the induced fan inlet decreases from 120 ft² to 48 ft². Again, as discussed above, frictional losses are negligible.

The mass flux is:

$$G_g = \dot{m}_g / A_g = 6750 \text{ lb/h ft}^2 \quad (108)$$

where

$$\begin{aligned} \dot{m}_g &= 324,100 \text{ lb/h} && \text{Table 3} \\ A_g &= 6 \text{ ft} \times 8 \text{ ft} = 48 \text{ ft}^2 && \text{Fig. 2} \end{aligned}$$

Draft loss:

$$\Delta P = N \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_g}{10^3} \right)^2 = 0.07 \text{ in. wg} \quad (109)$$

where

$$\begin{aligned} N &= 0.30 && \text{Ch. 3, Fig. 6} \\ B &= 30 \text{ in. Hg} \\ T &= T_2 \text{ for the air heater} = 390\text{F} \\ G_g &= 6750 \text{ lb/h ft}^2 \end{aligned}$$

The stack effect from the economizer outlet to the induced draft (ID) fan inlet is determined to be:

$$\Delta P_{SE} = SE \times Z = 0.30 \text{ in. wg} \quad (110)$$

where

$$\begin{aligned} SE &= 0.0059 \text{ in. wg/ft} && \text{Ch. 25, Eq. 3} \\ Z &= 50 \text{ ft} && \text{Fig. 2} \end{aligned}$$

The net static pressure at the induced draft fan inlet is calculated:

$$P_{\text{ID fan inlet}} = P_{\text{economizer outlet}} - \Delta P_{\text{economizer to air heater}} - \Delta P_{\text{air heater}} - \Delta P_{\text{air heater to ID fan inlet}} - \Delta P_{SE} = -5.69 \text{ in. wg} \quad (111)$$

where

$$\begin{aligned} P_{\text{economizer outlet}} &= -2.98 \text{ in. wg} \\ \Delta P_{\text{economizer to air heater}} &= 0.0 \text{ in. wg} \\ \Delta P_{\text{air heater}} &= 2.35 \text{ in. wg} \\ \Delta P_{\text{air heater to ID fan inlet}} &= 0.07 \text{ in. wg} \\ \Delta P_{SE} &= 0.30 \text{ in. wg} \end{aligned}$$

A straight flue runs from the induced draft fan outlet to the stack breaching. Friction again is negligible; however, an expansion loss at the stack breaching is included:

$$\Delta P = N \left(\frac{30}{B} \right) \left(\frac{T + 460}{1.73 \times 10^5} \right) \left(\frac{G_g}{10^3} \right)^2 = 0.22 \text{ in. wg} \quad (112)$$

where

$$\begin{aligned} N &= 1.0 && \text{Ch. 3, Fig. 7} \\ B &= 30 \text{ in. Hg} \\ T &= 390\text{F} \\ G_g &= 6750 \text{ lb/h ft}^2 \end{aligned}$$

For the stack, two components must be determined: stack draft and stack resistance. For standard air with 0.013 lb wg/lb dry air ($v = 13.70 \text{ ft}^3/\text{lb}$ at 80F and 30 in. Hg) and a typical flue gas ($v_g = 13.23 \text{ ft}^3/\text{lb}$ at 80F and 30 in. Hg), Chapter 25, Equation 3 and the ideal gas law (Chapter 3, Equation 16a) can be combined to calculate the stack draft, ΔP_{SD} :

$$\begin{aligned} \Delta P_{SD} &= 7.84 Z (0.00179 - 1/T) (B/30) \\ &= 0.45 \text{ in. wg} \end{aligned} \quad (113)$$

where

$$\begin{aligned} D_i &= \text{stack diameter} = 8 \text{ ft} && \text{Fig. 2} \\ Z &= \text{stack height} = 100 \text{ ft} && \text{Fig. 2} \\ T_1 &= \text{stack inlet gas temperature} \\ &= 390\text{F} \\ T_2 &= \text{stack exit gas temperature} \\ &= 340\text{F} && \text{Ch. 25, Fig. 11} \\ T &= (390 + 340)/2 = 365\text{F} = 825\text{R} \\ B &= 30 \text{ in. Hg} \end{aligned}$$

The stack resistance is calculated from Chapter 25, Equation 7.

Gas mass flux:

$$G_g = \dot{m}_g / A_g = 6449 \text{ lb/h ft}^2 \quad (114)$$

where

$$\begin{aligned} \dot{m}_g &= 324,100 \text{ lb/h} \\ A_g &= \pi D_i^2 / 4 = 50.3 \text{ ft}^2 && \text{Table 3} \end{aligned}$$

Reynolds number:

$$Re = \frac{G_g D_i}{\mu} = 8.9 \times 10^5 \quad (115)$$

where

$$\begin{aligned} G_g &= 6449 \text{ lb/h ft}^2 \\ D_i &= 8 \text{ ft} \\ \mu &= 0.06 \text{ lb/h ft} && \text{Ch. 3, Fig. 4} \end{aligned}$$

Stack resistance:

$$\begin{aligned} \Delta P_{SR} &= \frac{2.76}{B} \frac{T}{D_i^4} \left(\frac{\dot{m}_g}{10^5} \right)^2 \left(\frac{fL}{D} + N_e \right) \\ &= 0.22 \text{ in. wg} \end{aligned} \quad (116)$$

where

$$\begin{aligned} B &= 30 \text{ in. wg} \\ T &= (390 + 340)/2 = 365\text{F} = 825\text{R} \\ D_i &= 8 \text{ ft} \\ \dot{m}_g &= 324,100 \text{ lb/h} \\ f &= 0.012 \\ L &= 100 \text{ ft} \\ N_e &= \text{stack exit loss} = 1.0 \end{aligned}$$

Table 3
Ch. 3, Fig. 1
Fig. 2

The net static pressure at the induced draft fan outlet is calculated:

$$\begin{aligned} P_{ID \text{ fan outlet}} &= \Delta P_{SD} - \Delta P_{ID \text{ fan outlet to breaching}} - \Delta P_{SR} \\ &= 0.01 \text{ in. wg} \end{aligned} \quad (117)$$

where

$$\begin{aligned} \Delta P_{SD} &= 0.45 \text{ in. wg} \\ \Delta P_{ID \text{ fan outlet to breaching}} &= 0.22 \text{ in. wg} \\ \Delta P_{SR} &= 0.22 \text{ in. wg} \end{aligned}$$

The net operating conditions for the fans are summarized in Table 4.

Fan purchasing specifications add test block factors to each net condition to accommodate deviations from design. See Chapter 25 for further discussion.

Table 4
Fan Operating Conditions

Net design conditions	Units	Fans	
		Forced draft	Induced draft
Flow	lb/h	302,500	324,100
Static pressure rise	in. wg	6.59	5.70
Inlet temperature	F	80	390

Summary

This chapter is intended to be an introduction. The approach is to give the reader a realistic yet basic overview of boiler performance calculations. Although there are many variables in these calculations, the designer must pay particular attention to fuel ash characteristics. Ash laden fuels will degrade heat transfer, increase draft loss and promote erosion. The principles presented in this chapter are sound but the impact of ash can dramatically change a given result. Whether analyzing existing equipment or sizing new, be sure to understand the slagging and fouling characteristics of the specified fuel. (See Chapter 21.)

