Centralized and distributed computerized control systems can monitor fouling, verify that permissives have been satisfied, and activate sootblowers one by one through a prescribed sequence. Sequencing in the convection pass is situation-specific. Generally, the final sequence is selected by the boiler operators based on observed fouling patterns, accumulation rate, degree of difficulty in removing deposits in the various regions and temperature zones, and sootblowing system constraints. Constraints might include steam capacity (number of sootblowers that can be operated simultaneously) and the time it takes for each sootblower to run. These constraints may lengthen the elapsed time before critical sootblowers can be repeated.

The following guidelines are recommended as a starting point.

Convection pass deposits are easier to remove when they are fully solid and brittle. Even a thin layer of semi-molten deposits coating a thick and otherwise solid base increases the amount of impact energy required. For this reason, it is generally recommended to sequence sootblowers from front to back of the boiler. Starting at the positions nearest the furnace, each sootblower operation improves heat transfer at that point and makes it easier to remove deposits at points downstream, by lowering the gas temperature at these positions.

Among positions that are essentially at the same

point (temperature) in the gas stream, the choices are bottom to top, or top to bottom. In convection pass sections where the gas flow is predominantly upward (such as tube pendants suspended over the furnace and before the arch), progressing from lower to upper elevations is recommended. However, when deposits weighing several hundred pounds could be dislodged, the recommendation would be top to bottom. This reduces the chance that a slag fall from an upper location would land on a lower sootblower's lance tube.

Back pass/economizer cleaning

Later segments of the convection pass generally require a denser heat transfer surface arrangement due to the lower gas temperature. Tube spacing is generally smaller as there is a lower likelihood of deposit bridging. For many fuels, tubes may be finned and positioned in a staggered arrangement rather than simple rows and columns. Deposit characteristics are clearly different in this region, dusty and non-sintered for some fuels, and sometimes accompanied by lightweight clumps of ash (commonly referred to as *popcorn ash*). However, the denser tube arrangement can be problematic for many units firing western United States (U.S.) coals. This back pass region includes the economizer.

Principles

Ash deposits in this region often begin as a thin layer of dust on the tubes, which may eventually accumulate as unstable flags (wedge-shaped ash buildup) built up on the leading edge of the tubes. Fixed position sootblowers may be used where the deposits are dusty or loosely adhered. Only a portion of the cleaning is actually accomplished by impact energy of the nozzle jet. Most cleaning is accomplished by the momentary increase in gas flow past the deposits when the cleaning media combines with the flue gas flow to disrupt the flow pattern. This is referred to as *mass blowing*.

When a greater degree of energy is required, for example due to ash compacted between radial fins on the boiler tubes, rake-type sootblowers may be used.

When ash deposits are loose or accumulated in unstable buildups, sonic horns operated at optimal frequencies may be effective.

Cleaning devices

Fixed position sootblowers This type of sootblower is characterized by a tubular element fitted with a number of nozzles along its length, usually positioned along one side of the element. The nozzles are generally spaced to correspond to the boiler tube spacing and aligned so that one nozzle is aimed between each row of tubes. The element serves as a lance tube, but remains permanently inside the boiler flue gas. The fixed position sootblower with a rotating element is also called a rotary sootblower. One common rotary sootblower, the model G9B, is shown in Fig. 9.

The element is supported along its length with bearings, similar to the extended lance sootblower. When the sootblower is activated, the element is rotated. The rotating motion operates a cam which mechanically opens the poppet valve, and cleaning medium flows

Fig. 9 Model G9B electric motor driven rotary sootblower.

into a short feed tube and then into one end of the element to distribute among the nozzles. The cam can be configured to close the poppet valve after a prescribed arc or after a full revolution of the element.

To clean effectively, the rotary sootblower must provide sufficient flow to all nozzles in the element. The nozzles nearest the feed tube entrance receive a slightly higher portion of the flow. Design guidelines are established to limit the flow maldistribution to less than approximately 10% between the closest and farthest nozzle. However, to accomplish this, the size of the nozzles must be restricted and thereby tube bank penetration is limited. Nozzles are a convergent/divergent design with throat diameters ranging from 0.25 to 0.375 in. (6.35 to 9.53 mm).

A non-rotating version of the fixed position sootblower omits the feed tube and gear drive assembly. An isolation valve simply turns flow on and off, and the isolation valve must be opened and closed with an electric or pneumatic actuator.

Rake-type sootblowers The rake-type sootblower is particularly effective at removing deposits from tightly spaced tubes with radial fins. This is a retractable sootblower with no lance rotation; the lance tube design is T-shaped as shown in Fig. 10. The nozzles are located in the rake segment of the lance tube after the tee, which is the section oriented perpendicular to the direction that the lance travels. This lance is never fully retracted from the flue gas. Also, the lance tube may have more than one rake. The rake provides the ability to traverse a relatively low number of nozzles across a large area of tube surface. The nozzles will always be pointed directly into the tube bank and can not contribute to cleaning the tube bank upstream of the sootblower. They can, however, deliver more cleaning energy than a rotary sootblower.

Traveling crosswise to the economizer tubes is preferable, since this provides the maximum opportunity for cleaning flow to attack tube deposit buildup from

both sides (because of the diverging trajectory of cleaning flow) in addition to head on. However, the rake-type sootblower is still an effective approach to cleaning difficult ash buildups even if space constraints outside of the boiler dictate that the rake travel must be parallel to the economizer tubes. Nozzles range from 0.25 in. to 0.625 in. (6.35 to 15.9 mm).

Sonic horns The use of acoustic energy to propagate sound waves within the boiler enclosure can also dislodge deposits in the back pass regions of the boiler. Sonic horns produce acoustic waves at frequencies ranging from 20 to 200 hertz. Their use is generally limited to locations where the deposits are dry and loosely adhered. Example locations include a finned tube economizer with dry deposits trapped between the fins, and plates of an electrostatic precipitator. Fog horns have been used to clean deposits in fabric filter baghouses.

At present, most sonic horns operate at mid-range frequencies of about 75 hertz. At this frequency, a number of relatively closely spaced horns must be installed around the periphery of the boiler enclosure; each is operated intermittently, and operation alternates from one to the next. Their effectiveness is limited by the tendency for the sound pressure level to attenuate a short distance into the flue gas. A smaller number of horns is required when the operating frequency is lower, around 20 hertz, because of the ability of the long wavelength unit to establish acoustic resonance if the sound wave generator is carefully installed and adjusted. Lower frequencies are also more effective at extending the cleaning range deep into a staggered tube array.

SCR catalyst cleaning

The more common and reliable cleaning method for selective catalytic reduction (SCR) system catalyst is by sootblowing with steam or air. Catalyst plates have been cleaned by acoustic devices where site-specific conditions allow.

Principles

Sootblowers clean ash and ammonia salt particulate from the catalyst by providing a relatively low velocity of steam to each channel of the catalyst assem-

Fig. 10 Rake-type sootblower.

bly. The cleaning medium is almost always steam, but air can be used as an alternative. The steam velocity is low compared to sootblowers used for boiler cleaning to avoid mechanical or erosive damage to the catalyst substrate, yet high enough to dislodge loose particles in the catalyst channels and re-entrain them in the flue gas flow. Sootblowers cleaning the catalyst are designed to deliver steam in the range of 80 to 120 ft/s (24.4 to 36.6 m/s) to the catalyst surface. However, even at this relatively low velocity, it is critical to avoid moisture in the steam flow. Water droplets are erosive, can cause thermal shock on some catalyst designs, and could dissolve the thin vanadium pentoxide coating on the ceramic substrate.

Cleaning devices

Straight line sootblower The IK-525 Straight Line Cleaner is a retractable sootblower designed for applications where the lance tube is inserted and retracted without rotation. It is used with rake-type lance tube assemblies that reside permanently inside the flue gas. This sootblower cleans SCR catalyst assemblies, economizers, and air heaters, and is occasionally used for applications where lance tube rotation is undesirable or unnecessary, such as air duct cleaning.

SCR catalyst assemblies and air heaters are cleaned by directing steam or air flow directly into the narrow passages. An array of nozzles is positioned directly above or in front of the leading edge of the assembly. The nozzles are positioned in rake arms attached at right angles to a central lance tube. A single lance tube may be fitted with one to twelve rake arms. The lance tube is supported inside the flue gas chamber such that it holds the rake arm nozzles at a fixed distance from the leading edge of the catalyst or air heater assembly. The lance tube is inserted and retracted such that each rake arm advances to the starting position of the rake arm ahead of it. Cleaning can be during both the insert and retract pass of the rake arm, or during only the retract pass.

When the lance tube has a number of rake arms, it may be necessary to minimize the difference in cleaning medium flow as it is distributed to the arms. Therefore, the lance tube itself may consist of an upper and lower lance tube. The upper lance tube is aligned with the side wall penetration, and is the tube that penetrates the wall and telescopes over the stationary feed tube. Flow distribution pipes deliver cleaning medium flow to the lower lance tube. The rake arms are attached to the lower tube.

Flow distribution among the rake arms of each sootblower and among the nozzles is a primary consideration in the design of an SCR sootblower. The goal is to provide a uniform curtain of steam flow from each rake arm.

Various methods help avoid moisture, beginning with using a sufficiently superheated steam source. To avoid moisture from the enthalpy decrease associated with pressure drop and velocity increase between steam source and sootblower nozzles, it is generally recommended that the steam source for SCR applications be on the order of 50 to 100F (28 to 56C) superheated. The goal is to have the steam remain above saturation throughout the sootblower to the rake arm

nozzles, while satisfying thermal shock criteria imposed by the catalyst design. A common requirement is that the cleaning medium temperature at the point of contact with the catalyst surface must be within 100F (56C) of the catalyst (i.e., flue gas) temperature to avoid thermal shock.

A superheated steam source can still produce condensate if precautions are not taken to drain condensate collected in the sootblower supply piping, and preheat the steam header piping before operating the sootblowers. Condensate drain control systems are recommended in the sootblower piping system to ensure that the sootblower piping is maintained free of condensate between sootblower operations. In addition, the control system should include steam header warm-up before the sootblowers are operated. Generally this would consist of opening the steam isolation and control valves and a sootblower piping drain valve for about five minutes before permitting the first sootblower in a sequence to operate.

Catalyst manufacturers have established maximum sootblower pressures for each of their designs. Generally, these fall into two groups: one recommends supply pressures from 80 to 100 psig (552 to 689 kPa), and the other prefers supply pressures of 10 to 20 psig (69 to 138 kPa). The latter has become more common.

Popcorn ash

Some of the ash that makes its way past the boiler arch is the result of small agglomerations referred to as popcorn or large particle ash. Most of this is removed from the hopper underneath the economizer, but some could be carried to the SCR. SCR designs include a screen positioned immediately above the inlet face of the catalyst bank or at the outlet of the economizer. The screens protect the catalyst from this ash. Because most of these particles will not pass through the screen, they must be removed by manual vacuuming during an outage. Aerodynamic devices have also been used at the outlet of the economizer to trap these large particles.

Air heater cleaning

Regenerative air heaters

Regenerative air heaters, common in large electric utility steam generating plants, are susceptible to ash particles collecting between the corrugated plates that form the heat storage elements or baskets (see Chapter 20). Some flow path blockage occurs at the leading edge of the element. Some particles collect loosely on the upper surface, and smaller particles become wedged between the plates. Most of the pluggage that occurs in the baskets, however, is an accumulation of fine particles that adhere to moistened surfaces near the cold end of the channels. The moisture is generally a result of acid precipitation from the flue gas. Ash particles may also attach to ammonia salt deposition associated with an SCR upstream of the air heater.

Regenerative air heater elements are made of thin, corrugated steel plates. Deposits are removed by means similar to that described in SCR cleaning. Cleaning media must be aimed directly at the top sur-

face at relatively low velocities, to prevent the thin metal plates from being deformed or fatigued by flow-induced vibration. Unlike the SCR catalyst, the regenerative air heater is in motion.

Cleaning devices

Straight line sootblower The version of the straight line sootblower used in air heater cleaning applications is the model IKAH. The lance tube is shown in Fig. 11. It contains one small rake, so it is not fully retractable, although the components outside the boiler are similar to the fully retractable sootblower. The six nozzles located along the length of the lance tube provide five cleaning bands as the air heater rotates. When activated, the lance is slowly inserted and retracted while each nozzle traces a spiral cleaning path along the face of the air heater baskets. Generally, cleaning flow is only provided during the insertion pass. A pneumatic actuator opens and closes the poppet valve, directed by the sootblower control system.

Swing arm sootblower A swing arm sootblower was often included as part of the original equipment by the air heater manufacturer. The arm consists of a pivoting pipe extending into the space upstream of the air heater baskets with the tip turned to aim directly into the face of the baskets. A nozzle is installed in the tip to direct cleaning media into the baskets with sufficient flow to flush ash particles that have collected between the corrugated plates. The arm is slowly swiveled as the baskets are rotated past the nozzle. The cleaning path is spiral. The gear driven assembly that controls the arm movement is external to the air heater, and is located in the stationary part of the air heater element enclosure, ahead of the rotating basket segment.

Dual media air heater cleaner With increased use of low sulfur western North American coals and SCR systems, fouling of air heaters has become more difficult to manage. The high calcium content of western coals can lead to cementitious ash deposits if moisture is present, especially at the cold end of the air heater. Ammonia slip from the SCR can lead to tenacious salt deposits.

The dual media air heater cleaner has been used

Fig. 11 Model IKAH sootblower for air heater cleaning.

in recent years because of a superior cleaning capability with compressible media (steam or air), and a built-in capability to switch to high pressure water cleaning with highly precise nozzle position control. Dual media air heater cleaners have been installed at both the inlet and outlet face of the baskets on Ljungstrom-type air heaters.

The lance tube of the dual media cleaner is fully retractable, or if external clearance is not available, the lance tube can be configured with multiple nozzle assemblies and partial travel, making the sootblower beam much shorter. The nozzle assembly provides an array of converging/diverging nozzles for directing a jet of compressible cleaning media to the face of the baskets, and a second array of water jet nozzles. The lance tube does not rotate and is installed so that the nozzles are between 12 and 30 in. (30 to 76 cm) from the basket inlet. Cleaning is carried out during the retract pass of the lance, and the lance is controlled in a stepping mode; the lance tube advances one step and holds position for one, two, or three revolutions of the air heater before moving to the next position. The number of passes that the nozzle is held stationary is a function of radial position and operator selection.

The compressible flow nozzles are generally arranged in one of two possible arrays. The positioning of these nozzles provides a nearly uniform flow field between them and therefore thorough cleaning of the air heater basket channels that pass underneath the nozzle assembly. This allows for a substantial step size because of the wide cleaning band provided. Still, in this mode, the dual media sootblower typically requires 45 minutes to cover a 22 ft. (6.7 m) travel of the nozzle head. The compressible flow nozzle jets are typically supplied with steam or air at pressures ranging from 90 to 150 psig (621 to 1034 kPa).

The nozzle assembly also has a water jet nozzle array generally installed in pairs. The spacing between the pairs of water jet nozzles and the step size used during high pressure water wash ensure that every channel in the basket is cleaned by a water jet aimed directly at that single channel.

The compressible flow nozzles are occasionally supplied with low pressure, 100 psig (689 kPa) water to provide a soaking-type cleaning action. This is particularly effective when the material being removed is primarily salt deposits, and the dual media cleaner is positioned on the cold side (downstream) of the air heater baskets. With this flexibility, the dual media cleaner accommodates three modes of operation: high pressure steam cleaning for day-to-day cleaning maintenance, low pressure water wash for dissolving deposits, and high pressure water for semi-annual wash down. The high pressure water capability minimizes boiler down time and costly off-line water wash service contracts.