Chapter 23

Boiler Enclosures, Casing and Insulation

Boiler setting

The term *boiler setting* originally applied to the brick walls enclosing the furnace and heat transfer surfaces of the boiler. Today, boiler setting comprises all the water-cooled walls, casing, insulation, outer covering and reinforcement steel that form the outside envelope of the boiler and furnace enclosure. The term *enclosure* may refer to either the entire setting or to a part of it.

As larger capacity steam generating units were demanded, boiler settings underwent a long evolution from uncooled brick surfaces to today's water-cooled walls. Water-cooled walls began as widely spaced tubes exposed to the furnace and covered with insulating block. These progressed to tangent tubes covered with refractory. They gradually evolved to the present day construction of membrane tubes.

Design requirements

The boiler settings must safely contain high temperature pressurized gases and air. Leakage, heat loss and maintenance must be reduced to acceptable values. The following factors must be considered in the setting design:

1. Enclosures must withstand the effects of temperatures up to 3500F (1927C).
2. The effects of ash and slag, or molten ash, must be considered because:
 - a. destructive chemical reactions between slag and metal or refractory can occur under certain conditions,
 - b. accumulation of ash on the waterwalls can significantly reduce heat absorption,
 - c. ash accumulations can fall causing injury to personnel or damage to the boiler, and
 - d. high velocity ash particles can erode the pressure parts and refractory.
3. Provisions must be made for the thermal expansion of the enclosure and for differential expansion of attached components.
4. The buckstay system must accommodate the effects of thermal expansion, temperature and pressure stresses, as well as wind and earthquake loading appropriate to the plant site.
5. The effect of explosions and implosions must be considered to lessen the risk of injury to personnel and damage to equipment.
6. Vibrations caused by combustion pulsations and the flow characteristics of flue gas and air must be limited to acceptable values.
7. Insulation of the enclosures should limit the heat loss to an economical minimum.
8. Neither the exterior surface temperature nor the ambient air temperature should cause discomfort or hazard to operating personnel.
9. Enclosures must be gas-tight to minimize leakage into or out of the setting.
10. Settings of outdoor and indoor units that require periodic washdown must be weatherproof.
11. Settings must be designed for economic fabrication, erection and service life.
12. Serviceability, including access for inspection and maintenance, is essential.
13. Good appearance, in conjunction with cost and maintenance requirements, is desirable.

Tube wall enclosures

In today's units, water- or steam-cooled tubes, or both, are used as the basic structure of the enclosure in high temperature areas of the setting. Important types of water-cooled enclosures are membrane tubes, membrane tubes with refractory lining, flat stud tubes and tangent tubes. The facing page illustrates present day construction for tube wall enclosures.

Membrane tubes

Fig. 1 illustrates a typical furnace wall with membrane construction. These walls are water-cooled and constructed of bare tubes joined by thin membrane bars. The walls are gas-tight and do not require an exterior casing to contain the products of combustion. Insulation is placed on the outside of the wall and sheet metal or lagging is installed over the insulation to protect it.

Membrane tubes with refractory lining

There are several locations in selected types of boilers that require refractory lining on the furnace side of the tubes to protect the tubes from either erosion or

Fig. 1 Membrane wall construction.

corrosion from the products of combustion. Some of the most common applications are:

1. Cyclone-fired units: lower furnace and cyclone burner walls. (See Chapter 15.)
2. Circulating fluidized-bed boilers: lower furnace. (See Chapter 17.)
3. Refuse boilers: lower furnace. (See Chapter 29.)
4. Pulverized coal-fired boilers: burner throats. (See Chapter 26.)

Cylindrical pin studs, welded on the hot side of the tubes at close intervals, hold the refractory in place (Fig. 2). Lining the wall with refractory can also increase furnace temperature by reducing heat absorption where this is desired. The increase in temperature helps to maintain the coal, peat, or lignite ash in a liquid state, thereby preventing large ash buildup and allowing better removal of slag. These issues are discussed in more depth in Chapter 21. However, because of maintenance problems it is usually desirable to avoid refractory where technically acceptable.

Flat stud tube walls

These walls consist of tubes with small, flat bar studs welded at the sides (Fig. 3). These walls are typically backed by one of two construction methods which are usually found in the convection pass enclosure.

In the current method, the flat studded tubes are backed with refractory covered with a welded inner casing that is insulated and covered with metal lagging for protection. The casing is supported from channel tie bars welded to the tubes at each buckstay row. The walls are reinforced with buckstays and the

Fig. 2 Fully studded membrane walls.

inner casing is reinforced with stiffeners. Stiffener spacing and size are set by the design pressure of the walls between buckstays. This system provides a better gas-tight enclosure than the former method.

In former practice, as shown in Fig. 4, the tubes are backed with refractory, followed by a dense insulation and an outer cold casing. The casing is supported from the buckstays with expansion folds at the attachments. These folds minimize stresses in the casing caused by differential expansions between the hot tube wall and cold casing. This method is now obsolete, but found on many old boilers that are still in service.

While the construction of the casings described in the preceding paragraphs applies to areas of horizontal buckstay reinforcement, some industrial boiler designs require a vertical casing that is welded vertically to a bar located between two tubes (Fig. 5).

Tangent tube walls

These walls are constructed of bare tubes placed next to each other with a typical gap of 0.03125 in. (0.7937 mm). The refractory backup, casing and insulation system design, similar to that described for flat stud tube walls, has also been used with tangent tube walls. These walls are typically found in the furnace area of older boiler designs (Fig. 4).

Flat stud and tangent tube wall upgrades

In recent years, two methods have been used to provide a better enclosure seal on units with either inner (hot) or outer (cold) casing as the gas seal. In one method, on boiler enclosure areas with tangent tubes, a round bar is seal welded between each tube for the full length (Fig. 6). In the other method, where boiler enclosure areas have widely spaced tubes with flat studs, a flat bar is seal welded between the tubes just behind the flat studs over the full length (Fig. 7).

These methods have been effective on many boilers, providing an improved gas seal with considerably less maintenance and longer life than the casing seal

Fig. 3 Flat stud tube wall construction with inner casing shown.

Fig. 4 Tangent tube wall construction with outer casing shown.

they replaced. Their biggest drawback is high installation costs because the entire boiler must be stripped of its existing casing and insulation, then a new insulation and lagging system must be installed.

Casing enclosures

The casing is the sheet or plate attached to pressure parts for supporting, insulating, or forming a gas-tight enclosure.

A boiler unit contains many cased enclosures that are not water-cooled. These enclosures must be designed to withstand relatively high temperatures while having external walls that minimize heat loss and protect operating personnel.

Casings are constructed of sheet or plate reinforced with stiffeners to withstand the design pressures and temperatures. When the casing is directly attached to the furnace walls, expansion elements are added to allow for differential thermal expansion of the tubes and casing. The frontispiece shows typical enclosures including the hopper casing, windbox, tempering gas plenum and penthouse casing.

Hopper

Hopper enclosures are used in various areas of the boiler setting that may include the economizer hopper, furnace hopper enclosure and the wash hopper for dry bottom units.

The enclosure provided by the hopper casing may also serve as a plenum for the recirculating gas which leaves the economizer hopper through ports and enters the furnace through openings between tubes in the furnace hopper.

Windbox

The windbox is a reinforced, metal-cased enclosure that attaches to the furnace wall, houses the burners, and distributes the combustion air. It may be located on one furnace wall, on two opposite furnace walls, or on all furnace walls using a wraparound configuration. The attachments to the furnace walls must be gas-tight and permit differential thermal expansion between the tubes and casing.

For large capacity boilers, the windbox may be compartmented and placed only on the front and rear furnace walls. The windboxes are compartmented (internally separated with horizontal division plates) for better combustion air control.

Tempering gas plenum

This enclosure, located above the windbox, provides for the distribution and injection of flue gas which is used to temper the furnace gases and control the ash fouling of heating surfaces. It is constructed similarly to the windbox, but is normally protected on the inside by a combination of refractory and stainless steel shields opposite the gas ports.

Penthouse

The penthouse casing forms the enclosure for all miscellaneous pressure parts located above the furnace and convection pass roofs. It is a series of reinforced flat plate panels welded together and to the top perimeter of the furnace pressure parts. Various seals are used at the penetrations through the penthouse walls, roof and roof tubes. Some examples are cylindrical bellows or flexible cans sealing the suspension hangers, large fold (pagoda) seals around the steam piping and refractory or casing seals around heating surface tube penetrations through the roof tubes. On many utility and some industrial boilers a gas-tight roof casing is used on top of the roof tubes as the pri-

Fig. 5 Casing attachment to membrane wall.

Fig. 6 Tangent tubes with closure rods.

Fig. 7 Widely spaced tubes with flat studs and closure bars.

mary gas seal (pressure boundary). Penthouses may or may not be designed as pressure-tight enclosures with seal air. It depends upon whether the boiler is a pressure fired or a balanced draft unit and whether the roof seals are seal welded gas-tight or are the refractory type.

Design considerations

Resistance to ash, slag and erosion

Ash has a tendency to shed from a water- or steam-cooled metal surface, particularly when its temperature is well below the ash softening point. Wall type sootblowers remove ash in high temperature areas where it tends to adhere to the walls. (See Chapter 24.)

Extensive areas of exposed refractory must be avoided because large accumulations of ash could fall into the furnace damaging equipment or causing injury to personnel. Also, crotches in the tube wall should be designed to prevent ash and slag accumulation.

Pressure part erosion is reduced to acceptable levels by limiting the gas velocity through the unit. However, local high velocities can still occur in areas where gas bypasses baffles or heating surfaces. These high velocity lanes are best eliminated by proper design, baffle installation and routine maintenance.

Some unit designs such as process recovery, refuse and circulating fluidized-bed boilers require large areas of refractory on tube surfaces. In these units, the refractory system is designed to eliminate the effects of corrosion or erosion, or both, on pressure parts while minimizing the reduction in heat absorption by pressure parts.

Expansion

With the inner cased unit, Fig. 3, temperature differentials can occur between the casing and the tubes during startup. Expansion of the wall in the horizontal direction is governed by the temperature of the channel tie bar. Because the casing and the channels are at the same temperature, they can be welded together. Vertical expansion differences are accommodated by flexing of the casing flanges at the top and bottom of each casing section.

With a bottom supported unit, such as the PFI integral furnace boiler (Fig. 8) which is designed for pressure firing, the structure is fixed at a point at one end of the lower drum. Clearances, seals and supports are designed for known expansions in all directions from the fixed point.

With a top supported unit (see frontispiece), the expansion occurs downward from one elevation. The horizontal expansion of a boiler in both the fore and aft as well as in the side to side direction is determined by the location and method in which the hot boiler is tied to cold building steel. Typically, a combination of link ties and bumper ties is used to attach the hot boiler walls, via the buckstay system, to cold building steel.

Flues and ducts, piping, ash tanks and burner lines must be designed with expansion joints or seals to accommodate movement. Flexible metal bellows, metallic box fold joints, or non-metallic belts are used in

Fig. 8 Bottom supported unit.

flues and ducts while metal hoses and sliding or toggled gasketed couplings are used in piping. Water seals are generally used between ash hoppers or slag tanks and the associated furnace. With large units, the expansion may be as great as 12 in. (305 mm) between adjacent parts yet the joints must remain pressure-tight.

Support

The support of boilers is discussed in Chapter 40. It is generally more economical to support the smaller units from the bottom and the larger units from the top. In either case, the boiler setting is formed by the waterwalls when these are available.

For bottom supported units, the enclosure is usually supported from a common foundation with the boiler as shown in Fig. 8. For top supported units, cased enclosures are supported from the pressure parts with the exception of the penthouse enclosure which is supported directly from the structural steel by the hanger rods.

Explosions

In the design of settings, the effect of possible explosions must be considered to minimize the possibilities of personnel injury and serious equipment damage. It is imperative that all types of boilers be designed to minimize the risk and effect of explosion. This requires that all new boilers and boilers undergoing major alterations be designed and evaluated so that they are in compliance with the National Fire Protection Association (NFPA) 85 Standard, Boiler Combustion Systems Hazards Code. On units with fluid or fluidized fuels, care must be taken to avoid puffs that can occur from improper fuel and air mixture during startup. (See Chapter 11.) A better understanding of the technical problems and the development of adequate design and operating codes have eliminated most explosions.

The enclosure is designed to withstand common puffs and large transient gas-side pressure excursions. A design can be provided that results in the failure of

studs, stud attachments and welds rather than failure of tube walls in the event of a major furnace explosion. This minimizes the risk of release of large quantities of high pressure steam. Unfortunately, this design may also result in extremely hot gases being directed at platforms and steel in areas that were not designed to accommodate high temperature gases.

Explosion doors were once used on small furnaces to relieve excessive internal furnace pressure. These doors are no longer used because the rapid internal pressure increase from a fuel explosion is not significantly relieved by opening one or more doors. Explosion doors may also be more of a hazard than a safety margin because, in the event of a puff, they may discharge hot gases that would otherwise be completely contained within the setting.

The forces from normal operating negative or positive furnace gas-side pressures and from transient negative or positive furnace gas-side pressures, as defined by NFPA 85, are contained by rectangular bars called tie bars and/or channel tie bars attached to wall tubes to form continuous bands around the setting. Cold beams (*buckstays*), which are attached to the tie bars with slip connections, accommodate the gas-side pressure loadings and limit the inward and outward deflection of the wall tubes.

Because the buckstays are outside of the insulation, special corner connections are required that allow the walls to expand (Fig. 9). Forces generated by furnace gas-side pressures concentrate at the corner connections. These connections must be tight during startup when the walls have not fully expanded and during the normal operating fully expanded position.

The vertical tubes that span between the buckstays act as a beam to resist the internal furnace pressure. The larger the tube diameter and the heavier the tube wall, the farther apart the buckstays may be spaced, provided that allowable wall tube vibration limits are not exceeded. Permissible deflections and/or combinations of the positive or negative pressure loadings with wind or seismic loadings determine the size of the buckstay beam.

Implosions

Implosions are usually caused by an extremely rapid decay of furnace pressure due to sudden loss of fuel supply or by the improper operation of dampers

Fig. 9 Tie bar and buckstay arrangement at corner of furnace.

on units with high static pressure induced draft fans. The risk of furnace implosions exists whenever a fan is located between the furnace and the stack. This risk exists even if the furnace is not normally being operated at a negative pressure since the rapid furnace temperature decay occurring on a Master Fuel Trip (MFT) results in the furnace being exposed to the maximum head capacity of the fan on a transient basis during the fuel trip. This risk is also increased where axial flow forced draft (FD) fans are used since they can go into stall on the negative transient, blocking air flow into the furnace which is needed to restore the furnace pressure. The rules for determining minimum continuous and transient design pressures for the furnace enclosures can be found in the NFPA 85 Standard. In addition, induced draft fan controls are specified in NFPA 85 to minimize possible operating or control errors and to reduce the degree of furnace draft excursion following a fuel trip.