Tubular air heaters

Tubular air heaters are generally not as heavily fouled as regenerative air heaters, because their design affords less opportunity for deposits to collect. Most commonly, the flue gas passes through the tube side of this air heater design. Ash particles collect

loosely on the inside walls of these tubes although there is the potential for moisture from acid precipitation to act as a wetting agent.

Cleaning devices

Rake-type sootblower for tubular air heaters The IK-525 straight line sootblower is used to pass a rake-type lance tube over the face of the tubesheet that forms the tubular air heater inlet. Nozzles direct cleaning media (steam or compressed air) directly into the air heater tubes as the lance advances and retracts. The lance tube may have multiple rakes to shorten the length of the sootblower needed on the outside of the air heater. The lance tube travel achieves complete cleaning coverage of the air heater tubes, with only minimal overlap at the start and stop positions of the adjacent rake arms.

Air puff sootblowers Fixed position sootblowers with a pulsating output are occasionally used to clean tubular air heaters when external clearance is not available for a rake-type sootblower. The model A2E air puff sootblower includes a gear driven mechanism that abruptly turns the flow on and off 20 times during each main drive rotation. A fixed position tubular element installed above the face of the tubesheet has nozzles installed along its length directed at the tube inlets. An abrupt and repetitive disruption of the flue gas flow into the tubes, along with modest impact energy, is accomplished by pulsing the cleaning medium flow. The most aggressive cleaning is achieved by a non-rotating element, but the number of A2E sootblowers can be reduced by rotating the element to direct cleaning flow into tube rows on either side of the element. Supply pressures of 125 to 150 psig (862 to 1034 kPa) are typical for coal-fired boilers.

The air puff sootblower is also used to clean the back pass regions of oil-fired boilers, including the economizer. Supply pressures up to 200 psig (1379 kPa) are generally required.

Other cleaning applications

This chapter focuses primarily on cleaning equipment found on large coal-fired utility boilers. While the same cleaning equipment is generally applicable to all boiler designs, a few additional special application features include:

Coal-fired (and biomass-fired) industrial boilers These units also usually have a boiler or generating bank located in the convection pass. (See Chapters 27 and 30.) Boiler banks are generally cleaned with retractable IK-type sootblowers.

Oil-fired boilers As discussed in Chapter 21, oil firing produces significantly less ash than coal firing though the ash is often more corrosive. Generally, fewer sootblowers are needed for oil versus coal firing. In these units, G9B sootblowers may replace some of the IK retractable blowers in the convection section upstream of the economizer.

Process recovery (PR) boilers As discussed in Chapter 28, deposits are often more extensive and harder to remove in PR boilers. As a result, IK sootblowers are used in larger quantities throughout all of the boiler surfaces and are cycled more frequently.

Waste-to-energy (WTE) boilers Because of the very corrosive nature of the WTE boiler environment, special care in cleaning of the surfaces is needed as outlined in Chapter 29. It is very desirable to not clean the superheater tubes completely to expose bare metal as this will accelerate corrosion. To address this, a *rapping* cleaning system is employed in the superheater along with carefully applied sootblowers in a range of units. Where sootblowers are used, tube shields are frequently employed to provide additional sacrificial metal on the tubes closest to the sootblower installation. More detail is provided in Chapter 29.

Fluidized-bed boilers Lower operating temperatures generally make cleaning these units easier than pulverized coal-fired units, reducing the sootblower requirements. In circulating fluidized-bed units, sootblowers are not installed in the vertical furnace shaft. (See Chapter 17.)

Ash handling systems

The ash handling systems of a steam generating plant collect the ash and residue from the combustion of solid fuels from different points along the boiler flue gas stream (see Fig. 12), transport it to storage bins or silos, and prepare the ash for transport or disposal. Because the characteristics of ash are very different from the front to the back of the boiler, the collection, transport, and storage systems are usually separate for the furnace and collection points downstream.

In a coal-fired boiler, the general categories of ash are:

1. Bottom ash – the material that collects at the bottom of the furnace, possibly a heavy slag.
2. Mill rejects – the heavy pieces of stone, slate and iron pyrite that are discharged from the coal pulverizer.
3. Economizer ash or popcorn ash – the coarse and comparatively dense particles that drop out of the flue gas when the gas changes direction abruptly, such as in the back pass and air heater ducts.
4. Flyash – the fine ash particles that are collected in the dust collection equipment.

Although bottom ash and mill rejects are unique to pulverized coal-fired boilers, the above classification is generally useful for describing the different types of ash handling equipment. Common terms and definitions are provided in Table 1.

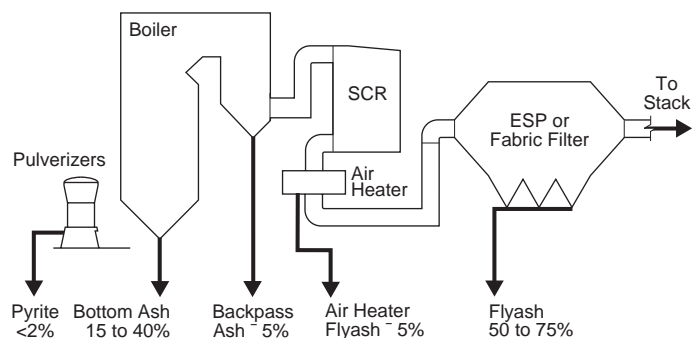

Fig. 12 Typical pulverized coal-fired boiler ash discharge locations and approximate amounts.

Bottom ash systems

Bottom ash is most often conveyed in a hydraulic system in which the ash is entrained in a high flow, circulating water system and delivered to either an ash pond or to dewatering storage bins. Alternatively, mechanical drag systems have been used to convey bottom ash to the dewatering storage bin because they use less water and usually have a lower initial cost. Both systems are designed to handle ash dropping into the conveyance system at temperatures as high as 2400F (1316C), requiring each system to have a quenching volume of water at the initial collection point. It is common for the bottom ash system to store as much as three days of ash output from the boiler.

Hydraulic bottom ash systems

The first component of the hydraulic conveying system is the water-filled hopper shown in Fig. 13. The bottom of the furnace terminates in a rectangular opening running across the width of the boiler (the floor of the boiler itself being a hopper). The bottom ash hopper fits up to this with its own sloped wall chamber so that ash and slag feed by gravity to a single outlet. On larger boilers, the bottom ash hopper may be divided into parallel chambers, referred to as *pant legs*, each having an outlet at its bottom as shown in Fig. 13. The outlet is sealed with a hydraulically driven gate controlled to open when the hopper is full, and coordinated with other hoppers so that only one hopper at a time empties into the conveying line.

The bottom ash hopper is filled with water to quench the hot ash as it enters, and is usually lined with refractory. The connection between the ash hopper and the bottom of the boiler seals the boiler gases and accommodates thermal expansion of the boiler. This is accomplished by a water trough design around the top of the hopper that keeps a steel plate skirt immersed in water. The skirt is attached to and moves up and down with the boiler, while the bottom ash hopper rests on the ground. Exposed refractory is kept cool by continuous water flow over the refractory surface. Cooling water supply is furnished either as overflow from the seal water trough or through embed-

Fig. 13 Typical gravity feed bottom ash hopper.

Table 1
Ash Handling Terminology

Slag	Characteristic ash removed from furnace walls
Bottom ash	Ash removed from the bottom of the furnace
Clinker	Large piece of bottom ash that must be broken up before transport
Flyash	Ash carried by the flue gas into the backpass region and beyond
Popcorn ash	Characteristic ash collected in economizer and air heater hoppers
Dust	Fine ash particulate, typically 50 to 75% of all ash from boiler
Hydroejector	Venturi device that pulls bottom ash into hydraulic transport system
Hydrobin®	Dewatering bin for removing water from bottom ash
Hydrovactor	Venturi device that provides vacuum source for pneumatic transport
Airlock valve	Two chamber device for feeding ash into higher pressure transport line
Materials handling valve	Valve that admits flyash and air flow into vacuum transport line
Collector	Ash/air separator and transfer tank from vacuum system to silo
Transporter	Flyash collection and aeration vessel for dense phase pneumatic transport
Vacuum/pressure transfer station	Collection and transfer vessel from vacuum line to pressurized line in combination vacuum/pressure pneumatic system
Drag chain	Primary mover in mechanical drag conveyor system
Flights	Attached to drag chain to push ash along stationary platform
Unloader	Device to unload dry ash storage silo into transport vehicles
Conditioner	Adds water to flyash during unloading to minimize airborne dust
Pugmill	One version of combined silo unloader/conditioner

ded refractory cooling water distribution piping. The cooling method selected is determined by the boiler operating pressure.

When the boiler is a continuously slagging wet bottom design, the ash hopper is replaced with a slag tank. The wet bottom boiler terminates in a cooling trough for the flowing slag. To break up strings of slag forming at this point, the cooling trough has a slag swiper that swings a water-cooled arm back and forth across the inlet opening. The slag tank may include agit-

ing jets in the water pool to granulate the slag as it solidifies. The remaining features of the slag tank are generally the same as a bottom ash hopper.

The bottom ash hopper or slag tank is sized to hold about eight hours of ash produced by the boiler. To empty the hopper, the discharge gate opens and the contents enter a gate housing, which directs the ash into a clinker grinder where the slag is crushed. Clinker grinders have a variety of designs classified in terms of the maximum particle size that remains after passing through the grinder. Specified particle sizes range from cubes measuring 0.75 in. (1.9 cm) on all sides, to pieces 2.5 in. (6.4 cm) in diameter. Smaller particles require a lower water flow rate to transport them and have a lower tendency to plug the line, particularly in the valves and fittings of the transport piping. However, smaller particle sizes also tend to make it more difficult to separate the water at the end of the conveyance line.

Clinker grinders are either single or double roll design. The rolls are the elements that rotate and grind the slag with protruding teeth. A double roll design rotates the shafts counter to one another so that particles are pulled in and crushed as they pass through the grinder. A single roll design uses a stationary breaker bar for the opposing force.

The crushed particles are fed into the conveying line both by gravity and pump suction. The pump may be a centrifugal slurry pump or an ejector (jet pump). Slurry pumps are used to transport the ash longer distances, in particular when the frictional and elevation head loss exceeds about 150 ft. (45.7 m). Ejectors are often chosen for their ease of maintenance because they have no moving parts. A centrifugal pump is still required to produce the high pressure water that supplies the ejector and the energy efficiency of the system is lower, but by using the ejector, the coarse ash and slag particles do not pass through the pump itself.

In both cases the ash particles are diluted into a slurry that is about 20% solids by weight entering the piping system. The goal of the piping layout is to use the least number of bends possible because of the extremely erosive nature of this mixture, and the need to minimize pressure drop. The piping is either hard iron alloy or lined pipe. Lining materials include basalt and ceramics. Elbows and lateral fittings (used to merge two lines) are usually made of harder material, and are uniquely made with extra material thickness at points where solid particles tend to impact the pipe. When additional material is cast into the design, it is referred to as integral wear back fitting.

The piping system delivers the mixture to an ash pond or a Hydrobin® dewatering storage bin (Fig. 14 and chapter frontispiece). Two dewatering bins are used in each installation. One receives ash from the boiler while the other is draining or decanting water from the collected solid material.

A Hydrobin is initially filled partially with water. Incoming ash slurry is dropped into the center onto a sloped bar screen that acts as a partial classifier. Coarser material is forced to the sides of the cylindrical bin while the finer particles drop into the center. Later, while draining, the coarser particles act as a filter to trap fines before they reach the decanting el-

ements along the wall.

The bin quickly fills with water from the incoming slurry, although it may take a day or more to fill to capacity with solid material. Until the bin is filled with solids, loading continues and excess water is extracted from the top and returned for reuse in the conveying lines. At the top of the Hydrobin, an underflow baffle directs all incoming material downward and helps prevent the fines from simply floating across the surface to the overflow. After the water flows under the baffle, it flows over a serrated weir as overflow. The concentration of suspended solids contained in the overflow return line is dependent on ash particle size distribution in the slurry, ash particle density, and the water flow rate going over the weir. The larger or denser the particles, the greater their tendency to sink rapidly to the bottom of the bin.

Mechanical drag systems for bottom ash

The first element of a mechanical drag system is a transition chute that mates up to the bottom opening of the boiler. The transition chute uses a water-filled trough to seal boiler gases by immersing the seal plate at the bottom of the boiler in the trough. The remainder of the transition chute provides storage volume for bottom ash, mainly for periods when the drag system is unavailable. The bottom of the chute funnels down with its sloped side walls to drop ash onto the center of a conveyor. For bottom ash, the conveyor itself is always submerged in water, but the transition chute may be dry or filled with water up to the top of the sloping side walls. These two types of transition chutes are shown in Fig. 15. When it is water-filled, the transition chute is referred to as a hopper and the overall system is referred to as a submerged chain conveyor (SCC).

The drag conveyor consists of two chains traveling horizontally underneath the chute, and once past the chute, turning upward along a dewatering incline. Flight bars are attached to the chains at regular intervals. The flight bars drag across a stationary plate while the bottom ash drops from the transition chute. The ash lands between the flight bars and gets pushed from underneath the chute, then up the incline to lift the ash from the quenching water pool. At the end of the incline, the residual moisture in the ash is generally about 20 to 30% by weight.

At the top of the incline, the ash is dumped into either a bunker or a discharge chute and onto another conveyor or series of conveyors. If necessary, a clinker grinder may be installed at the discharge end of the first conveyor. Ultimately, the bottom ash is dumped into a storage bin or dewatering bin. Normally, ash removal from the boiler is continuous, but the storage or dewatering bins may provide up to three days storage to accommodate pickup schedules. If a dewatering bin is used, a settling tank and surge/storage tank may be used to clarify the drained water for reuse.

To maintain the water trough seal at the boiler hopper skirt, water must be continuously circulated. Because of the low water inventory, a heat exchanger is commonly needed in the recirculation line to keep the water below about 140F (60C).

The submerged mechanical drag system requires

Fig. 14 Hydrobin® dewatering bin.

approximately 12 to 15 ft (3.7 to 4.6 m) height under the furnace throat opening on large utility boilers; smaller boilers require less distance. This allows the boiler to be located closer to the ground and reduces the cost of structural steel and other supporting components.

The drag chain system is typically installed on wheels in a rail or track system underneath the boiler, and one or both of the side plates at the bottom of the boiler are hinged. This allows the conveyor system to be removed for service (such as chain or flight replacement) and provides open access to the bottom of the boiler during outages.

Plunger ash extractor

The ash discharged from the stoker on mass burn municipal solid waste (MSW) units consists of ash and slag similar to that derived from other combusted fuels, except that the MSW fuel has a high ash content and includes oversize bulky wastes (OBW). This system is discussed in more detail in Chapter 29.

Mill rejects

Pulverizer rejects (often called pyrites) are commonly dumped into the bottom ash conveyance system. A mill storage hopper is installed at each pulverizer to collect the rejects. This hopper is sealed to the

mill outlet spouts with seals that can accommodate positive pressure and pressure surges that occur when the mill is purged with inert gas.

When the bottom ash is conveyed with a hydraulic system, ejectors are used at each mill storage hopper to pull the dry mill rejects into the high velocity water flow for transport. The resulting slurry from each mill is piped into a common pyrites holding bin as shown in Fig. 16. The common holding bin is generally emptied at the same time that the boiler's bottom ash hoppers are emptied, using the same transport piping to the dewatering bin or pond.

Although it is common for mill rejects to be conveyed in the bottom ash hydraulic transport system, the much heavier pyrites impose a substantial burden on the hydraulic system. Often, the water flow must be increased to entrain these heavier particles. An economic tradeoff is made between the cost of an independent mill reject transport or a shared system. The shared system must include pumps selected for transporting the most difficult material, and the dewatering bins must be sized for higher water flow when mill rejects are transported with the bottom ash.

Economizer ash systems

The flyash removed from hoppers under the economizer, SCR, and air heater tends to contain larger particles along with the fine dust-like ash collected in air cleaning devices. The larger particles (popcorn ash) may contain concentrations of unburned carbon. Because of the high gas temperatures at these points, the ash may tend to sinter and become difficult to remove if permitted to sit for long periods. For this reason, it is common to provide crushers to reduce the particle sizes to about 0.25 in. (0.6 cm) in diameter for pneumatic transport. Alternatively, small, dry secondary hoppers can be installed under each economizer

Fig. 15 Transition chutes for mechanical drag systems.

Fig. 16 Basic ash system including mill rejects.

or air heater hopper to continuously receive the ash. By removing the ash from the hot gas stream, the tendency to sinter is eliminated and the ash remains as primarily a fine dust with some popcorn ash particles.

This ash is generally combined with the flyash transport system, whether vacuum or pressurized pneumatic. A pressurized system requires an airlock valve to discharge the ash into the conveyance piping. A materials handling valve is used to dump ash into a vacuum system.

Economizer ash is occasionally mixed with a hydraulic bottom ash conveyance system. Because water is very difficult to remove from this ash, this is generally done only when the bottom ash is being disposed of in a fill area. Dewatering bins are not well suited to handling economizer ash.

Mechanical drag systems may also be used for economizer ash, and are particularly suitable when the ash is to be reinjected into the furnace. In this application, the drag unit is dry and sealed. A single drag unit will normally collect from all economizer hoppers. The ash is then discharged through a rotary feeder into a storage tank. If the ash is to be combined with the flyash transport, the storage tank discharges into the pneumatic system with an airlock valve or materials handling valve.

Flyash systems

Most of the ash from a pulverized coal-fired boiler is carried through the boiler and air heater by the flue gas. As much as 50 to 70% of the ash generated by

combustion of pulverized coal is removed from the flue gas by an air cleaning device, such as a filter baghouse or electrostatic precipitator. (See Chapter 33.) Baghouses and precipitators have rows of collection hoppers that are emptied regularly by the flyash transport system.

Flyash consists of fine particles with low density. These particles are rarely transported in a water slurry because they can not be easily separated from the water at the end of the transport process. For this reason, flyash is almost always transported pneumatically. Pneumatic transport systems generally fall into three general types:

1. vacuum systems,
2. pressure systems, or
3. combination vacuum/pressure systems.

Vacuum systems

A vacuum system uses air, below atmospheric pressure, to entrain and convey ash particles. For systems with short transport distances, this often provides the lowest initial cost. A vacuum system uses fewer components and requires less clearance under the precipitator or baghouse. A vacuum system operates cleaner because any leaks merely pull ambient air into the system. Because of the low pressure of air in the system, transport distances are limited and larger line sizes may be necessary to avoid excessive piping wear.

The first point in the vacuum transport system is a material handling valve, attached to the outlet of each hopper. These valves empty the hoppers into the con-

veying system and in their full open position regulate the flow of ash to provide a quick but steady dispensing of the collected ash. A single pipe runs underneath each row of hoppers collecting the flow from the material handling valves. At one end, an air inlet valve opens to supply air for transporting the ash when a vacuum is applied at the other end of the pipe. Then, one at a time, the material handling valves are opened and ash flows into the pipe. Each material handling valve may use integrally mounted air inlet check valves. These are located just behind the gate so that they are opened by vacuum after the material handling valve itself is opened. These air inlet valves improve ash flow from the hopper into the conveying line.

The material handling valve can serve as a tee connection to the conveyance pipe, or may be connected to the conveying line with a short length of pipe. Integral wear back fittings or fittings with a replaceable wear back are commonly used in vacuum systems.

At the silo, the ash is separated from the conveying air in a two-chamber collection vessel. The collection vessel allows continuous collection of ash from the conveying line at vacuum pressures, and facilitates the gravity feed transfer of this ash into a silo at atmospheric pressure.

The vacuum source is located at the discharge end of the piping system, downstream of the separation equipment on the silo, to minimize the amount of abrasive ash that is drawn through the vacuum producer. The vacuum may be produced hydraulically or mechanically.

Pressure systems

Pressurized conveying of flyash offers some advantages over vacuum systems. Because they are not limited by one atmosphere of pressure differential from pickup point to the silo and vacuum producer, these systems can convey over longer distances. Also, the ash/air separation equipment can be simplified at the storage silo. However, because the feeding device at each pickup point is complicated by the need to transfer ash from the low pressure hoppers into the high pressure conveying line, the feeding device is larger. This requires more space under the precipitator or baghouse, and has a higher initial cost because the transfer equipment must be provided at each of the numerous pickup points. This offsets the cost savings of the simpler silo separation equipment. Pressurized systems are generally chosen with conveying distances greater than 750 ft (228 m), and considering the lower operating costs of a pressurized system. Pressurized systems may also be required at higher altitudes, because of the lower differential pressure available for a vacuum system.

The starting point for a pressurized system is a positive displacement blower which provides air flow and pressure for conveying the flyash. The blower feeds a piping system that branches out to collect ash from the numerous hoppers under the precipitator or baghouse.

An airlock valve dumps ash from each hopper into the conveying line (see Fig. 17). This valve consists of two chambers, upper and lower, with three gates: one to close off the opening to the hopper, one between the upper and lower chamber, and a cut-off gate to empty

the lower chamber of each airlock into the conveying pipe one at a time.

An equalizer valve is required for each airlock valve. The equalizer valve has two positions: one to equalize the pressure between the hopper and upper chamber of the airlock, and the other to equalize pressure between the conveying pipe and the upper chamber. It is inevitable that some of the abrasive ash flows through the equalizer valve each time it changes position, so it is designed to be self-cleaning and includes wear resistant surfaces at key points.

To operate the airlock valve, all three gates are initially closed. The pressure of the upper (primary) chamber is equalized with that of the overhead hopper. The gate valve above the primary chamber is then opened for a preset period of time. This dwell time allows a measured amount of flyash to flow by gravity into the primary chamber. At the end of the loading cycle the upper gate is closed to isolate the chamber from the hopper. The upper chamber is then pressurized to a level slightly greater than the conveying line pressure. Finally, the gate between the upper and lower chamber is opened and ash is forced down into the conveying line through an intake tee. The intake tee imparts swirl within the lower chamber for better ash pickup performance. The cut-off gate below the lower chamber is a manual gate used to isolate the airlock for maintenance.

In some cases, it is necessary to include an aeration device to counteract the tendency of the ash to compact in the hopper and the upper chamber of the airlock valve. The design of the airlock is modified slightly as shown in Fig. 18.

Fig. 17 Airlock valve (without aeration).

When the airlock valve is attached to an economizer hopper, the top gate is commonly left open until the upper chamber is ready to be emptied. This allows the much hotter economizer ash to collect in the upper chamber of the airlock valve to get the ash out of the hot flue gases and reduce the tendency of the ash to sinter and form large chunks. If this occurs despite the use of the airlock as a collection device, then a rotary feeder may be used to break the ash into smaller, transportable pieces.

Automatic butterfly valves at the heads of the branch lines provide branch isolation when ash is being removed from the other branches. Manually operated knife gate valves are provided at the ends of each branch line for maintenance purposes. An overall schematic of a pressurized conveyance system is shown in Fig. 19.

With a pressurized system, the conveying air and entrained ash are simply dumped into a dry storage silo. Ash settles in the silo and air is removed from the top through a self-cleaning bag vent filter. In some cases, the air flow is routed through a duct to the precipitator inlet.

Combination vacuum/pressure systems

Combination systems are used to transport ash longer distances than a vacuum system alone can accommodate, while keeping some of the advantages of the vacuum system, such as its lower space requirement. In the combination system, the initial withdrawal of ash from the hoppers is by a vacuum sys-

Fig. 19 Pressure flyash system.

tem. Ash is delivered to an intermediate collection vessel where it is transferred to a pressure conveying system for final delivery to a distant dry storage silo.

The vacuum system is the same as that described from hopper pickup to the intermediate collection vessel. The intermediate collection vessel can be either a transfer tank or a surge bin. In principle, the surge bin is identical to a dry storage silo, including the primary and secondary separation equipment on the roof. The surge bin is smaller than a storage silo, but provides an intermediate storage volume for ash. The surge bin dumps into airlock valves underneath the bin, which feed ash into the higher pressure line of the pressure conveying system. The pressurized conveying system is the same as described earlier, except that the airlock valves collect from a surge bin.

A vacuum-pressure transfer tank is often used as the intermediate collection vessel. As shown in Fig. 20, the transfer tank is a vessel with three chambers: upper, middle, and lower. The upper chamber is always at the vacuum pressure of the vacuum conveying line, and the lower chamber is always at the higher pressure of the pressurized conveying line. Dump valves are located between the chambers. Ash continuously collects in the upper chamber, which also serves as the primary stage of air/ash separation with the centrifugal separator design of the upper chamber. After a pre-set period of time, the pressure in the upper and middle chamber is equalized, and the dump valve between the upper and middle chamber is opened. When the middle chamber has emptied the upper chamber, the upper dump valve closes. Another valve equalizes the pressure between the middle and lower chamber, and the lower dump valve is opened.

Air that is separated from the ash in the upper chamber is sent to a secondary collector, which includes a fabric bag filter, and then to the inlet of the vacuum producer.

A variation of the vacuum-pressure transfer tank is available for high temperature material separation and transfer. The high temperature tank has a single chamber that provides a centrifugal separator incorporated in the top of the tank, and a bottom section. The tank is constructed with materials and wear surfaces suitable for handling material up to 750F (399C). This tank dumps into airlock valves as shown in Fig. 21. The airlock valves are used as pickup points for the pressurized conveying system.

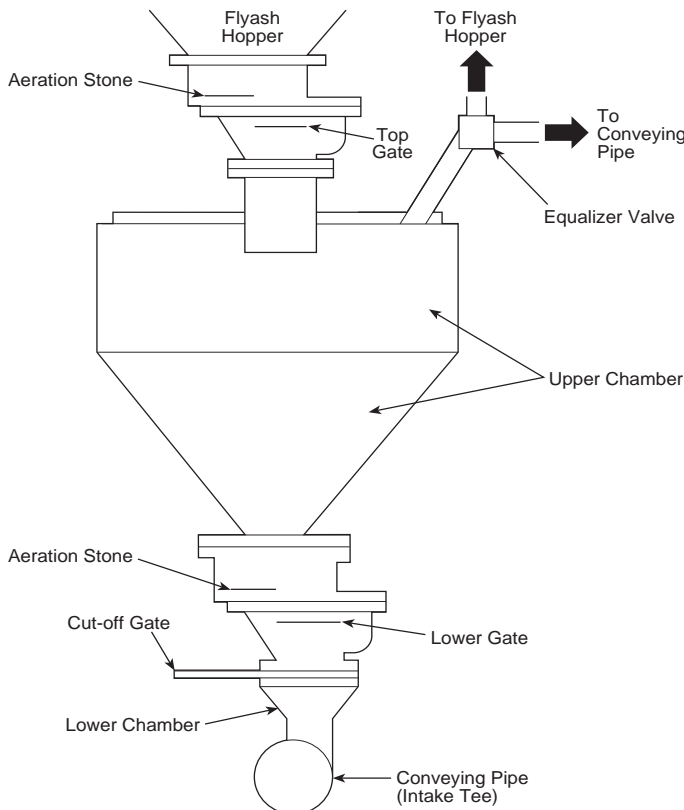

Fig. 18 Airlock valve (with aeration).

Fig. 20 Collection equipment for vacuum-pressure flyash system.

Dense phase systems

An option available for pressurized transport systems is to operate at higher ash to air ratios, which uses less air, smaller transport pipe sizes, and potentially causes less wear of system components. When the weight ratio of flyash to air exceeds about 15 to 1, the transport is referred to as dense phase.

In the systems described up to this point (dilute phase), the ash feed regulating valves were designed to deliver ash into the conveying line as individual particles that would become thoroughly entrained in the air flow. The air flow velocity would generally be maintained above the point where particles would drop out of the flow and drag along the bottom of the pipe.

In dense phase transport, the ash is initially fluidized and transported at lower velocities. The ash is transported through the line in a dense fluid-like condition, often dropping from suspension and resembling moving and shifting sand dunes as the ash moves along the pipe. The key to dense phase transport is that the ash must have a consistency that lends itself to fluidization. Different ash types have different tendencies.

The facilitating element of a dense phase system is the fluidizing vessel commonly called a *transporter*. Ash is delivered to this vessel in batches from the hoppers. When filled with ash, the inlet valve is closed and compressed air is pumped into the vessel.

The transporter vessel can be a top or bottom discharge design. A top discharge, fluidizing transporter vessel is shown in Fig. 22. Compressed air is pumped

into the vessel through an aeration device (stone, ceramic, or metal element) in the bottom of the vessel. The ash becomes fluidized and the pressure in the transporter vessel builds. The aerated ash begins to flow into the conveying line soon after the compressed air is pumped into the transporter vessel. Elastomer-lined pinch valves (not shown) admit ash to the conveying line from one transporter vessel at a time.

A bottom discharge transporter vessel is shown in Fig. 23. In this design, compressed air is also pumped into the vessel, forcing ash into the conveying line. Transport is enhanced by pulsing the air flow into the vessel, and alternating between an injection point in the side of the transporter vessel and an injection point in the conveying line itself. The ash is also fluidized in this design before entering the conveying line, but not in the transporter vessel. Instead, the fluidization with compressed air is done in a holding bin above the transporter vessel so that the ash is already fluidized when it enters the transporter vessel.

A primary advantage of dense phase transport is lower air velocity. This allows use of less expensive, unlined steel pipe. However, much longer radius turns must be used in place of elbows or standard fittings to avoid plugging.

Separation and storage

At the end of the transport piping, ash is separated from the conveying air flow and collected in a dry storage silo. In a pressurized system, the air and ash flow empties into the silo and the air flow is vented from the top of the silo. A fabric (bag) filter may be used to capture any fine dust that is not separated by gravity in the silo, or a vent fan may be used to draw the air from the roof of the silo and pump it back into the

Fig. 21 Vacuum-pressure system for hot flyash.

Fig. 22 Top discharge transporter vessel for dense phase system.

precipitator or baghouse. This venting system must accommodate both the conveying air flow rate and compressed air that is pumped into the silo to aerate the stored ash.

In a vacuum system, a primary collector transfers the ash from the low pressure of the vacuum transport line to the silo, which is at or slightly above atmospheric pressure. The collector is a two chamber device installed on the roof of the silo (Fig. 24). The upper chamber is a centrifugal separator and storage reservoir. A gate between the upper and lower chambers opens periodically to empty ash to the lower chamber, after the chamber pressures have been equalized. Then, the gate is closed, the pressure in the lower chamber is raised to that of the silo, and a gate valve between the lower chamber and the silo is opened. The collected ash flows into the silo by gravity. Therefore, the upper chamber can continuously collect ash from the transport line.

An alternate primary ash collector design replaces the centrifugal separator section shown in Fig. 24 with a stone box inlet pipe that directs the ash downward into the storage section of the upper chamber. Mounted directly above the upper chamber is the pulse-jet style bag filter that removes any fine dust from the transport air stream as the air travels to the vacuum source.

Air removed by the centrifugal separator of the primary collector is sent to a bag filter to remove any fine dust. A secondary collector is sometimes installed upstream of the bag filter. The vacuum source draws air from the bag filter, which by connection back through

the secondary and primary collectors serves as the motive force for the vacuum transfer system.