Vibration

Excessive vibration can cause failures of the tubes, insulation, casing and supports. These vibrations can be produced by external rotating equipment, furnace pulsations from the uneven combustion of the fuel, or turbulence in the flowing streams of air or gas in flues, ducts and tube banks.

Tube walls, flues and ducts are designed to limit vibration during normal operating conditions. In regard to wall tube vibrations, buckstays are typically spaced to ensure that the natural frequency of the wall tubes is greater than or equal to 6 hertz. The moment of inertia of a buckstay must be chosen to ensure that the buckstay natural frequency is greater than or equal to 3 hertz, based on a simply loaded uniform beam. Flues, ducts and casings are similarly stiffened by bars or structural shapes to limit vibration. This stiffening is particularly necessary in sections of flues and ducts where the flow is highly turbulent, as in the fan discharge connecting piece. Every effort should be made to eliminate the sources of severe vibration, such as unbalanced rotating equipment, poor combustion and highly turbulent or unbalanced air or gas flow.

Heat loss

Heat loss from a boiler setting is reduced by insulation, usually as an integral part of the boiler enclosure. (See Figs. 1 through 4.) There is an economical balance between the value of the heat loss and the cost of the insulation and installation.

The insulation system is designed to provide both safety for personnel and minimal heat loss. In addition, indoor units require ventilation for both operator comfort and room air change.

The materials used most frequently for heat insulation are listed below.

Mineral wool

This material is comprised of molten slag, glass or rock, blown into fibers by steam or an air jet or spun by high speed wheels.

Mineral wool base block Mineral wool fibers and clay, molded under heat and pressure to form blocks, are used to insulate membrane tube walls and boiler casings up to temperatures of 850, 1200 or 1900F (454, 649 or 1038C) depending upon the grade.

Mineral wool blanket Mineral wool fibers, compressed into blanket form and held in shape between hexagonal wire mesh or expanded metal lath, are used on all types of enclosures with external metal lagging or casing and for piping inside cased enclosures. The temperature limit is normally 1200F (649C).

Calcium silicate block

Reacted hydrous calcium silicate block is used on enclosures and piping, generally below 1200F (649C).

High temperature plastic

Insulating cement made of mineral wool fibers processed into nodules and dry mixed with clay forms a tough, fibrous monolithic insulation in final dried condition. Drying shrinkage is as much as 40%, but there is a tendency to crack upon drying. This material is used principally on irregularly shaped valves and fittings and to fill gaps between block insulation. Insulating cement is available in grades useable up to 1900F (1038C).

Ceramic fiber

High purity ceramic fibers, with melting points above 3000F (1649C), are occasionally used for tube enclosure seals where resiliency or high temperature insulation is required.

Heat loss calculations

Calculations of the heat flow through a composite wall are discussed in Chapter 4. Thermal conductivities of a wide range of commercial refractory and insulating materials, at the temperatures for which they are suitable, are given in Fig. 10. Combined heat losses (radiation plus convection) per square foot (square meter) of outer wall surface are given in Fig. 11 for various ambient air velocities and surface air temperature differences. The American Boiler Manufacturers Association (ABMA) Radiation Loss Chart provides a quick approximation for radiation loss, expressed as a percentage of gross heat input (Fig. 12).

Ventilation, surface temperature, conditions

To maintain satisfactory working conditions for personnel around a boiler, a cold face temperature of 135F (57C) or less is considered satisfactory. Heat losses, corresponding to these surface temperatures, range from 90 to 130 Btu/h ft² (284 to 410.1 W/m²), which can be readily absorbed by the air circulation generally provided in present day boiler rooms.

Insulating a boiler to reduce heat loss to a value that can readily be absorbed by the total volume of room air does not in itself assure comfortable working conditions. Proper air circulation around all parts of the boiler is also necessary to prevent the accumulation of heat in the areas frequented by the operating

Fig. 10 Thermal conductivity of various refractory materials.

personnel. This can be helped by using grating rather than solid floors, by ample aisle space between adjacent boilers, by the location of fans to assist the circulation of air around the boiler and by installing ventilating equipment to assure adequate air exchange.

Good ventilation does not greatly increase overall heat loss. Air velocity affects the surface heat transfer coefficient. This can be verified by data from Fig. 11. However, surface conductance is only a small part of the total resistance to heat flow. For example, an increase in air velocity from 1 to 10 ft/s (0.3 to 3 m/s), for the conditions given in Fig. 13, will increase the heat loss rate through the wall by only 2%.

Unlike heat loss, outer surface temperature is considerably affected by the surrounding conditions. In the situation shown in Fig. 14, where two walls of similar temperatures are close together, the radiant heat transfer from either wall is negligible. The natural circulation of air through such a cavity is inadequate to cool the walls to a temperature suitable for personnel working in the vicinity. From Fig. 15 it can be seen that a considerable change in surface film resistance will cause an appreciable change in lagging or surface temperature while not affecting the heat loss through the wall to any extent.

Increased insulation thickness would not significantly reduce the surface temperature in the cavity shown in Fig. 14. Cavities should therefore be avoided in areas where operators work. Ventilating ducts to reduce the air temperature in such a cavity can be installed if necessary.

Fig. 11 Heat loss from wall surfaces (radiation + convection)
(Source – ASTM Standards, Part 13, 1969).

Leakage

Continuing efforts have been made over the years to reduce air infiltration into boiler settings. Such in-leakage increases gas flow and the heat rejected to the stack, thereby lowering boiler efficiency and increasing the amount of induced draft fan power. (See Chapter 10.)

Corrosion

One of the advantages of membrane walls compared to cased walls is that they eliminate flue gas corrosion on the cold face of the enclosure walls. Most flue gases contain sulfur; therefore, metal parts of the setting must either be kept above the dew point of the gases or out of contact with the gases. (See Chapter 21.) The dew point generally ranges between 150 and 250F (66 and 121C) and is dependent on the fuel, its sulfur content and the firing method.

Flues carrying low temperature spent gases should be insulated on the outside to inhibit corrosion. This is particularly necessary on outdoor units. Water-cooled doors and slag tap coils require water temperatures above 150F (66C) to keep the cooling coils above the dew point of the gases.

When casing is located outside of insulation or refractory, it is still subject to the action of the flue gases. When this type of casing is subjected to a temperature below the dew point, an asphalt mastic or other type of coating is needed to protect it from corrosion on the inside. This problem requires special attention in the design of outdoor installations where temperatures may, at times, be below flue gas dew point temperatures.

Fig. 12 Radiation loss in percent of gross heat input (American Boiler Manufacturers Association).

Fig. 13 Temperature gradients through tube and brick wall.

With the use of externally insulated casing, corrosion problems are greatly reduced because the flue gases are completely contained by a metal skin, which is well above the dew point temperature. However, even with the inner casing, seals and expansion joints must be insulated properly to avoid cold spots and consequent corrosion.

Fig. 14 Cavities tend to raise wall surface temperatures.

Fig. 15 Effect of surface film resistance on surface temperature and heat loss rate.

Resistance to weather

Outdoor boiler installations are possible in mild climates. While the initial cost of the plant is reduced, maintenance of the boiler and auxiliary equipment must be considered. Severe weather can extend outage time and increase maintenance expenses. These units must also have sufficient reinforcement to withstand the pressure and suction forces of the wind.