Storage silos are usually sized to store three days of ash produced by the boiler at full load. Larger boilers have ash silos installed in pairs, so that one can be unloaded or serviced while the other collects ash.

Silos may be made of carbon steel or reinforced concrete construction. The silo has either a cone-shaped or flat bottom, with aeration devices installed inside along the bottom to ensure that the ash will flow freely when the silo is unloaded. Silos may be as tall as 75 ft (23 m). This height tends to compress the ash if well-distributed aeration is not maintained. Heaters may be used to heat the aeration air flow and prevent moisture.

The silo itself is elevated to provide clearance for rail cars or disposal trucks. When the ash is loaded into a closed transport, the silo is fitted with an unloader consisting of a retractable chute. The central telescoping pipe directs ash down into the vehicle's storage tank, while the chute provides a vent path for displaced air from the tank. An exhaust fan pumps the displaced air and dust back into the silo.

Silo unloading equipment

When flyash is to be hauled away by open trucks, dust conditioning is added to the silo unloading equipment. Most commonly, this is simply the addition of water during silo unloading to moisten the ash and minimize the fine particulate that otherwise becomes airborne. The challenge is to add and mix sufficient

Fig. 23 Bottom discharge transporter vessel for dense phase system.

water to keep the dust down, while avoiding the potential to make cement by adding too much water to the calcium compounds. The appropriate amount of moisture is highly dependent on ash composition.

Dust conditioning equipment falls into two general types: batch mixers and continuous mixers. Batch mixers are vessels that collect a load of ash based on weight, stir the ash with mixing paddles and wall scrapers, and slowly add water until a well mixed batch of moistened ash is ready for unloading. Because the ash is weighed as it is loaded into the mixer, the moisture content can be carefully controlled to avoid problems such as cementing, dry pockets of ash, or free-standing water.

Batch mixers may not be rapid enough to support transport schedules. Continuous mixers are smaller and less expensive, and have capacities that allow trucks to be filled in a matter of minutes, one after another.

When the first several truckloads of ash are unloaded from the silo, the head of ash in the silo can be on the order of 40 to 50 ft (12 to 15 m). Simply opening a valve at the bottom of the silo would discharge at too high of a rate to be practical for an operator to control or condition. Continuous mixers use a motor-driven rotary feeder or metering feed gate at the inlet, or an inlet design that limits the input rate.

In high capacity, rotating drum continuous unloaders, incoming ash is aerated in the feed chute before entering the drum. The rotating drum tumbles the ash past a series of scrapers and a spray nozzle manifold. This type of continuous unloader can condition up to 8000 ft³ (226 m³) of flyash per hour, but can be more susceptible to dust bypass.

A lower cost option for continuous conditioning and unloading is referred to as a pugmill. A metering feed gate admits ash into the pugmill's mixing chamber. The mixing chamber is a U-shaped channel with two motor driven shafts with paddles for mixing and propelling the ash from inlet to exit. Spray nozzles are distributed within the chamber for thorough wetting. The chamber is oriented with a slight downward slope to assist ash movement and to drain the pugmill when it is manually cleaned. The top cover of the pugmill is hinged so that the entire chamber is accessible when

Fig. 24 Primary ash collector.

out of service. For ash that has a high tendency to become cement-like, the mixing chamber can be lined and the paddles can be constructed of a high strength, non-stick polymer material.

Hydrobin® dewatering storage bins.

Chapter 25

Boiler Auxiliaries

A variety of auxiliary components are needed for the modern steam generating system to function effectively and efficiently. While space prevents an in-depth review of all items, several deserve special attention. Safety and relief valves are critical to assure the continued safe operation of the boiler. The interplay of dampers, stack design, and fans ensures proper air and gas flow for optimum combustion. Finally, a specialty condenser is used to supply high purity water for attemperator spray in industrial boilers where such water is not typically available.

Safety and relief valves

The most critical valve on a boiler is the safety valve. Its purpose is to limit the internal boiler pressure to a point below its safe operating level. To accomplish this goal, one or more safety valves must be installed in an approved manner on the boiler pressure parts so that they can not be isolated from the steam space. The valves must be set to activate at approved set point pressures (discussed below) and then close when the pressure drops below the set point. When open, the set of safety valves must be capable of carrying all of the steam which the boiler is capable of generating without exceeding the specified pressure rise.

The American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, Section I, outlines the minimum requirements for safety and safety relief valves applying to new stationary water tube power boilers. The Code also covers requirements for safety and safety relief valves for other applications beyond the scope of this text. By Code definition, a *safety valve* is used for gas or vapor service, a *relief valve* is used primarily for liquid service, and a *safety relief valve* may be suitable for use as either a safety or a relief valve.¹

Fig. 1 shows a typical Code approved spring loaded safety valve for steam service. No other valves may be installed between the pressure vessel and the safety valve, nor on the discharge side of the safety valve. The inlet nozzle opening must not be less than the area of the valve inlet, and unnecessary pipe fittings must not be installed. These valves are designed for large

initial opening at the upstream static pressure set point and for maximum discharge capacity at 3% above set point pressure.¹

Fig. 2 shows a typical power actuated type safety valve that may be used in some Code approved applications. Power actuated valves are fully opened at the set point pressure by a controller with a source of power such as air, electricity, hydraulic fluid, or steam.

Fig. 3 shows a typical spring loaded relief valve for liquid service designed for a small initial opening at the upstream static pressure set point. The valve will

Fig. 1 Spring loaded safety valve (courtesy of Dresser Industries, Inc.).

Fig. 2 Typical power actuated safety valve (courtesy of Dresser Industries, Inc.).

continue to open as pressure increases above set point pressure to prevent additional pressure rise.

Because of variations in power boiler designs, Code interpretations are sometimes necessary. It is also necessary to comply with local ordinances. The owner's approval must be obtained for all safety valve settings.

For drum boilers with superheaters, The Babcock & Wilcox Company (B&W) follows the Code procedure in which the safety valves are set such that the superheater valve(s) lift first at all loads. This maintains a flow of steam through the superheater(s) to provide a measure of overheat protection. This method permits the piping and valves downstream of the superheater to be designed for a lower pressure than other methods. This method is required on hand controlled units, stoker or other fuel-bed-fired units, and brick set units. Another method may be used for all other types of boilers that permits the drum safety valves to lift first. This method could allow a reduced flow condition to occur in the superheater while the boiler is still at a high heat input level. As a result, some superheater materials can exceed temperature limits.

The required valve relieving capacities for waste heat boiler applications are determined by the manufacturer. Auxiliary firing must be considered in the selection of safety or safety relief valves. The Code required relieving capacity must be based on the maximum boiler output capabilities by waste heat recovery, auxiliary firing, or the combination of waste heat recovery with auxiliary firing.¹

Additional Code requirements are applicable for

modified existing boilers or new boilers installed in parallel with old boilers, or boilers operated at an initial low pressure but designed for future high pressure (increases or decreases in operating pressure). Additional requirements, including mounting, operation, mechanical, material, inspection and testing of safety and safety relief valves are specified in the Code.

Code requirements for once-through boilers

For safety valve requirements on once-through boilers, the Code allows a choice of using the rules for a drum boiler or special rules for once-through boilers. Power operated valves may be used as Code required valves to account for up to 30% of the total required relief valve capacity. If the power relief valve discharges to an intermediate pressure (not atmospheric), the valve does not have to be capacity certified, but it must be marked with the design capacity at the specified relieving conditions. However, it is important to remember that, in order for a power relief valve discharging to an intermediate pressure to be counted as part of the required safety valve relieving capacity, the intermediate pressure zone must be fully protected with its own relieving capacity.

The power relief valve must be in direct communication with the boiler, and its controls must be part of the plant's essential service network, including required pressure recording instruments. A special iso-

Fig. 3 Spring loaded pressure relief valve (courtesy of Crosby Valve & Gage Company).

lating stop valve may be installed for power relief valve maintenance provided redundant relieving capacity is installed. Provided all the Code requirements are met or exceeded, the remaining required relief capacity is met with spring loaded valves set at 17% above master stamping pressure. The superheater division valves (Chapter 19) are part of the power relief valve system so that credit may be taken for the spring loaded superheater outlet valve(s) relieving capacity as part of the total required relieving capacity. With a superheater division valve, the code requires 6 lb/h relieving capacity per each square foot of superheater heating surface (0.008 kg/s per m²). The blowdown of the spring loaded valves shall not be less than 8% nor more than 10% of set pressure. (See Code, Section 1.)¹

Air and flue gas dampers

Dampers are used to control flow and temperature of air and flue gas. They can also be used to isolate equipment in the air or flue gas streams when such equipment is out of service or requires maintenance.

The Air Movement and Control Association in Publication 850-02, *Application and Specification Guide for Flue Gas Isolation and Control Dampers*, defines both the isolation and control functions for the selection of dampers.²

Isolation dampers may be the nominal shutoff or zero leakage type. Shutoff dampers are used in applications where some limited leakage is tolerable. All types of dampers, with appropriate blade seals, can be used. Zero leakage dampers are designed to prevent any flow media leakage past the closed damper. This is accomplished by overpressurizing the blade seal periphery with seal air, which leaks back into the system. Guillotine-type dampers are best suited for this service. A pair of dampers or pairs of blades within one damper with an overpressurized air block between them can also be used. In heat recovery steam generator (HRSG) applications, diverter dampers are often used along with stack cap dampers to assist in maintaining boiler temperature during overnight shutdowns.

Control dampers are capable of providing a variable restriction to flow and may be of several varieties.²

Balancing dampers are used to balance flow in two or more ducts. *Preset position* dampers are normally open or normally closed dampers which move to an adjustable preset position on a signal. *Modulating* dampers are designed to assume any position between fully open and fully closed in response to a varied signal (either pneumatic or electric). A positioner with feedback indication is normally required.²

Dampers may also be classified by shape or configuration. Damper shape classifications that are commonly used in the fossil fuel-fired steam generation industry are *louver*, *round* (or *wafer*) and *guillotine* (or *slidegate*).

Louver dampers

A louver damper, as shown in Fig. 4, is characterized by one or more blades that mount into bearings

located in a rigid frame. They are generally rectangular in shape. One blade shaft end extends far enough beyond the frame so that a drive can be mounted for damper operation. Ideally, blade shape is determined by the amount of pressure drop that can be tolerated across the open damper. In reality, it is usually a compromise among the following design goals: the ideal shape required for minimizing pressure drop, the ideal shape for minimizing initial cost, and the ideal shape to attain the required structural strength to withstand pressure and temperature conditions. An unreinforced flat plate is the simplest shape but is relatively weak and offers the greatest pressure drop. Air foil shaped blades have lower pressure losses and have somewhat greater strength. If uniform downstream flow distribution is required, opposed blade rotation is used; otherwise, parallel blade rotation may be used. (See Fig. 5.)

If the louver damper is to be used for isolation purposes, thin, flexible metallic seal strips are mounted on the blades to minimize leakage around the closed blades. Seal strips are not required in applications where louver dampers are used for flow control.

Depending on the application, louver dampers may have internal or external bearings. External bearings are of the self-aligning and self-lubricating ball or sleeve type, which require a mounting block and packing gland. In extreme conditions, packing glands may have a seal air provision. Internal bearings are machined castings with a self-cleaning feature. These types of bearings do not require lubrication and elimi-

Fig. 4 Opposed-blade louver damper (adapted from Mader Damper Co.).

Fig. 5 Louver damper blade arrangement options (courtesy of Air Movement and Control Association, Inc.).

nate the need for the damper shaft to penetrate the frame, eliminating the maintenance associated with shaft seals.

Round or wafer dampers

Round dampers, as shown in Fig. 6, can be used for control or shutoff service. Due to higher allowable velocity limits, they are usually smaller than louver dampers and have a smaller seal edge to area ratio, which makes them more efficient for shutoff applications. They can also be configured in a two or more blade configuration with opposed operation for flow control as shown in Fig. 7, although this arrangement tends to reduce sealing efficiency.

Guillotine or slidegate dampers

Guillotine dampers have an external frame and drive system that can insert and withdraw the blade which acts as a blanking plate in the full cross-section of the duct. This minimizes the sealing edge required for any given duct size. The blade periphery is surrounded by, and forced between, flexible metal sealing strips. On zero leakage dampers, such as

Fig. 6 Wedge seat round damper (courtesy of Damper Design, Inc.).

Fig. 7 Two-bladed wafer damper.

shown in Fig. 8, the blade edge extends through the frame into a seal chamber that is pressurized by a seal air blower. Seals for this type of damper are normally designed to eliminate reverse flexing. The blade is actuated by a chain and sprocket, pneumatic cylinder, hydraulic cylinder, or screw-type mechanism, connected to a drive which is mounted on the frame. Guillotines are typically large and used for isolation service, preferably in horizontal ducts. It is not uncommon for blade thickness to reach 0.75 in. (19 mm), and blade thicknesses exceeding 1 in. (25.4 mm) have been used.

Fig. 8 Guillotine damper (courtesy of Effox, Inc.).

Expansion joints

Expansion joints are used in duct systems, wind-boxes, and other areas of the boiler and air quality control system islands to allow for relative movement between components of a system. This relative movement is usually caused by thermal expansion and contraction. Expansion joints are available in various configurations and can feature flow liners and insulation pillows to allow for a wide range of temperature and dust conditions. They are generally of metal construction or constructed of elastomers and composite materials, and are designed for maximum flexibility under the required service conditions.

The most common configuration for a metallic expansion joint is the multi-leaf or box fold joint. (See Fig. 9.) The box fold is normally external but can be internal if space considerations require. However, if an internal fold is used, the additional pressure drop caused by the flow area restriction must be accounted for when sizing the draft equipment. Also, internal folds could be subject to erosion damage in a dirty gas environment. If the external fold expansion joint is placed in a dirty environment, the folds are packed (intermediate temperature fiberglass insulating block is a typical packing) and the packed folds are shielded, typically with 10 gauge sheet of the same class material as the duct. Hinged shields are often used to permit field packing of the joint folds. The extent and location of packing and shielding are dictated by the joint designer's field experience. Nonmetallic joints also require packing and shielding as dictated by the designer's field experience.

Fig. 9 Multi-leaf metallic expansion joint with pinned support connection.

A metallic expansion joint can accept toggle and axial motion but is unable to accept significant shear motion. For that reason, whenever two components must be connected that are displacing relative to one another in a shear plane, two metallic expansion joints must be employed by placing them at opposite ends of a duct *toggle section* as shown in Fig. 9. A metallic joint has a pinned support connection which defines its toggle axis. Side pins are used to transmit gravity loads across a joint and may pass through either round or slotted holes. Center pins may also be used to transmit loads of pressure and to actuate another expansion joint in series.

Nonmetallic joints (Fig. 10) are able to accept shear (three-way) motion, which is their primary advantage over metallic joints. For this reason, nonmetallic joints do not require a toggle section and only one joint is required for most applications. Nonmetallic joints are made with reinforced elastomers or Teflon coated woven fiberglass, and are normally the plain flat belt type. Flanged or U-type joints are also available. If design temperatures are above the use limit of the belt material, composite belts with an insulation liner are used and may include an insulation pillow for the higher temperatures.

It is essential that all relative motions between components be completely accounted for when designing

Fig. 10 Nonmetallic expansion joint.

the connecting expansion joint, and that design pressures and temperatures appropriate for the type of service be used for material and thickness selection. Failure to do so can result in premature failure of the expansion joint.

Stacks and draft

An adequate flow of air and combustion gases is required for the complete and effective combustion of fossil and chemical fuels. Flow is created and sustained by stacks and fans. Either the stack alone, or a combination of stack and fans, produces the required pressure head to generate the required flow.