Lagging is an outer covering over a wall used for protecting the insulation from water or mechanical damage. It is relatively simple to make a metal lagged unit rainproof. Joints and flange connections are overlapped and flashings are used around openings. Welding of joints or the use of mastic compounds is necessary in areas which are difficult to seal.

Sloping roofs are required and are particularly important on aluminum lagging where pockets of water would eventually stain the surface. Direct contact between aluminum and steel must be avoided to prevent galvanic corrosion of the aluminum in the presence of moisture. Roof flashings should be designed so that water runoff does not wet the aluminum.

Weather hoods should be used to keep rain, snow and ice from contacting outdoor safety valves. Nozzle and valve necks must be insulated and protected with sheet metal or outer waterproof covering. Outdoor control lines containing air or flue gas, drain and sampling lines and intermittently operated steam and water lines should be insulated and protected by electric resistance heating tape. Steam pipe tracer lines may also be used in some cases. Dry air should be supplied for control lines and sootblowers. Steam and water lines outside the setting must be completely drainable.

Fabrication and assembly

The setting must be designed for economical fabrication and assembly. This requires integration of all shop and field methods and practices. Small units can be completely shop assembled. For larger units the trend has been toward shop subassembly of large components.

Shipping clearances usually limit the size of shop-assembled wall panels to 16 ft (4.9 m) in width or 105 ft (32 m) in length. These size criteria can not be used simultaneously. That is, as the panels are made longer, the maximum width will be less and as the width is increased the maximum length decreases. Shop assembly of components permits better quality control of the more complicated parts.

Casing enclosures, tube connections to headers, tie bars, doors and other attachments are normally of welded construction. New and improved materials and attachment methods reduce the manhour requirements for insulating boilers/auxiliary equipment and installing metal lagging.

Serviceability

Many setting details must be designed to simplify operation and maintenance. Working areas around the unit should have adequate lighting and comfortable temperatures. Clearances for servicing and removing parts should be provided. Access through the setting is necessary for inspection of boiler internals. Suitable platforms for access doors, sootblowers, instruments and controls are essential.

Inspection doors allow observation of combustion conditions and the cleanliness of heat absorbing surfaces. Figs. 16 and 17 illustrate inspection doors for balanced draft and pressurized settings. Safety is provided by two types of interlocks which assure that compressed air is properly aspirating the aperture before the door is opened. A feature of this door is that the aspirating jet does not restrict the comparatively wide view angle.

The tube bends that form openings must have the smallest possible radius. The length of the stud plate closures around the opening is minimized so that the plates can be adequately cooled by welded contact to the tubes, thereby preventing burn back and subsequent overheat of seals.

Appearance

The setting should present a good appearance and be designed so that it can be retained indefinitely with a minimum of housekeeping. The outer surface should be easy to clean. Equipment handling flue gas, coal, ash or oil should be designed to minimize leakage.

Light gauge metal lagging is generally used as an outer covering. This is particularly true for outdoor units where it is relatively simple to make the metal lagging water-tight. Many types of covering are found in older installations including plastic insulation, insulating cement, canvas and welded steel casing.

Figs. 1, 2 and 3 show metal lagging. Light gauge galvanized steel or clad aluminum sheets are commonly used. Galvanized steel is generally less expensive than aluminum, but for outdoor units it may be necessary to paint the galvanized steel after weathering, unless the climate is dry. The clad aluminum may be preferable because it only requires painting under more severe conditions.

Chapter 24

Boiler Cleaning and Ash Handling Systems

The combustion of virtually all fuels generates ash, or inert residuals of combustion. As discussed in Chapter 21, the ash can accumulate on surfaces exposed to the flue gas stream causing reduced performance, flow obstruction, accelerated corrosion and increased mechanical loadings. Specialized *boiler cleaning systems* are installed in boilers and environmental control systems to permit on-line deposit removal and control for optimized overall system operation. In addition, specialized *ash handling systems* are incorporated into the power plant designs to collect and remove the ash from the boiler and emissions control systems for safe and environmentally acceptable disposal.

Boiler cleaning systems

Steam generating plants are cleaned on-line by regularly removing ash deposits that accumulate on heat transfer surfaces. This maintains maximum thermal efficiency of the boiler (optimizes heat rate) and maintains flue gas temperatures within design conditions at key locations. This, in turn, supports the optimum operation of air pollution control equipment. On-line cleaning also prevents the blockage and plugging of gas passages in the boiler.

This chapter discusses the methods and types of equipment used for on-line cleaning (see Fig. 1). For this purpose, it is convenient to separate the discussion by regions of the boiler and downstream equipment, since these generally require different cleaning methods and devices.

The following terminology and definitions are useful to the discussions of regional cleaning.

Sootblower terminology

Cleaning medium

An effective method of on-line boiler cleaning is to direct a concentrated jet of cleaning medium against the soot or ash buildup. The cleaning medium may be saturated steam, superheated steam, compressed air or water. Combinations of water with other media, such as steam or air, have also proven effective but can cause boiler tube damage.

Superheated steam is the most widely used medium for several reasons. Boiler-generated steam avoids the cost and maintenance of a compressor. Because it is generally extracted from a high pressure steam outlet and its pressure reduced by regulating valves, steam provides flexibility in case more aggressive cleaning is required. Superheated steam is generally recommended over saturated steam to avoid condensation in the cleaning flow, which can accelerate boiler tube erosion or result in thermal cracking.

Compressed air is often used as the cleaning medium on larger boilers. The source may be high pressure 250 to 500 psig (1.7 to 3.4 MPa) reciprocating compressors or high flow rate centrifugal compressors discharging at pressures from 150 to 225 psig (1.03 to 1.55 MPa).

Water is used in the most aggressive cleaning situations, such as removing more tenacious slag from furnace walls, or cement-like deposits in air heater baskets.

Fig. 1 Long retractable IK sootblower used to remove ash deposits in utility boilers.

Peak impact pressure

Peak impact pressure (PIP) is the stagnation pressure measured directly along the centerline of the sootblower nozzle at distances downstream of the nozzle outlet. Peak impact pressure is maximized by designing the nozzle to achieve a highly concentrated jet at the greatest possible distance from the nozzle outlet. Because most sootblowers are operated with supersonic flow exiting the nozzles, ideal nozzle design involves the avoidance of shock waves at the nozzle outlet and minimum shear interaction with the flue gas environment.

Jet progression velocity

Jet progression velocity is the linear velocity at which the jet passes over a surface, directing a concentrated jet of cleaning medium. This is a function of the nozzle rotational speed and distance from the surface.

Cleaning radius and tube bank penetration

The cleaning radius refers to the distance to which a particular sootblower can clean a surface, when the path between the sootblower nozzle outlet and the surface is unobstructed. Although commonly used, this term is misleading because the area cleaned is not often circular. Tube bank penetration is the maximum effective cleaning distance when directed into a bank of tubes.

Wall box

A wall box attaches to the boiler side wall at the opening made for the cleaning device. The wall box provides structural support for the front end of long retractable sootblowers, or the entire weight of furnace wall blowers. The wall box provides an opening for the lance tube to pass into the boiler, and a sleeve and seal plate to minimize flue gas escape to the atmosphere when the lance is retracted from the boiler.

Lance tube

The lance tube is the tubular component of a retractable-type sootblower that travels into and out of the combustion zone and flue gas passages. The lance tube is fitted with nozzles at the tip and possibly along its length to accelerate and direct cleaning flow onto the surface to be cleaned.

Feed tube

The feed tube is the stationary tube that feeds cleaning medium to the moving lance tube or rotating element. The outer surface of the feed tube serves as a sealing surface for the packing assembly that slides and/or rotates with the lance tube.

Element

An element serves the same function as the lance tube, but remains inside the flue gas passage permanently.

Furnace cleaning

The furnace is a large unobstructed chamber where fuel and air are mixed and nearly all of the combustion occurs. The walls, slopes and floor tend to collect the non-combustible fuel components. In most power boilers (particularly pulverized coal-fired units), effi-

cient heat transfer is necessary for effective boiler circulation, an efficient heat balance, and to minimize pollutant gas species. However, in some boiler types, such as black liquor recovery boilers and fluidized beds, little or no on-line furnace cleaning is attempted because of adverse impact on the combustion process.

Principles

Ash deposits on the side walls and hopper slopes are generally heavier than those found elsewhere in the boiler. When removed, these deposits fall and contribute to bottom ash.

Because these ash deposits collect on surfaces that are exposed to intense heat, they may melt at their surface after building to a sufficient thickness. Depending on chemical composition, the ash may collect in a loosely bound, porous layer that can be relatively easy to remove by on-line steam cleaning, or the ash may fuse into a dense sheet-like deposit known as *slag*. Slag removal often requires on-line water cleaning. The rapid quenching creates cracks and fissures, dislodging the slag in pieces or patches as the water jet continues its travel across the surface. The water jet also provides significant mechanical impact energy. This technique is not used on boiler surfaces lined with refractory.

Cleaning devices

Short retractable furnace wall sootblower When the furnace wall ash deposits are loosely adhered, a short travel retractable-type sootblower (called an *IR* or *wall blower*) directs steam or compressed air to remove the deposits. This design (see Fig. 2) consists of a poppet valve, feed tube, lance tube, and a drive mechanism for inserting the sootblower tube and rotating it in the fully inserted position. The lance tube has one nozzle near the tip. When at rest, the nozzle is located outside of the boiler and within a sleeve (a short segment of pipe welded to a wall box) to protect it from the furnace radiated heat. When the sootblower is activated, the lance tube is advanced to where the nozzle is about 1.5 in. (38 mm) from the face of the boiler tubes. The feed tube remains stationary while the lance tube telescopes to extend the nozzle.

The poppet valve is mechanically opened by the advancing lance tube drive mechanism and cleaning flow begins. Steam flows through the poppet valve, into the feed tube, to the lance tube and out through the nozzle. Once fully inserted, the lance tube is rotated one, two, or three revolutions while blowing a high pressure cleaning medium aimed nearly parallel to the boiler side wall. The cleaning radius is a function of the cleaning medium's pressure, the type of nozzle, the nature of the deposit, and the boiler surface. In general, on bituminous coal deposits, the normal effective cleaning area of an IR sootblower is elliptical with a vertical axis of 12 ft (3.66 m) and a horizontal axis of 10 ft (3.05 m). This area is typical when supplying either 150 psig (1034 kPa) air or 200 psig (1379 kPa) steam. For subbituminous or lignite deposits, the effective cleaning area may be much smaller.

Waterlance When ash deposits consolidate into a dense slag layer, mechanical impact energy alone may

Fig. 2 Model IR wall blower (on newer designs, the control box is mounted separately).

not be sufficient to clean effectively. A waterlance removes slag by directing a concentrated water jet and precisely controlling the pattern and progression velocity of the water.

Shown in Fig. 3, the waterlance consists of a lance tube with a single nozzle, a drive assembly for inserting the lance tube into the boiler, and valves for turning a high pressure water source on and off. At rest, the nozzle is located inside a wall box sleeve. When activated, the lance tube is advanced along a helical path. Water flow is delayed until the nozzle is about 19 in. (48 cm) from the rest position. The nozzle is installed at a backrake angle to direct the water jet back toward the wall. Once water flow is established, the helical path creates a spiral cleaning pattern on the furnace wall.

The total travel length is about 3 ft (0.91 m). The most common backrake angles are 15 and 20 deg (0.26 and 0.35 rad) as measured from the perpendicular to the lance tube axis. These nozzle orientations achieve

Fig. 3 Waterlance.

a typical cleaned area of 175 and 350 ft² (16.3 and 32.5 m²), respectively.

Once the lance reaches its fully inserted position, water flow is shut off, compressed air is delivered to the lance tube to purge water from the lance, and the lance is removed as quickly as possible.

A partial arc waterlance operates similarly, except that the water is turned on and off during each rotation so that the water jet cleans a partial circle. Examples of cleaning patterns achieved by a partial arc waterlance compared to the standard waterlance are shown in Fig. 4. The partial arc waterlance avoids water jet impingement on corner wall tubes, around burners, or in other sensitive regions.

Selective pattern waterlance Because of the relatively low flow rate of its water jet, waterlance cleaning is generally effective up to 30 ft (9.14 m) from the nozzle. The selective pattern waterlance is designed to accommodate this distance limitation (between the nozzle and cleaning surface) by using a much longer lance tube and cleaning surfaces other than the wall through which the waterlance was inserted. This approach is particularly well-suited for the underside of the furnace's nose arch and hopper slopes. It has also been used effectively to clean wing walls and surfaces between wing walls, division panels, and the leading edge of tube pendants at the top of the furnace.

To maintain a constant jet progression velocity on the surfaces, drive motor control programming may be extensive. In addition, the water may be turned on and off one or more times within each revolution

Fig. 4 Partial arc waterlance cleaning patterns.

to achieve a desired cleaning pattern. The selective pattern waterlance frequently uses more than a single nozzle in the lance tube to achieve close side-to-side spacing of the cleaning jet patterns, and for lance tube cooling. During the retraction of the lance tube, the water flow may be pulsed and is eventually terminated.

HydroJet® A more recently adopted technology is the HydroJet® boiler cleaning system shown in Fig. 5. The HydroJet directs a jet of water through a side wall opening to clean surfaces on the opposite side of the furnace. The lance tube on a HydroJet remains outside the boiler. Its nozzle is installed in the leading tip of the lance tube and the lance tube is articulated by a two-axis drive system to aim the nozzle at the surface to be cleaned.

The water flow required to deliver a concentrated jet across the width of the furnace and still achieve effective cleaning is greater than that of the waterlance. Overall, this injection of a sufficient volume of cold water into the flue gas significantly affects the boiler heat rate. However, the HydroJet offers several advantages that make it an attractive cleaning option. With a range of motion of $\pm 45^\circ$ (0.79 rad) in both the horizontal and vertical directions, a single HydroJet can provide the cleaning coverage equivalent to many waterlances, depending on the size and layout of the furnace. Without a traversing lance tube, this device requires much less outboard space on the side of the boiler and is tolerant of low-quality water.

The heat rate penalty of either a waterlance or Hydrojet can be estimated by calculating the heat energy required to evaporate the water jet. See Equation 1.

$$Q_{\text{loss}} = \dot{m}_w (H_1 - H_2) \quad (1)$$

Fig. 5 HydroJet® boiler cleaning system.

where

- Q_{loss} = heat penalty, Btu/h (kw)
- \dot{m}_w = mass flow rate of the water jet, lb/h (kg/s)
- H_1 = enthalpy of the water leaving the HydroJet nozzle, Btu/lbm (kJ/kg)
- H_2 = enthalpy of steam at the pressure and temperature of the flue gas exiting the air heater, Btu/lbm (kJ/kg)

Generally, atmospheric pressure and the flue gas exit temperature from the air heater are a good approximation for determining H_2 for this purpose. Although the evaporated water is heated to superheated temperatures in the furnace, this steam is cooled along with the flue gas through the remainder of the flue gas path and useful energy is extracted.