Draft is the difference between atmospheric pressure and the static pressure of combustion gases in a furnace, gas passage, flue or stack. The flow of gases through the boiler can be achieved by four methods of creating draft, referred to as forced draft, induced draft, balanced draft and natural draft.

Forced draft boilers operate with the air and combustion products (flue gas) maintained above atmospheric pressure. Fans at the inlet to the boiler system provide sufficient pressure to force the air and flue gas through the system. Any openings in the boiler settings, such as opened doors, allow air or flue gas to escape unless the opening is also pressurized.

Induced draft boilers operate with air and gas static pressure below atmospheric. The static pressure is progressively lower as the gas travels from the air inlet to the induced draft fan. The required flow through the boiler can be achieved by the stack alone when the system pressure loss is low or when the stack is tall; this is called *natural draft*. For most modern boilers, a fan at the boiler system outlet is needed to draw flow through the boiler. Unlike forced draft units, air from the boiler surroundings enters through (infiltrates) any openings in the boiler setting.

Balanced draft boilers have a forced draft air fan at the system inlet and an induced draft fan near the system outlet. The static pressure is above atmospheric at the forced draft fan outlet and decreases to atmospheric pressure at some point within the system (typically the lower furnace). The static pressure is subatmospheric and progressively decreases as the gas travels from the balance point to the induced draft fan. This scheme reduces both flue gas pressure and the tendency of hot gases to escape. There are also power savings for this method because forced draft air fans require smaller volumetric flow rates and therefore less energy for a given mass flow. Most modern boilers are balanced draft for these reasons.

Draft loss is the reduction in static pressure of a gas caused by friction and other nonrecoverable pressure losses associated with the gas flow under real conditions. As discussed in Chapter 3, static pressure is related to the total pressure at a location by the addition of the velocity or dynamic pressure.

$$P_{total} = P_s + P_v = P_s + \frac{V^2}{2g_c v} \quad (1)$$

where

$$\begin{aligned} P_{total} &= \text{total pressure, lb/ft}^2 \text{ (N/m}^2\text{)} \\ P_s &= \text{static pressure, lb/ft}^2 \text{ (N/m}^2\text{)} \\ P_v &= \text{velocity pressure, lb/ft}^2 \text{ (N/m}^2\text{)} = V^2 / 2g_c v \\ V &= \text{average gas velocity} \\ v &= \text{specific volume of the gas} \\ g_c &= \text{conversion constant} \\ &= 32.17 \text{ lbf ft/lbf s}^2 = 1 \text{ kgm/Ns}^2 \end{aligned}$$

Stack effect

Stack effect (SE), or chimney action, is the difference in pressure caused by the difference in elevation between two locations in vertical ducts or passages conveying heated gases at zero gas flow. It is caused by the difference in density between air and heated gases, whether air or flue gas. The stack effect is independent of gas flow and can not be measured with draft gauges. Draft gauges combine stack effect and flow losses. The intensity and distribution of this pressure difference depends on the height, the arrangement of ducts, and the average gas temperature in the duct and ambient air temperature.

Based upon this definition, the overall stack effect in its most general form is defined as:

$$\Delta P_{SE} = \frac{g}{g_c} Z (\rho_a - \rho_g) = \frac{g}{g_c} Z \left(\frac{1}{v_a} - \frac{1}{v_g} \right) \quad (2)$$

where

$$\begin{aligned} \Delta P_{SE} &= \text{stack draft effect driving pressure, lb/ft}^2 \text{ (N/m}^2\text{)} \\ g &= \text{acceleration of gravity} = 32.17 \text{ ft/s}^2 \text{ (9.8 m/s}^2\text{)} \\ g_c &= 32.17 \text{ lbf ft/lbf s}^2 \text{ (1 kgm/Ns}^2\text{)} \\ Z &= \text{elevation between points 1 and 2, ft (m)} \\ \rho_a &= \text{density of air at ambient conditions, lb/ft}^3 \text{ (kg/m}^3\text{)} \\ \rho_g &= \text{average density of flue gas, lb/ft}^3 \text{ (kg/m}^3\text{)} \\ v_a &= \text{specific volume of air at ambient conditions, ft}^3\text{/lb (m}^3\text{/kg)} \\ v_g &= \text{average specific volume of flue gas, ft}^3\text{/lb (m}^3\text{/kg)} \end{aligned}$$

The customary English units used for draft calculations are inches of water for draft pressure loss and feet for stack height or elevation. Using this system of units, the incremental stack effect (inches of pressure loss per foot of stack height) can be evaluated from:

$$SE = \left(\frac{1}{v_a} - \frac{1}{v_g} \right) \left(\frac{1}{5.2} \right) \quad (3)$$

where

$$SE = \text{stack effect, in./ft}$$

For convenience, Table 1 provides the specific volume of air and flue gas at one atmosphere and 1000R (556K). Assuming air and flue gas can be treated as ideal gases, the ideal gas law in Chapter 3 permits calculation of the specific volume at other conditions:

Table 1
Sample Specific Volumes at 1000R (556K)
and One Atmosphere

Gas	v_b (ft ³ /lb)	v_b (m ³ /kg)
Dry air	25.2	1.57
Combustion air (0.013 lb water/lb dry air)	25.4	1.58
Flue gas (3% water by wt)	24.3	1.5
Flue gas (5% water by wt)	24.7	1.54
Flue gas (10% water by wt)	25.7	1.60

$$v = v_R \left(\frac{T_f}{T_R} \right) \left(\frac{B_R}{B} \right) \quad (4)$$

where

- v = specific volume at T_f and B , ft³/lb (m³/kg)
- v_R = specific volume at T_R and B_R , ft³/lb (m³/kg)
- T_f = average fluid temperature, R (K)
= T_f (F) + 460 (T_f (C) + 256)
- B = barometric pressure (see Table 2), in. Hg (kPa)
- T_R = 1000R (556K)
- B_R = 30 in. Hg (101.6 kPa)

Table 3 provides a reference set of values for SE at one atmosphere. The total theoretical draft effect of a stack or duct at a given elevation above sea level can be calculated from Equation 1 or from:

$$\text{Stack draft} = Z (SE) \left(\frac{B_{\text{elevation}}}{B_{\text{sea level}}} \right) \quad (5)$$

where

- Z = stack height, ft (m)
- SE = stack effect, in./ft (Table 3 or Equation 2)
- $B_{\text{elevation}}$ = barometric pressure at elevation (Table 2)
- $B_{\text{sea level}}$ = barometric pressure at sea level (Table 2)

The average gas temperature in these calculations is assumed to be the arithmetic average temperature entering and leaving the stack or duct section. For gases flowing through an actual stack, there is some heat loss to the ambient air through the stack struc-

Table 2
Barometric Pressure, B — Effect of Altitude

Ft Above Sea Level	Pressure in. Hg	kPa	Ft Above Sea Level	Pressure in. Hg	kPa
0	29.92	760	6000	23.98	609
1000	28.86	733	7000	23.09	586
2000	27.82	707	8000	22.22	564
3000	26.82	681	9000	21.39	543
4000	25.84	656	10,000	20.58	523
5000	24.90	632	15,000	16.89	429

Values from Publication 99, Air Moving and Conditioning Association, Inc., 1967.

ture. There is also some infiltration of cold air. The total loss in temperature in a stack depends upon the type of stack, stack diameter, stack height, gas velocity, and a number of variables influencing the outside stack surface temperature. Fig. 11 indicates an approximate stack exit temperature relative to height, diameter, and inlet gas temperature.

Sample stack effect calculation

Fig. 12 illustrates the procedure used in calculating stack effect. The stack effect can either assist or resist the gas flow through the unit. The three gas passages are at different temperatures and the example is at sea level. For illustrative purposes, assume atmospheric pressure, i.e., (draft = 0) at point D.

Stack effect always assists up-flowing gas and resists down-flowing gas. Plus signs are assigned to up flows and minus signs to down flows. Using values from Table 3 for an ambient air temperature of 80F (27C), the stack effect in inches of water for each passage is:

Stack effect C to D = + (110 × 0.0030) = +0.33 in. H₂O

Stack effect B to C = - (100 × 0.0087) = -0.87 in. H₂O

Stack effect A to B = + (50 × 0.0100) = +0.50 in. H₂O

Fig. 11 Approximate relationship between stack exit gas temperature and stack dimensions.

Table 3
Reference Set of Stack Effect (SE) Values
in. of H₂O/ft of Stack Height — English Units Only

Reference Conditions:

Air — 0.013 lb H₂O/lb dry air: 13.7 ft³/lb, 80F, 30 in. Hg
Gas — 0.04 lb H₂O/lb dry gas: 13.23 ft³/lb, 80F, 30 in. Hg
Barometric pressure 30 in. Hg

Avg. Temp in Flue or Stack, T _g	Ambient Air Temperature, T _a , F			
F	40	60	80	100
250	0.0041	0.0035	0.0030	0.0025
500	0.0070	0.0064	0.0059	0.0054
1000	0.0098	0.0092	0.0087	0.0082
1500	0.0112	0.0106	0.0100	0.0095
2000	0.0120	0.0114	0.0108	0.0103
2500	0.0125	0.0119	0.0114	0.0109

If draft gauges are placed with one end open to the atmosphere at locations A, B, C and D of Fig. 12, the theoretical zero flow draft readings are:

Draft at D = 0 in. H₂O

Draft at C = draft at D minus stack effect C to D
= 0 - (+ 0.33) = - 0.33 in. H₂O

Draft at B = draft at C minus stack effect B to C
= - 0.33 - (- 0.86) = + 0.53 in. H₂O

Draft at A = draft at B minus stack effect A to B
= + 0.53 - (+ 0.50) = + 0.03 in. H₂O

Note that because the calculation of stack effect in this example is opposite to the gas flow, stack effects are subtracted in calculating static pressures or drafts. If the stack effect is in the direction of gas flow, stack effects should be added.

The net stack effect from A to D in Fig. 12 is the sum of all three stack effects and is -0.03 in. For this reason, fans or stack height must be selected not only to provide the necessary draft to overcome flow loss through the unit, but also to allow for the net stack effect of the system.

In some boiler settings, gases leak from the upper portions when the unit is operating at very low loads or when it is taken out of service. The leakage can occur even though the outlet flue may show a substantial negative draft. The preceding example illustrates this type of low to no flow condition with a suction or negative pressure at the bottom of the uptake flue C-D and positive pressures at both points A and B in Fig. 12.

Chimney or stack

Early boilers operated with natural draft caused by the stack effect alone. However, for large units equipped with superheaters, economizers and especially air heaters, it is not practical or economical to operate the entire unit from stack induced draft alone. These units require fans to supplement the stack induced draft. The entire unit might be pressurized by a forced draft fan or the unit might use both induced and forced draft fans for balanced draft operation. The

combination of only an induced draft fan and stack is not commonly used.

The required height and diameter of stacks for natural draft units depend upon:

1. draft loss through the boiler from the point of balanced draft to the stack entrance,
2. average temperature of the gases passing up the stack and the temperature of the surrounding air,
3. required gas flow from the stack, and
4. barometric pressure.

No single formula satisfactorily covers all of the factors involved in determining stack height and diameter. The most important points to consider are: 1) temperature of the surrounding atmosphere and temperature of the gases entering the stack, 2) drop in temperature of the gases within the stack because of heat loss to the atmosphere and air infiltration, and 3) stack draft losses associated with gas flow rate (due to fluid friction within the stack and the kinetic energy of gases leaving the stack).

Stack flow loss

The net stack draft, or available induced draft at the stack entrance, is the difference between the theoretical draft calculated by Equations 2, 3 and 4 and the pressure loss due to gas flow through the stack.

From Equation 46 in Chapter 3 for friction loss, plus one velocity head exit loss ($G^2v/2gc$):

$$\Delta P_l = f \frac{L}{D} \frac{G^2}{2g_c} v + \frac{G^2}{2g_c} v \quad (6)$$

Fig. 12 Diagram illustrating stack effect, or chimney action, in three vertical gas passes arranged in series.

where

- ΔP_l = stack flow loss, lb/ft² (N/m²)
 f = friction factor, dimensionless (Chapter 3, Fig. 1: ≈ 0.014 to 0.017)
 L = length of stack = Z , ft (m)
 D = stack diameter, ft (m)
 G = mass flux = \dot{m}/A , = lb/h ft² (kg/m² s)
 \dot{m} = mass flow rate, lb/h (kg/s)
 A = stack cross-sectional area, ft² (m²)
 v = specific volume at average temperature, ft³/lb (m³/kg)
 g_c = 32.17 lbf ft/lbf s² (1 kgm/Ns²)

For English units this reduces to:

Stack flow loss =

$$\Delta P_l = \frac{2.76}{B} \frac{T_g}{D_i^4} \left(\frac{\dot{m}}{10^5} \right)^2 \left(\frac{fL}{D_i} + 1 \right) \quad (7)$$

where

- ΔP_l = stack flow loss, in. of water
 \dot{m} = mass flow rate, lb/h
 B = barometric pressure, in. Hg
 T_g = average absolute gas temperature, R
 D_i = internal stack diameter, ft
 f = friction factor from Chapter 3, Fig. 1, dimensionless
 L = stack height above gas entrance, ft

The equation user is reminded that there is a gas-flue-to-stack-entrance exit loss that is not included in the above equation, which must be accounted for when determining overall system pressure losses.

Stack flow losses for natural draft units are typically less than 5% of the theoretical stack draft. Also, that part of the loss due to unrecoverable kinetic energy of flow (exit loss) is from three to seven times greater than the friction loss, depending on stack height and diameter.

Sample stack size selection

Tentative stack diameter and height for a given draft requirement can be calculated using English units with Figs. 11, 13 and 14 and an assumed stack exit gas temperature. Adjustments to these values are then made as required, by verification of the assumed stack exit temperature, a flow loss check and altitude correction, if necessary. The following example illustrates this sizing procedure:

Unit Specifications:

Fuel	Pulverized coal
Steam generated, lb/h	360,000
Stack gas flow, lb/h	450,000
Stack inlet gas temp., F	550
Required stack draft (from point of balanced draft to stack gas entrance), in. H ₂ O	1.0
Plant altitude	Sea level

Initial Assumption:

Stack exit gas temperature, F	450
-------------------------------	-----

Fig. 13 Stack height required for a range of stack drafts and average stack gas temperatures.

If the stack gas flow is not specified, the following approximate ratios may be used:

Type of Firing	Gas Weight/Steam Flow Ratio
Oil or gas	1.15
Pulverized coal	1.25
Stoker	1.50

The stack diameter to the nearest 6 in. increment from Fig. 14 for 450,000 lb/h stack gas flow is 14 ft 6 in. For the required stack draft of 1.0 in. (increased to 1.1 in. for safety) and an average stack gas temperature of 500F, based on the specified inlet temperature of 550F and assumed exit temperature of 450F, Fig. 13 gives an approximate height of 187 ft. A check of the assumed stack exit temperature is obtained from Fig. 11, with the tentative height of 187 ft, diameter of 14 ft 6 in. and inlet temperature of 550F. This result is 430F, or an average stack temperature of 490F and draft of 1.1 in. H₂O. Fig. 13 is again used to establish a stack height neglecting stack flow losses. This height is 190 ft.

Assuming a stack flow loss of 5%, the final required stack height is 200 ft (190/0.95). This represents the active height of the stack. The height of any inactive section from foundation to stack entrance must also be included.

The stack flow loss is checked using the above values for diameter, height, average gas temperature and gas flow in Equation 6. A check of available net draft, using Equation 2, indicates that the 1.0 in. draft requirement is amply covered.

If the plant is not located at sea level, the draft re-

Fig. 14 Recommended stack diameter for a range of gas flows.

quirement of the unit must be increased by multiplying the draft by the altitude factor $30/B$ and the theoretical stack draft decreased by multiplying the theoretical draft by $B/30$, where B is the normal barometric pressure, inches of mercury, at the boiler site (Table 2).