The boiler operator must also consider the impact on superheat temperatures, water wall circulation, furnace pressure, and burner tilts if the boiler is fitted with this feature. Each time the HydroJet is operated, excursions of these parameters are possible. This is managed by minimizing required flows through advanced nozzle designs, operating the HydroJet for short periods of time, cleaning small areas, and pausing between areas.

Control considerations

Permanently installed sensors have improved substantially and are successfully used in feedback control algorithms. Heat flux sensors may be installed in furnace wall tubes and monitored to detect heat transfer reduction associated with ash or slag buildup and the thermal shock incurred during cleaning. Emissivity probes can also be used to detect highly reflective deposits that will degrade radiative heat transfer to the furnace wall tubes. Optical pyrometers for measuring flue gas temperature can assess local or overall gas temperatures.

Control systems address furnace cleaning by dividing the surfaces that can be reached into relatively small segments or zones. In the case of a waterlance or an IR wall blower, a zone is the entire area that can be cleaned by one device. In the case of a HydroJet, a zone may be 5 to 10% of the total area that is within the reach of a single device. The division of the furnace area is made by observations to identify areas that generally accumulate deposits at about the same rate. Judgment is applied to ensure that cleaning a zone will not create an upset large enough to destabilize the boiler's overall operation.

In addition to using sensors to signal the control system when a particular area in the furnace requires cleaning, the control logic will employ permissives. Permissives are additional conditions that must be satisfied before the boiler cleaning device is activated. Permissives that are included in a furnace cleaning control system are specific to each boiler, and may include the following:

1. minimum elapsed time since the last cleaning of a particular zone,
2. furnace exit gas temperature, above the minimum recommended point for furnace cleaning,
3. superheat temperature, above the minimum recommended operating point,

4. reheat temperature, above the minimum recommended operating point,
5. superheater spray flows, above the minimum recommended operating point,
6. boiler load, above the minimum recommended load for furnace cleaning, and
7. burner tilts, lower than the recommended degree for furnace cleaning.

Unique applications

Hopper slopes High ash content fuels, in particular brown coal, tend to accumulate ash at such a high rate on the hopper slopes that it can bridge over the bottom opening in a matter of hours. This has been effectively avoided by installing selective pattern waterlances directly above the bottom ash opening and controlling the water jets to sweep the hopper slope on both sides.

Wing walls Tube sections that extend from the front wall of the furnace to the roof, referred to as wing walls, are cleaned by selective pattern waterlances. Slag accumulation on wing walls not only renders needed heat transfer surface ineffective, but is also a common source of major slag falls leading to boiler hopper damage. The face of these tube walls is only accessible by inserting a lance tube from the front wall in between adjacent wing walls. The selective pattern waterlance is often configured to continue past the wing walls to clean superheater pendants or division walls, maintaining the required jet progression velocity control despite the complex geometry changes between wing walls and other surfaces.

Overfire air ports When using overfire air ports to stage combustion and reduce nitrogen oxides (NO_x), a heavy slag buildup could accumulate above and around each air port. This slag accumulation can affect the flow distribution and penetration of overfire air into the furnace. This accumulation also presents a personnel hazard during an outage.

A water cleaning device, designed specifically for overfire air ports, has been used to remove this slag while the boiler is on-line. This special waterlance is referred to as an *eyebrow cleaner* because of the physical appearance of the slag accumulation pattern. The unit has a retractable lance tube that sits at rest inside a sleeve passing through the air duct to the overfire air ports. A high velocity water jet is used as the cleaning medium, and safeguards are included to ensure that refractory installed in the air ports is not damaged by the waterlance's operation.

Convection pass cleaning

Downstream of the furnace, heat is removed from the flue gas by steam-cooled or boiling-water cooled wall tubes and tube banks contained in the convection pass. (See Chapter 19.) In these tube banks, heat absorption is dominated by convection heat transfer from the flue gas to the outer surface of the tubes. Individual tube banks in this region may include primary and secondary superheaters or reheater.

The first segment of the convection pass is a critical region for on-line boiler cleaning because this is

the first point at which the flue gas encounters narrow passageways between the tubes. At this point, the flue gas often contains a substantial concentration of ash particles, and the gas temperature may be high enough that the particles are in a semi-molten state. Under these conditions, deposits tend to collect on the leading edge of each tube bank and between tubes that are lined up behind one another. Deposits that collect between the tubes are referred to as *platenized buildup*, and are difficult to remove with on-line cleaning. Fortunately, it is usually leading edge buildup that has the more pronounced effect on gas path blockage.

Principles

Deposits in the convection pass are removed primarily by the mechanical impact energy delivered by a retractable sootblower. At the highest temperature locations, the outermost surface of the deposits may be in a semi-molten state, for which mechanical impact alone may not be sufficient. This condition is addressed in the section that describes Precision Clean® sootblower control technology. Throughout most of the convection pass, gas temperatures are lower and the deposits are relatively brittle if removed periodically to preclude sintering. In this case, the impact energy of a sootblower nozzle creates cracks and fissures in the deposits. Deposits break off in relatively large pieces, often from their own weight, once deep cracks have been created by the impact energy.

At even lower temperatures, the deposits are much more porous and are only loosely adhered to the tube surface, and to one another. In this case, cleaning is accomplished by the abrasion-like action of the cleaning medium. Ash particles are removed as small particles being swept off the surface, for as long as the nozzle is aimed at the surface.

The challenge in the convection section is to properly sequence the delivery of cleaning media at sufficiently high velocity to tube surfaces located within an array of tightly spaced rows and columns. The impact energy required to break up the deposits generally requires nozzle exit velocities well above the speed of sound. Immediately after exiting the nozzle, the cleaning media begins to decelerate. Depending on the strength of the deposits, this can limit the effective range of sootblower nozzles to between 2 and 13 ft. (0.6 to 4 m).

Cleaning devices

Long retractable sootblower Two common long retractable sootblowers, the IK-500 and IK-600®, are shown in Figs. 6 a and b. Each has a lance tube with nozzles near the front tip, a carriage for inserting the lance tube into the boiler, and a poppet valve for turning the cleaning medium on and off. A stationary feed tube delivers cleaning flow from the poppet valve to the lance tube as it slides over the feed tube. The carriage contains a gear set that drives the lance into and out of the boiler along a helical path.

The nozzles are commonly installed perpendicular to the longitudinal axis of the lance tube. As the cleaning media jet leaves the nozzle, it spreads outward and

Fig. 6a Model IK-525 sootblower.

Fig. 6b Model IK-600® sootblower.

is effective at removing some of the platenized buildup in addition to deposits in the direct line of sight of the nozzle centerline. This perpendicular nozzle orientation is preferred when the side-to-side spacing between tube rows is less than 18 in. (46 cm). With smaller spacing between tubes, deposits can build up and bridge the gap to close off the gas passageway. The perpendicular nozzles provide the deepest penetration to ensure that the gas path remains unobstructed.

When the side-to-side spacing between tube rows is greater, the nozzles may be oriented 5 or 10 deg (0.088 to 0.175 rad) from the perpendicular axis. This configuration is referred to as *lead-lag* nozzles, since one will be oriented forward of the perpendicular and the other slightly backward. This design has greater potential for removing the platenized deposit buildup between tubes within a row, and is used when there

is little or no potential for deposits to bridge from row to row. Lead-lag nozzles have been particularly effective at cleaning division panels and pendant sections at the entrance to the convection pass.

Sootblower nozzle performance In long retractable sootblowers, nozzles are installed in the side wall of the lance tube. Within the lance tube, the compressible cleaning media travels at subsonic speed, generally Mach 0.3 or lower. Most sootblower nozzles are designed to accelerate the flow to supersonic conditions.

Nozzle performance is assessed by measuring the peak impact pressure of the cleaning media jet at points downstream of the nozzle outlet. Within limits, the higher the impact energy, the more effective the nozzle will be at fracturing and removing ash deposits.

The effect that nozzle design has on peak impact pressure is illustrated by the comparison of three sootblower nozzles in Fig. 7. All three nozzles have the same throat diameter, and because all three accelerate the fluid to the speed of sound at the throat, the flow rates are identical at any pressure shown on the graph. In this figure, the peak impact pressure measured at a distance of 30 in. (76 cm) from the nozzle outlet is plotted as a function of supply pressure for each nozzle. The supply pressure at the nozzle inlet can be altered by adjusting the pressure drop in the sootblower's poppet valve.

The development of high performance nozzles has changed the previous operating approach. When using nozzles that were only slightly supersonic (Ground Flush and Hi-PIP, for example), it was generally true that the higher the density of the cleaning media, the better the cleaning. For a system using steam, this meant that less superheat was better for cleaning, and saturated steam was better than superheated steam. However, the performance of the newer class of supersonic nozzles depends on having no water droplets in the divergent section of the nozzle body to avoid the flowfield disturbances and to achieve full expansion of the steam jet. To avoid water droplets, it is generally necessary to have 25 to 50F (14 to 28C) of superheat at the inlet to the sootblower. The presence of condensate in the steam supply, or the formation of condensation in the sootblower lance tube, has a significant degrading effect on high performance nozzles. It can be severe enough to negate the benefit of a nozzle replacement project.

Fig. 7 Sootblower nozzle performance comparison at 30 in. (76.2 cm) from outlet.

Precision Clean® sootblower control A standard sootblower translates and rotates the lance tube at a constant speed throughout its travel. As the lance tube rotates, the nozzles sweep along the face of the tube bank. With constant speed rotation, the jet progression velocity (inverse of dwell time) varies significantly as the nozzle sweeps along the face of the convection tube bank, from a point close to a point far away.

The required dwell time varies with deposit types and deposit surface condition. Surface condition becomes particularly important when the deposit is semi-molten. In this situation, dwell time becomes one of the most significant factors in deposit removal.

A field-proven technique to address the dwell time issue is to control the rate of lance tube rotation to achieve a constant jet progression velocity within a defined arc. The arc includes surfaces that are within the effective range of the sootblower nozzle's impact energy. Outside this arc, the lance tube is simply rotated as quickly as possible until the next control segment (arc) for constant jet progression velocity is reached. This technique, referred to as Precision Clean sootblower control, significantly improves and extends the cleaning effectiveness of a sootblower and can be retrofit to existing sootblowers.

One way cleaning At the cooler end of the convection pass, sootblowers often clean adequately during a single pass of the lance tube alone. This is almost always the case in the economizer, and often in the primary superheater of a power boiler. In an industrial boiler, this may apply to the entire convection pass.

With one way cleaning, flow is most often low during lance insertion and high during lance withdrawal from the boiler. This patented technique most often involves a remotely activated isolation valve in the cleaning media supply line, with a bypass containing a flow orifice. The orifice provides a minimum amount of cleaning media flow when the isolation valve is closed, sufficient to keep the lance tube from overheating. The poppet valve remains unchanged. A transient heat transfer calculation is performed to determine the bypass cooling flow rate.

Oscillator sootblowers Sootblowers are often installed in locations where a high energy cleaning jet can cause damage. This might include the attachment point of generating bank tubes to the steam drum, locations near the face of a tube bank, and areas prone to sootblower-induced tube erosion or tube vibration.

Oscillator sootblowers have a mechanical linkage on the carriage that causes the lance tube to sweep a limited arc back and forth as it travels into and out of the boiler. The arc can be altered by gear set changes. Generally, the lance is fitted with pairs of nozzles so that cleaning is two-sided and the thrust of one nozzle jet is balanced by the thrust of the other. In some applications the lance tube may be fitted with a nozzle on only one side and thrust-balancing orifices on the other. A typical cleaning pattern is shown in Fig. 8.

Extended lance sootblowers As the flue gas temperature is lowered in the convection pass, additional cleaning options become available. Generally, when the gas temperature is below 1100F (593C), extended lance or fixed position sootblowers can be used. Use

Fig. 8 Cleaning pattern of oscillator sootblower.

of specialized materials can permit the use of extended lance or fixed position sootblowers at higher temperatures. Both are distinguished by their lance tube design, that continuously remains inside the flue gas pathway. Fixed position sootblowers are discussed under *Back pass/economizer cleaning*.

An extended lance sootblower is still a retractable sootblower, although the beam and drive assembly are only long enough to translate the lance tube a fraction of its length. The extended lance tube is fitted with more than one nozzle assembly. A half-travel version, for example, has two nozzle assemblies: one at the front tip of the lance tube and the second at mid-length. Each assembly may consist of a pair of identical nozzles diametrically opposed to balance the thrust, or can have a single nozzle with or without thrust balancing orifices on the opposite side. Extended lance sootblowers fitted with 2, 3 and 4 nozzle assemblies are common.

Bearing plates support the lance tube inside the boiler. These plates are mounted to structural members inside the boiler, and the lance passes through an oversized opening in the plate to limit tube deflection. The most distant bearing is installed so that the lance tip is supported in the rest position (when the lance is retracted to the rear stop of the carriage travel). Additional bearings may be used if the gas temperature is high enough to induce stress relaxation in the lance tube material (sagging).

The extended lance sootblower is generally used to accommodate exterior space constraints. This sootblower is also used to address unique design challenges posed when the convection section is partitioned, and it is not permissible to expel a cleaning jet

into a cavity or sleeve between the partitioned chambers. Extended lance sootblowers are used when a concentrated jet of supersonic cleaning media is needed for effective cleaning.

Diagnostic and sootblower control techniques

Modern boiler cleaning systems often incorporate on-line diagnostic sensors and advanced control algorithms to increase cleaning effectiveness and boiler efficiency while reducing the consumption of sootblower media and reducing potential damage to the boiler.

Flue gas temperature is commonly monitored at the furnace exit to detect general fouling on the furnace walls. Load (fuel firing rate) and burner tilt position must be considered. Flue gas temperature is also useful for detecting fouling in segments of the convection pass. This is done with heat balance and heat transfer calculations for a particular tube bank to determine a fouling factor. Deposit accumulations are detected by tracking the fouling factor over time.

Pressure drop of the flue gas across tube banks is an indication of deposit accumulation. Unfortunately, by the time the deposit accumulation results in a measurable pressure drop increase, the deposits are already heavy and are likely difficult or impossible to remove with on-line cleaning alone. In recovery boilers, an operation called chill-and-blow can often disrupt the deposits enough that sootblowers can remove them, or can at least extend the time until the boiler must be shut down for a water wash.

The motor current on the forced or induced draft fan can also be monitored to detect deposit accumulation. Similar to flue gas pressure drop, by the time this parameter shows a measurable change the boiler deposits may be too extensive to remove with on-line cleaning.