External factors affecting stack height

The stack also functions to disperse combustion gases. Increasing stack height enlarges the area of dispersion. In narrow valleys or locations where there is a concentration of industry, it may be necessary to provide increased stack height.

Some power plants located near airports are prohibited from using stacks high enough to provide adequate dispersion. In such cases, the stack may be reduced in diameter at the top to increase the discharge velocity, simulating the effect of a higher stack. However, necking down the stack adds an appreciable amount of flow resistance which can only be accommodated by a mechanical draft system.

Stack design

After the correct stack height and diameter are established, there are economic and structural factors to consider in designing the stack. Stack material selection is influenced by material and erection costs, stack height, means of support (i.e., whether the stack is supported from a steel structure or a foundation), and erosive and corrosive constituents in the flue gas. After selecting the material, the stack is checked for structural adequacy, making both a static and a dynamic analysis of the loads.

Stack operation and maintenance

All connections to the stack should be air tight and sealed with dampers when not in use. Cold air leaks into the stack during operation, reducing the average

gas temperature and the stack effect. Leaks also increase the gas flow and erosion potential in the stack.

A stack is subjected to the erosive action of particulate, acid corrosion from sulfur products, and weathering. Erosion is most common at the stack entrance, throats, necked down (reduced diameter) sections, and locations where the direction or velocity of gas changes. Abrasion resistant materials or erosion shields at these locations can reduce stack maintenance.

Fans

A fan moves a quantity of air or gas by adding sufficient energy to the stream to initiate motion and overcome resistance to flow. The fan consists of a bladed rotor, or impeller, which does the actual work, and usually a housing to collect and direct the air or gas discharged by the impeller. The power required depends upon the volume of air or gas moved per unit of time, the pressure difference across the fan, and the efficiency of the fan and its drives.

Power

Power may be expressed as shaft horsepower, input horsepower to motor terminals if motor driven, or theoretical horsepower which is computed by thermodynamic methods.

Fan power consumption can be expressed as:

$$\text{Power} = k \frac{\Delta P \dot{V}}{\eta_f C} \quad (8)$$

where

- Power = shaft power input, hp (kW)
- ΔP = pressure rise across fan, in. wg (kPa)
- \dot{V} = inlet volume flow rate, ft³/min (m³/s)
- η_f = fan mechanical efficiency, 100% = 100
- k = compressibility factor, dimensionless (see equation 9 below and Table 4)
- C = constant of 6354 (1.00 for SI)

The compressibility factor k is calculated using the following formula:

$$k = \frac{\frac{\gamma}{\gamma-1} \left[\left(\frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right]}{\frac{P_2}{P_1} - 1} \quad (9)$$

where

- γ = specific heat ratio (1.4 for air)
- P_1 = absolute inlet pressure (any unit)
- P_2 = absolute outlet pressure (any unit, $P_2 = P_1 + P_T$)

An approximate value for k can be calculated by using:

$$k_{\text{approx}} = 1 - \frac{P_T}{C_{EST}}$$

where

$$\begin{aligned} P_T &= \text{fan total pressure, in. wg} \\ C_{EST} &= 1150 \text{ for } P_T < 10 \text{ in. wg} \\ &= 1200 \text{ for } P_T < 40 \text{ in. wg} \\ &= 1250 \text{ for } P_T < 70 \text{ in. wg} \end{aligned}$$

All fluids and especially gases are compressible. The effects of compressibility are accounted for in the fan laws by including a compressibility coefficient.

Approximate ranges of fan efficiencies and compressibility factors for use in Equation 8 are provided in Table 4. The term fan efficiency can be misleading because there are a number of ways it can be defined. Fan efficiency can be calculated across the fan rotor only, across the fan housing (inlet to outlet) with no allowance for efficiency losses caused by inlet or outlet duct configuration, or across the housing with losses induced by inlet and outlet ducting included. The fan vendor can usually recommend the best duct arrangement at the fan inlet and outlet to minimize these losses. To select the proper fan motor, shaft input power must be calculated using the efficiency that accounts for all of the losses associated with the fan type, including losses caused by inlet and outlet duct arrangement.

In order to use the above formula, the volume flow must be known. Since the engineer often calculates boiler air and flue gas flows in mass units (lb/h, kg/s, etc.) by using the various heat and material balances published in performance test codes or other standards, it is advantageous to have a quick conversion method for calculating volume flow (cfm, m³/s). The conversion formula for arriving at volume flow when mass flow is known is:

$$\dot{V}(\text{cfm}) = \dot{m} \times \rho_{ref} \times \left(\frac{T_a}{T_{ref}} \right) \times \left(\frac{P_{ref}}{P_a} \right) \times F \quad (10)$$

where

$$\begin{aligned} \dot{V} &= \text{volumetric flow rate, cfm or ft}^3/\text{min (m}^3/\text{s)} \\ \dot{m} &= \text{gas flow, lb/h (kg/s)} \\ \rho_{ref} &= \text{gas density at reference temperature, lb/ft}^3 \text{ (kg/m}^3\text{)} \\ T_a &= \text{actual temperature, R (K)} \\ T_{ref} &= \text{reference temperature, R (K)} \\ P_{ref} &= \text{reference pressure, psi (Pa)} \\ P_a &= \text{actual pressure, psi (Pa)} \\ F &= \text{time unit correction factor} \\ &= 1/60 \text{ English Units (1.00 for SI)} \end{aligned}$$

Another method used to calculate power consumption involves the concept of adiabatic head. If total pressure rise is known, adiabatic head can be calculated using the following formula:

$$Hd = \frac{(k)(\Delta P)(C)}{\rho} \quad (11)$$

where

$$\begin{aligned} Hd &= \text{developed adiabatic head of gas column, ft (m)} \\ k &= \text{compressibility factor} \end{aligned}$$

Table 4
Mechanical Efficiency — Approximate Ranges (η_f)

Centrifugal fan							
	Paddle blade						45 to 60%
	Foward curved blade						45 to 60%
	Backward curved blades						75 to 85%
	Radial tipped blades						60 to 70%
	Air foil						80 to 90%
	Axial flow fan						85 to 90%
Approximate compressibility factors (air)							
$\Delta P/P$	0	0.03	0.06	0.09	0.12	0.15	0.18
k	1	0.99	0.98	0.97	0.96	0.95	0.94

ΔP = total pressure increase, in. wg (kPa)

ρ = actual density, lb/ft³ (kg/m³)

C = constant of 5.20 (1.00 for SI)

Using the adiabatic head concept as defined by Equation 11, fan shaft input power can be calculated as:

$$\text{Power} = \frac{(\dot{m})(Hd)(C)}{\eta_f} \quad (12)$$

where

\dot{m} = gas flow, lb/h (kg/h)

C = constant of 0.505×10^{-6} (2.724×10^{-6} for SI)

Fan performance

Stacks seldom provide sufficient natural draft to cover the requirements of modern boiler units. These higher draft loss systems require the use of mechanical draft equipment, and a wide variety of fan designs and types is available to meet this need.

Fan performance is best expressed in graphic form as fan curves (Fig. 15) which provide static pressure (head), shaft horsepower and static efficiency as functions of capacity or volumetric flow rate. Because fan operation for a given capacity must match single values of head and horsepower on the characteristic curves, a balance between fan static pressure and system resistance is required.

Varying the operating speed (rpm) to yield a family of curves, as shown in Fig. 16, will change the numerical performance values of the curve characteristics. However, the shape of the curves remains substantially unaltered. Changes in operation of fans can generally be predicted from the *Laws of Fan Performance*:

1. *Fan speed variation* (for constant fan size, density and system resistance)
 - a) Capacity [ft³/min (m³/min)] varies directly with speed.
 - b) Pressure varies as the square of the speed.
 - c) Power varies as the cube of the speed.
2. *Fan size variation* (geometrically similar fans, constant pressure, density and rating)
 - a) Capacity varies as the square of wheel diameter.
 - b) Power varies as the square of wheel diameter.
 - c) Rpm varies inversely as wheel diameter.

Fig. 15 Characteristic curves for two types of centrifugal fans operating at 5500 ft (1676 m) elevation and 965 rpm.

3. *Gas density variation* (constant size and speed plus constant system resistance or point of rating).
 - a) Capacity remains constant.
 - b) Pressure varies directly as gas density.
 - c) Power varies directly as gas density.

Operating a fan at a temperature below design temperature will cause the shaft horsepower requirement to increase as a function of density ratio or absolute temperature ratio. In addition, if a different gas of a higher density is handled, the shaft horsepower will increase with the ratio of the densities. Because such operating conditions typically occur at startup, the inlet vanes or inlet louvers should be closed before the fan is started up.

The pressure increase of the fan also will rise as a function of the higher gas densities. This condition

should be taken into account when designing flues, ducts, expansion joints, dampers, and other components.

In summary, as temperature decreases, density increases, and pressure rise of the fan increases. As an example:

Temperature	Density (lb/ft ³)	Static pressure rise (in. wg)
300F	0.0504	30.0
250F	0.0538	32.1
100F	0.0684	40.8

Geometrically similar fans have similar operating characteristics. Therefore, the performance of one fan can be predicted by knowing how a smaller or larger fan operates. The two main performance factors (speed and head) are linked in the concept of specific speed and specific diameter.

Specific speed is the rpm at which a fan would operate if reduced proportionately in size so that it delivers 1 ft³/min of air at standard conditions, against a 1 in. wg static pressure.

Fig. 16 Graph showing how desired output and static pressure can be obtained economically by varying fan speed to avoid large throttling losses.

Specific diameter is fan diameter required to deliver 1 ft³/min standard air against a 1 in. wg static pressure at a given specific speed. The fan laws lead to these equations:

$$\text{Specific speed } (N) = \frac{\text{rpm} \left(\text{ft}^3/\text{min} \right)^{\frac{1}{2}}}{\left(\text{SP} \right)^{\frac{3}{4}}} \quad (13)$$

$$\text{Specific diameter } (D) = \frac{D \left(\text{SP} \right)^{\frac{1}{4}}}{\left(\text{ft}^3/\text{min} \right)^{\frac{1}{2}}} \quad (14)$$

where flow in ft³/min is at standard conditions, *SP* is static pressure (in. wg) and *D* is fan diameter (in.).

Because there is only one value of specific speed at the point of maximum efficiency for any fan design, that value serves to identify the particular design. The same is true for specific size. If either specific speed or specific size can be established from the requirements of an application, only those designs with corresponding identifying values need to be considered.

Fan capacity margins

To make sure that the fans will not limit boiler performance, margins of safety are added to the calculated or net fan requirements to arrive at a satisfactory test block specification. These margins are intended to cover conditions encountered in operation that can not be specifically evaluated. For example, variation in fuel ash characteristics or unusual operating conditions slag or foul heating surfaces. The unit then requires additional draft. Air heater leakage can increase to higher than expected levels because of incorrect seal adjustment or seal wear. Stoker-fired boilers, burning improperly sized coal, may require more than normal pressure to force air through the fuel bed. A need for rapid load increase or a short emergency overload often calls for overcapacity of the fans. The customary margins to allow for such conditions include: 1) 15 to 20% increase in the net weight flow of air or gas, 2) 20 to 30% increase in the net head, and 3) 25F (14C) increase in the air or gas temperature at the fan inlet.

System effects and fan margin

System effects is a label given to adverse conditions at the fan inlet and outlet that can cause increased static pressure losses. These conditions may not have been foreseen by the fan purchaser or the fan supplier. It is important to account for all system effects and to ensure that they are included in the fan's net static pressure requirements. If system effects are not fully considered, fan margins will be less than anticipated. System effects may include:

1. elbows located close to fan discharge,
2. insufficient duct length at the fan discharge,
3. improper inlet conditions, e.g. elbow located too close to the fan inlet, or
4. elbows without turning vanes or splitters.

The fan manufacturer can review the proposed ductwork layout and offer suggestions to minimize these effects. Of particular importance are effects caused by improper design of the transition duct from fan outlet(s) to final duct cross-section downstream of fan outlet. The ideal evase shape for low pressure drop may not be attainable in the space available.

Typical fan applications

Forced draft fan

Boilers operating with both forced and induced draft use the forced draft fan to push air through the combustion air supply system into the furnace. (See Fig. 17.) The fan must have a discharge pressure high enough to equal the total resistance of air ducts, air heater, burners or fuel bed, and any other resistance between the fan discharge and the furnace. This makes the furnace the point of balanced draft or zero pressure. Volume output of the forced draft fan must equal the total quantity of air required for combustion plus air heater leakage. In many installations, greater reliability is obtained by dividing the total fan capacity between two fans operating in parallel. If one fan is out of service, the other usually can carry 60% or more of full boiler load, depending on how the fans are sized.

To establish the required characteristics of the forced draft fan, the system resistance from fan to furnace is calculated for the actual weight of air required for combustion plus the expected leakage from

Fig. 17 Forced draft centrifugal fan for a 364 MW outdoor unit.

the air side of the air heater. It is design practice to base all calculations on 80F (27C) air temperature entering the fan. The results are then adjusted to test block specifications by the margin factors previously discussed.

Forced draft fan selection should consider the following general requirements:

Reliability Boilers must operate continuously for long periods (up to 18 months in some instances) without shutdown for repairs or maintenance. Therefore, the fan must have a rugged rotor and housing and conservatively loaded bearings. The fan must also be well balanced and the blades shaped so that they will not collect dirt and disturb this balance.

Efficiency High efficiency over a wide range of output is necessary because boilers operate under varying load conditions.

Stability Fan pressure should vary uniformly with volumetric flow rate over the capacity range. This facilitates boiler control and assures minimum disturbance of air flow when minor adjustments to the fuel burning equipment change the system resistance. When two or more fans operate in parallel, the pressure output curves should have characteristics similar to the radial tip or backward curved blade fans in order to share the load equally near the shutoff point.

Overloading It is desirable for motor driven fans to have self-limiting horsepower characteristics, so that the driving motor can not overload. This means that the horsepower should reach a peak and then drop off near the full load fan output (Fig. 16).

Induced draft fan

Units designed to operate with balanced furnace draft or without a forced draft fan require induced draft to move the gaseous products of combustion.

The gas weight used to calculate net induced draft requirements is the weight of combustion product gas at maximum boiler load, plus any air leakage into the boiler setting from the surroundings and from the air side to the gas side of the air heater. Net gas temperatures are based on the calculated unit performance at maximum load. Induced draft fan test block specifications of gas weight, negative static pressure and gas temperature are obtained by adjusting from net values by margins similar to those used for forced draft fans.

An induced draft fan has the same basic requirements as a forced draft fan except that it handles higher temperature gas which may contain erosive ash. Excessive maintenance from erosion can be avoided by protecting casing and blades with replaceable wear strips. Because of their lower resistance to erosion, air foil blades should be treated with caution when considering an induced draft application. Air foil blades are very susceptible to dust erosion and, if hollow, they can fill with dust and cause rotor imbalance should the blade surface wear through. Bearings, usually water-cooled, have radiation shields on the shaft between the rotor and bearings to avoid overheating.

Gas recirculation fans

As discussed in Chapter 19, gas recirculation fans are used in various boiler arrangements for controlling steam temperature, furnace heat absorption,

slagging of heating surfaces, and control of NO_x emissions in oil- or gas-fired burners. They are generally located at the economizer outlet to extract gas and inject it into the furnace at locations dependent on the intended function. These multiple purposes are also an important consideration in properly sizing and specifying gas recirculation fans. Selection may be dictated by the high static pressure required for tempering furnace temperatures at full load on the boiler unit, or by the high volume requirement at partial loads for steam temperature control.

Even though gas recirculation fans have the same basic requirements as induced draft fans, there are additional factors to consider, such as being subjected to large amounts of abrasive ash. The gas recirculation fan typically operates at higher gas temperatures, so intermittent service may cause thermal shock or unbalance. When the fan is not in service, tight shutoff dampers and sealing air must be provided to prevent the back flow of hot furnace gas, and a turning gear is often used on large fans to turn the rotor slowly to avoid distortion.

Primary air fans

Primary air fans on pulverized coal-fired boilers supply pulverizers with the air needed to dry the coal and transport it to the boiler. Cold primary air fans should be designed for duty similar to forced draft fans. Primary air fans may be located before the air heater (cold primary air system) or downstream of the air heater (hot primary air system). The cold primary air system has the advantage of working with a smaller volumetric flow rate for a given mass flow rate. This method will pressurize the air side of the air heater and encourage leakage to the gas side. The hot primary air system avoids primary air heater leakage, but requires a higher fan design temperature and larger volumetric flow rate.

Fan maintenance

Fans require frequent inspection to detect and correct irregularities that might cause problems. However, they should also have long periods of continuous operation compared with other power plant equipment. This can be assured by proper lubrication and cooling of fan shafts, couplings and bearings.

A fan should be properly balanced, both statically and dynamically, to assure smooth and long-term service. This balance should be checked after each maintenance shutdown by running the fan at full speed, first with no air flow and second with full air flow.

Fans handling gases with entrained abrasive dust particles are subject to erosion. Abrasion resistant materials and liners can be used to reduce such wear. In some cases, beads of weld metal are applied to build up eroded surfaces.

Fan testing

It is difficult to obtain consistent data from a field test of fans installed in flue and duct systems because it is seldom possible to eliminate flow disturbances from such things as bends, change in flow area, and dampers. Structural arrangements at the fan entrance and discharge also materially affect field performance

results. The consistent way to verify fan performance is on a test stand. (See Fig. 18.)

Fan types

There are essentially two different kinds of fans: centrifugal and axial flow. In a centrifugal fan, the air or gas enters the impeller axially and is changed by the impeller blades to flow radially at the impeller's discharge. The impeller is typically contained in a volute-type housing. In an axial flow fan, the air or gas is accelerated parallel to the fan axis.

Centrifugal fans

Centrifugal fans can utilize several types of impellers: airfoil, backward inclined, radial tipped, and forward curved. Fans with forward curved impellers are typically used for low-capacity applications and are seldom found in industrial applications. Characteristic traits of centrifugal fan impellers are:

Airfoil This impeller is capable of attaining the highest efficiency. It has the highest specific speed (it must run faster to develop a given pressure at a given diameter). Sound levels tend to be lower than the other types. It is not satisfactory for high dust loads; the blades can not easily be made wear resistant and it is prone to dust buildup on the backs of blades. The hollow blades have potential for water and dust ingress. Tip speed limits increase with reduced tip width.

Backward inclined

Curved backward inclined (CBI) offers high efficiency (although not as high as airfoil impellers). This design is satisfactory for dust loads and can accept removable wear plates. This design is prone to buildup on the backs of blades. It is economical to manufacture and sound levels are marginally lower than airfoil impellers. Specific speed is high.

Flat backward inclined is excellent for high dust loads and can easily accept removable wear plates. Efficiency is lower than for a curved backward design. It is economical to manufacture, has a high specific speed, and is prone to dust buildup on the backs of blades.

Radial tipped This design is excellent for dust loading, can accommodate removable wear plates satisfactorily, and has very few dust buildup problems. However, it has the lowest efficiency of the four types. This impeller has tip speed limitations and therefore is not suitable for very high pressure rise applications.

A further summary of these impeller types is given in Table 5.

Control of centrifugal fan output

Very few applications permit fans to always operate at the same pressure and volume discharge rate. Therefore, to meet requirements of the system, some means of varying the fan output are required such as damper control, inlet vane control, and variable speed control.

Damper control introduces sufficient variable resistance in the system to alter the fan output as required. The advantages are:

1. lowest initial capital cost of all control types,
2. ease of operation or adaptation to automatic control,

3. least expensive type of fan drive; a constant speed induction type AC motor may be used, and
4. continuous rather than a step-type control making this method effective throughout the entire fan operating range.

The primary disadvantage of damper control is wasted power. Excess pressure energy must be dissipated by throttling. Outlet damper control (usually with opposed blade type dampers) is inefficient and is not often used. Inlet box damper control with parallel blades pre-spins the entering air or gas in the same direction as impeller rotation, making this method more efficient than outlet damper control.

The most economical control is accomplished with variable inlet vanes (VIVs), designed for use with both dirty air and clean air. These vanes change position with flow and produce a more efficient pre-spin than inlet dampers. VIVs are the most common type of flow control for constant speed fans. The relative location and types of flow control devices are shown in Fig. 19.

Operating experience on forced draft, primary air and induced draft fans has proven that inlet vane control is reliable and reduces operating cost. It also controls stability, controls accuracy, and minimizes hysteresis. Inlet vane control (Fig. 20) regulates air flow entering the fan and requires less horsepower than outlet damper control at fractional loads. The inlet vanes give the air a varying degree of spin in the direction of wheel rotation, enabling the fan to produce the required head at proportionally lower power. Although vane control offers considerable savings in efficiency at any reduced load, it is most effective for moderate changes close to full load operation. The initial cost is greater than damper control and less than variable speed control.

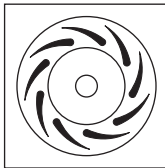

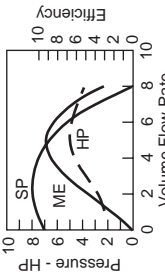

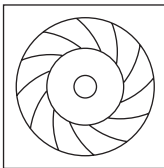

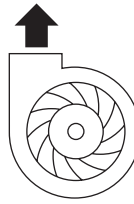

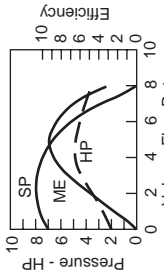

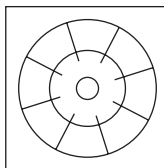

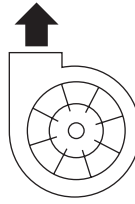

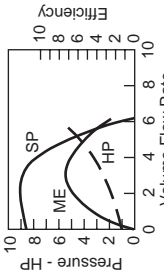

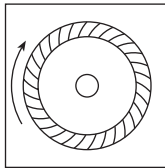

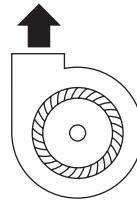

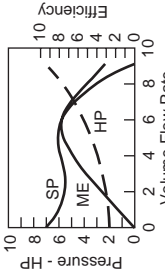

Fig. 18 Full-scale testing of variable-pitch axial flow fan.

Table 5
Centrifugal Fans³

Table 5 Centrifugal Fans ³					
Type	Impeller Design	Housing Design	Performance Curves	Performance Characteristics	Applications
Airfoil	 <p>Highest efficiency of all centrifugal fan designs. 9 to 16 blades of airfoil contour curved away from the direction of rotation. Air leaves the impeller at a velocity less than its tip speed and relatively deep blades provide for efficient expansion within the blade passages. For given duty, this will be the highest speed of the centrifugal fan designs.</p>	 <p>Scroll-type, usually designed to permit efficient conversion of velocity pressure to static pressure, thus permitting a high static efficiency; essential that clearance and alignment between wheel and inlet bell be very close to reach the maximum efficiency capability. Concentric housings can also be used as in power roof ventilators, because there is efficient pressure conversion in the wheel.</p>	 <p>Pressure - HP</p> <p>Volume Flow Rate</p>	Highest efficiencies occur 50 to 65% of wide open volume. This is also the area of good pressure characteristics; the horsepower curve reaches a maximum near the peak efficiency area and becomes lower toward free delivery, a self-limiting power characteristic as shown.	General heating, ventilating and air-conditioning systems. Used in large sizes for clean air industrial applications where power savings are significant.
Backward-Inclined	 <p>Efficiency is only slightly less than that of airfoil fans. Backward-inclined or backward-curved blades are single thickness. 9 to 16 blades curved or inclined away from the direction of rotation. Efficient for the same reasons given for the airfoil fan above.</p>	 <p>Utilizes the same housing configuration as the airfoil design.</p>	 <p>Pressure - HP</p> <p>Volume Flow Rate</p>	Operating characteristics of this fan are similar to the airfoil fan mentioned above. Peak efficiency for this fan is slightly lower than the airfoil fan. Normally unstable left of peak pressure.	Same heating, ventilating, and air-conditioning applications as the airfoil fan. Also used in some industrial applications where the airfoil blade is not acceptable because of corrosive and/or erosive environment.
Radial	 <p>Simplest of all centrifugal fans and least efficient. Has high mechanical strength and the wheel is easily repaired. For a given point of rating, this fan requires medium speed. This classification includes radial blades and modified radial blades, usually 6 to 10 in number.</p>	 <p>Scroll-type, usually the narrowest design of all centrifugal fan designs described here because of required high velocity discharge. Dimensional requirements of this housing are more critical than for airfoil and backward-inclined blades.</p>	 <p>Pressure - HP</p> <p>Volume Flow Rate</p>	Higher pressure characteristics than the above mentioned fans. Power rises continually to free delivery.	Used primarily for material handling applications in industrial plants. Wheel can be of rugged construction and is simple to repair in the field. Wheel is sometimes coated with special material. This design also used for high pressure industrial requirements. Not commonly found in HVAC applications.
Forward-Curved	 <p>Efficiency is less than airfoil and backward-curved bladed fans. Usually fabricated of lightweight and low cost construction. Has 24 to 64 shallow blades with both the heel and tip curved forward. Air leaves wheel at velocity greater than wheel. Tip speed and primary energy transferred to the air is by use of high velocity in the wheel. For given duty, wheel is the smallest of all centrifugal types and operates at lowest speed.</p>	 <p>Scroll is similar to other centrifugal fan designs. The fit between the wheel and inlet is not as critical as on airfoil and backward-inclined bladed fans. Uses large cut-off sheet in housing.</p>	 <p>Pressure - HP</p> <p>Volume Flow Rate</p>	Pressure curve is less steep than that of backward-curved bladed fans. There is a dip in the pressure curve left of the peak pressure point and highest efficiency occurs to the right of peak pressure, 40 to 50% of wide open volume. Fan should be rated to the right of peak pressure. Power curve rises continually toward free delivery and this must be taken into account when motor is selected.	Used primarily in low-pressure heating, ventilating, and air-conditioning applications such as domestic furnaces, central station units, and packaged air-conditioning equipment from room air-conditioning units to roof top units.

Fig. 19 Centrifugal fan flow control devices.³

Electric motors are normally used for fan drives because they are less expensive and more efficient than other types of drives. For fans of more than a few horsepower, squirrel cage induction motors predominate. This type of motor is relatively inexpensive, reliable, and highly efficient over a wide load range. It is frequently used in large sizes and can be used with a magnetic or hydraulic coupling for variable speed installations.

Variable speed motors are attractive because they reduce shaft speed (saving operating power) at reduced flow rates. However, variable speed motors require a higher initial cost which may not be offset by the lower power requirements at reduced fan load conditions. Speed control also results in some loss in motor efficiency because no variable speed driver works as efficiently throughout the entire fan load range as a direct connected, constant speed AC motor. The efficiency loss depends upon the type of speed variation equipment being used.

Variable speed control for centrifugal fans can be achieved by use of hydraulic couplings, variable speed DC motors, two-speed motors, and variable speed steam turbines. Hydraulic coupling losses can become quite severe at low loads, to where a thorough evaluation of power savings over the boiler operating load range does not produce enough monetary savings in power consumption to justify the high initial cost.

For some variable speed installations, particularly in the smaller sizes, wound rotor (slip-ring) induction motors are used. If a DC motor is required, the compound type is usually selected. The steam turbine drive costs more than a squirrel cage motor, but is less expensive than any of the variable speed electric motor

arrangements in sizes above 50 hp (37 kW). A steam turbine may be more economical than the electric motor drive in plants where exhaust steam is needed for process, or on large utility units using the extraction steam for feedwater heating.

Two-speed motor drives can be a reasonable alternative because initial cost is more attractive when compared to the variable speed alternatives. Advantages offered by a two-speed motor drive over a single speed drive are:

1. sound level is lower at maximum continuous rating (MCR),
2. the rate of wear on impeller and other fan components is substantially reduced,
3. bearing life is increased,
4. impeller stresses are reduced and fatigue life is extended, and
5. power consumption at net and reduced load conditions is reduced.

Disadvantages of the two-speed motor drives are:

1. larger fans have higher initial cost,
2. higher motor cost,
3. plant operators are sometimes uncomfortable with shifting to alternate speeds,
4. if reserve margins on flow and pressure at net conditions are not sufficient, the fan may shift to high speed too often or at too low an operating load; anticipated power savings at high boiler loads may not be realized, and
5. if reserve margins at the low speed are too high, power savings at the normal operating condition are not enough to offset the increased initial cost of the two-speed system.

Fan curves for a unit set for both high and low speed operation are shown in Fig. 21.

Axial flow fans

In an axial flow fan, the impeller is predominantly parallel to the axis of rotation. The impeller is contained in a cylindrical housing. Axial fans for indus-

Fig. 20 Inlet vane control.

Fig. 21 Fan curves for high and low speed operation.

trial use are normally of the vane axial type, meaning they have either inlet or discharge guide vanes, or both. There are three types of vane axial fans:

1. Fixed pitch: Impeller blades are permanently secured at a given angle on the impeller hub.
2. Adjustable pitch: Impeller blade angle can be mechanically altered when the impeller is at a standstill.
3. Variable pitch: Impeller blade angle can be mechanically or hydraulically altered while the impeller is rotating.

Variable pitch axial flow fans used in fossil power generating systems can be more energy efficient than equivalent centrifugal type fans. Fig. 22 compares the power consumption of the primary air, forced draft and induced draft fans for a typical 500 MW coal-fired unit using variable pitch axial flow fans with the same unit using backward curved, inlet vane controlled centrifugal fans. At 100% unit load, auxiliary power savings using a variable pitch axial flow fan will be 4000 kW, or about 7% of the total auxiliary power consumption.

Performance and control characteristics

Fig. 23 shows the characteristic performance field of a variable pitch axial flow fan. Several major benefits observed from this figure for axial flow fans include:

1. The areas of constant efficiency run parallel to the boiler resistance line resulting in high efficiency over a wide boiler load range.
2. There is also a large control range above, as well as below, the area of maximum efficiency permitting the fan to be designed for net boiler conditions, while the test block point remains within the control range.
3. The lines of constant blade angle are actually individual fan curves for a given blade setting. Because the curves are very steep, a change in resistance produces very little volume change.
4. As the blade angle is adjusted from minimum to maximum position, the flow change is nearly linear, as shown in Fig. 24.

These last two characteristics provide stable fan and boiler control.

Parallel operation

Variable pitch axial flow fans can be operated in parallel provided care is taken to avoid operating either fan in the stall area discussed below. With two fans in operation, the resistance line for one fan is influenced by the other fan as well as by the boiler conditions. Two fans together will develop the pressure required to overcome the boiler resistance, but individual volume flows need not be equal. However, to obtain the most efficient fan operation and to avoid operation in a range close to the stall line, it is best to keep both fans operating in parallel in their design condition.

The suggested control logic for starting, stopping and supervising the operation of variable pitch axial flow forced draft and induced draft fans is very similar to that of centrifugal fans. An additional requirement of the logic is to prevent damage to the fan while

Fig. 22 Power savings.

Fig. 23 Performance field for variable pitch axial flow fan.

maintaining an open flow path through the boiler to prevent furnace pressure excursions.

Stall characteristics

Axial flow fans have a unique characteristic called *stall*. Stall is the aerodynamic phenomenon which occurs when a fan operates beyond its performance limits and flow separation occurs around the blade. If this happens, the fan becomes unstable and no longer operates on its normal performance curve. Extended operation in the stall region should be avoided. Unpredictable flow vibrations occur which can damage the rotating blades.

The curves in Fig. 25, marked A, are the normal fan performance curves for a constant blade angle. Each blade angle curve has an individual stall point, identified as S on the diagram. The curve C connects all the stall points S and is generally referred to as the stall line.

The dashed curves B are the characteristic stall curves for three different blade angles. The curves show the path that the fan will follow when operating in a stalled condition.

Fig. 26 explains the stall phenomenon in relation to the fan and boiler system. If the normal boiler system resistance (curve B) increases for any reason (for instance, a furnace pressure excursion caused by a main fuel trip), the normal operating point X will change to meet a new higher system resistance (curve B₁) by traveling along the fan performance curve A. If the operating point arrives at point S, the fan will stall. Because of the relationship between the fan performance curve D in the stall area and the upset system resistance (curve B₁), a new operating point X₁ will be found where the system resistance (curve B₁) and the stall curve B intersect. When the system resistance is reduced to curve B, the fan will recover from the stall and return to its normal performance curve A.

In the case of an upset as described above, the blade angle can be reduced until the fan regains stability. The fan will be stable when the new performance curve A₁ provides a stall point S, which is higher than the system resistance (curve B₁).

Fig. 24 Variable pitch blade control characteristics.

Stall prevention

When axial fans are sized properly and the system resistance line is parabolic in shape, the probability of experiencing stall is low. The possibility of a stall increases if a fan is oversized in regard to volume capacity, if the system resistance increases significantly, or if the fans are operated improperly.

The degree of stall protection desired in the control system depends on individual owner philosophy. A visual indication of head and volume (or blade angle) in the control room is a minimum requirement for satisfactory operation.

Fan arrangement

Axial flow fans designed for today's large fossil fueled steam generating systems are compact and rela-

Fig. 25 Actual stall curves.

Fig. 26 Stall as related to the boiler.

tively light. By concentrating the load carrying parts of the rotor on a small radius, a low flywheel effect or moment of inertia (Wk^2) is obtained. The low weight, unbalanced forces and inertia of the axial flow fan permit either horizontal or vertical arrangement on steel construction using a dampening frame. This provides greater arrangement flexibility. Axial fans installed at grade require less of a concrete foundation than centrifugal fans.

A horizontal fan arrangement is generally the economic preference for forced draft and primary air fans. Induced draft fans can be arranged horizontally, or vertically inside the stack should available plant space be at a premium.

Induced draft fan blade wear

Fan blade wear for induced draft fans is a function of dust loading (including excursions due to particulate collection equipment malfunction), particle hardness, particle size distribution, the relative blade to particle velocity, the blade material, and the angle of attack. The fan designer has little control over the first three and must therefore look to other areas to address blade wear issues. Wear is inherently more uniform over variable pitch axial flow fan blades. By selecting a two-stage fan at a lower speed (rpm) instead of a faster one-stage fan, the tip velocity can be reduced. Abrasion resistant material coatings can also be added to the blade wear areas. Additionally, the blades can be made easily removable for fast replacement.

Aerodynamic characteristics

Fig. 27 shows a fan selection diagram used to determine the most economical fan for a given set of performance conditions. The performance requirements for a 500 MW coal-fired boiler using pairs of induced, forced and primary fans are superimposed on the fan-type selection diagram.

When specific speed increases, the diameter ratio of a centrifugal fan increases toward unity. As unity is approached, the design becomes less practical in the high specific speed range because the diameter ratios decrease.

System resistance is plotted in Figs. 16 and 20 along with the fan characteristic of static pressures at various speeds. If the fan operates at constant speed, any flow rate less than that shown at the intersection of the system resistance and specified rpm curves must be obtained by adding resistance through throttling the excess fan head.

Plotting characteristics on a percentage basis shows some of the many variations available in different fan designs. Fig. 28 is such a plot with 100% rated capacity selected at the point of maximum efficiency. Some fans give steep head characteristics, while others give flat head characteristics. Some horsepower characteristics are concave upward, others are concave downward. The latter have the advantage of being self-limiting, so that there is little danger of burning out the driver or little need for oversizing the motor.

Centrifugal fans have a steep head characteristic and are attractive for high static, low flow rate applications. Fans with steep head characteristics also require high tip speeds for the specified head. Therefore, centrifugal fans are usually equipped with wear liners when there is heavy dust loading in the gas. In contrast, axial flow fans are more suitable for use where static pressure requirements tend to decrease as flow requirements decrease. Application of axial flow fans to systems where pressure requirements may suddenly increase at reduced flow conditions must be carefully reviewed to ensure that the change in static requirements does not cause the fan to stall.

Types of fan shaft bearings

The types of bearings used in fans are anti-friction (grease lubricated roller or oil lubricated roller) and sleeve.

The choice in a given fan application depends largely on the end user. In most centrifugal fan applications, the industry prefers sleeve bearings for their reliability and for the ease of replacing worn liners. In some instances, anti-friction bearings, either grease or oil lubricated, may be chosen. Smaller higher speed fans and axial flow fans usually employ anti-friction bearings. Larger lower speed fans and fans with high moments of inertia will more often use sleeve bearings, as will centrifugal fans with large diameter impellers.

Sleeve bearings rely on a continuously maintained oil film to provide a very low friction protective layer between shaft and bearing surface. When the fan is at rest, there is contact between the shaft and bearing surface. Shortly after shaft rotation begins, an oil film is established (by the lubrication system) that prevents contact between metal surfaces.

Acoustic noise

Fans produce two distinct types of noise as follows:

1. *Single tone noise* is generated when the concentrated fluid flow channels leaving the rotating blades pass a stationary object (straightener vanes or nose). The distance from the rotating blades to stationary objects affects the sound intensity, with the blade-passing frequency and its first harmonic being most dominant.

Fig. 27 Fan type selection diagram.

2. *Broad band noise* is produced by high velocity fluid rushing through the fan housing and, as the name implies, covers a wide frequency range.

From the outside, the apparent source of both types of fan noise is the fan housing. The sound travels out of the inlet box opening, through the discharge ductwork and through the casing of the fan. All three areas must be acoustically analyzed and individually treated to achieve an acceptable installation. Fig. 29 illustrates noise distribution characteristics around a fan.

Inlet sound levels from forced draft and primary air fans are most commonly controlled by the installation of an absorption-type silencer. Fan casing noise can usually be effectively controlled by the use of mineral wool insulation and acoustic lagging. Fan discharge noise, however, requires a more detailed evaluation to determine the most cost-effective method of control. For forced draft and primary air fans, insulating the outlet ducts or installing an absorption-type discharge silencer can be effective. For induced draft fans, installation of thermal insulation and lagging on the outlet flues will generally be sufficient. For situations where stack outlet noise must be reduced, an absorption-type discharge silencer can be used. However, this will not work on coal-fired units as the sound absorbing panels

will become plugged with flyash. In this instance, a resonant-type discharge silencer with a self-cleaning design must be used. Typical noise attenuation devices are shown in Fig. 30.

Condensing attemperator system

Superheater spray water attemperation is the primary method of steam temperature control on most boilers. This spray water is introduced between stages of the superheater or, in some cases, immediately downstream of the superheater outlet. If feedwater is used as the source for this attemperation, it must have very low solids content in order to avoid introducing potentially damaging deposits in the superheater or in the turbine.

Many industrial plants do not have the water treatment facilities capable of meeting the low solids feedwater requirements for spray attemperation. If feedwater quality does not meet the solids criteria established for spray water, a condensing attemperator system can be used to provide a low solids spray water source.

A schematic diagram of a typical condensing attemperation system is shown in Fig. 31. The system typically consists of a condensing heat exchanger (condenser), spray water flow control valve, spray water

Fig. 28 Selected centrifugal and axial flow fan characteristic curves.

attenuator and occasionally, a condensate storage tank and a condensate pump. The basic design philosophy of this system is that saturated steam from the boiler steam drum is routed to the shell side of a vertical condenser, where it is condensed and subcooled. This condensate then flows through the spray water piping and control valve to an interstage attenuator or to a terminal attenuator.

Most condensing attenuation systems are driven by the pressure differential between the drum and the point in the steam path where the spray water is introduced. Condensers are normally located above the steam drum in order to increase the hydrostatic head available to the attenuator. If the available pressure differential is not sufficient to overcome the system resistance developed at the design spray water flow, then a condensate pump must be used. In order to avoid the need for a condensate pump, system resistance losses are usually minimized by using a low pressure drop attenuator if system spray characteristics over the boiler operating range permit its use.

Fig. 29 Fan sound patterns.⁴

Boiler feedwater is the cooling medium that flows through the tube side of the condenser. Fig. 31 shows the feedwater flowing from the economizer outlet to the condenser and from the condenser to the drum. Alternate locations may be upstream of the economizer inlet or an intermediate header in a multi-bank economizer.

The spray water condenser is a vertical, head down shell and tube heat exchanger arrangement (Fig. 32). The feedwater tube bundle is of the inverted U-tube type construction. Feedwater enters and leaves the tube bundle at the bottom of the inverted U-tubes. The cylindrical shell enclosure features a drum steam inlet near the top of the shell and a condensate outlet close to the bottom of the shell.

During normal operation, the condenser system will experience cyclic operation. At times there will be no spray flow demand and the condensate level on the shell side of the condenser will rise to the top of the tube bundle. This is a desirable operating characteristic of the inverted U-tube arrangement. It prevents

Fig. 30 Fan noise attenuation devices.⁴

Fig. 31 Schematic arrangement of vertical condenser system.

steam pockets from being trapped at the top of the condenser shell which could cause water hammer and subsequent cracking of the shell.

The spray water condenser must be designed to withstand significant temperature transients and gradients. At times the condenser will be almost flooded with water and the whole assembly will be close to feedwater temperature. A sudden requirement for spray water can drop this water level quickly, exposing significant lengths of shell and internals to saturated steam temperature. In some cases this can mean a sudden rise in shell temperature of as much as 300F (167C).

Notes:

1. Alternate location of condensate outlet. Feedwater inlet must be on same side as condensate outlet.
2. 1 NPS Stub with socket weld fitting, capped for shipment.

Fig. 32 General arrangement of vertical head down condenser.

Section III

Applications of Steam

The six chapters in this section illustrate how the subsystems described in Section II are combined to produce modern steam generating systems for specific applications. A number of steam generating unit and system designs for various applications are described and illustrated.

Chapter 26 begins the section with a discussion of large fossil fuel-fired equipment used to generate electric power. Both large and small industrial units, as well as those for small electric power applications, are then described in Chapter 27. The next four chapters address specialized equipment for specific applications. Unique designs for steam producing systems are used in pulp and paper mills, waste-to-energy plants, biomass-fired units, and marine applications. Biomass-fired systems in particular are receiving increased interest as renewable energy resources grow in importance.

Chapter 26

Fossil Fuel Boilers for Electric Power

Most of the electric power generated in the United States (U.S.) is produced in steam plants using fossil fuels and high speed turbines. These plants deliver a kilowatt hour of electricity for each 8500 to 9500 Btu (8968 to 10,023 kJ) supplied from the fuel, for a net thermal efficiency of 36 to 40%. They use steam driven turbine-generators of up to 1300 MW capacity with boilers generating from one million to ten million pounds of steam per hour. A typical coal-fired facility is shown on the facing page.

Modern fossil fuel steam plants use reheat cycles with nominal steam conditions of 3500 psi/1050F/1050F (24.1 MPa/566C/566C) for supercritical pressure systems, and 2400 psi (16.5 MPa) with superheat and reheat steam temperatures ranging from 1000 to 1050F (538 to 566C) for subcritical pressure systems. For some very small units, lower steam conditions may be applied. In selected global locations where higher cycle efficiencies are required, supercritical pressure steam conditions on the order of 4300 psi/1075F/1110F (29.6 MPa/579C/599C) and 3626 psi/1112F/1130F (25.0 MPa/600C/610C) have been used.

Most power plants in the U.S. and around the world are owned and operated by: 1) investor owned electric companies, 2) federal, state or local governments, or 3) finance companies.

These owners, whether public or private, have been generally known as *utilities*. During the 1980s and 1990s, there was a trend toward new types of companies supplying significant portions of new generation. However, the fundamental approach to selecting power generation equipment will remain unchanged.

Selection of steam generating equipment

The owner has several technologies to choose from based upon fuel availability, emissions requirements, reliability, and project timing. One of the common choices for modern electric power generation is the high pressure, high temperature steam cycle with a fossil fuel-fired boiler.

Each new electric generating unit must satisfy the user's specific needs in the most economical manner.

Achieving this requires close cooperation between the equipment designers and the owner's engineering staff or consultants. The designers, owner and engineering group must identify those equipment features and characteristics that will reliably produce low cost electricity. The primary costs of electricity include: 1) capital equipment, 2) financing charges, 3) fuel, and 4) operation and maintenance. The owner, prior to issuing equipment specifications, reviews and surveys all cost factors. (See Chapter 37.)

The capital cost survey must include all direct costs such as the boiler, steam turbine and electric generator, emissions control equipment, condenser, feedwater heaters and pumps, fuel handling facilities, buildings, and real estate. In addition, finance charges, including interest rates, loan periods, source of funds and tax considerations must be added. Fuel and emission control reagent costs need to be evaluated based on the initial costs, plant capacity variations expected during the life of the plant, and forecasts of cost changes during plant lifetime. The operation and maintenance costs should be estimated based on other current plants with similar equipment, fuels and operating characteristics. Operating and maintenance costs are heavily affected by personnel requirements, and consideration should be given to the availability of skilled labor as well as to the cost of retaining the skilled staff during the plant lifetime.

Plant efficiency, fuel use and capital cost are critically related. Higher plant thermal efficiency obviously reduces annual fuel costs; however, fuel savings are partially offset by the associated higher capital costs. Therefore, selection of the desired plant efficiency should carefully consider the economic tradeoffs between capital and operating costs.

Other important criteria are the location of the electric generating plant with respect to fuel supply and the areas where electricity is used. In some cases, it is more economical to transport electricity than fuel. Some large steam generating stations have been built at the coal mine mouth to generate electricity which is then used several hundred miles away. If the user is a member of a broader grid of interconnected util-

ity companies, the future requirements of other system members may also be an important factor.

In power plant planning, substantial time and effort are required to establish accurate basic plant assessment data with comprehensive consideration of engineering factors and plans for future expansion or changes. The accuracy of these data is critical if the experience and craftsmanship of the boiler manufacturer and other suppliers are to fully benefit the plant designer and owner. The owner should, at the outset, decide who is to prepare these data. If the owner lacks personnel with the necessary qualifications, consulting engineers should be used. A thorough discussion with the boiler manufacturer will provide many details to help the owner make correct decisions.

Before the boiler and other major equipment items can be selected, the basis of operation and arrangement of the entire steam plant must be planned. Ultimately the available data must be translated into the form of equipment specifications so that the manufacturers of various components can provide apparatus in accordance with the user's requirements. After equipment selection, construction drawings must be prepared for the foundations, building, piping and walkways. The construction work must be coordinated utilizing modern schedule and control techniques for effective management and completion of erection. Ideally, the construction planning begins at the start of the conceptual engineering so that the site arrangement and project schedule facilitate efficient construction practices. Modularization of major components can be incorporated into the design where site conditions permit.

Boiler designer's requirements

The most important factors to the boiler designer are the steam conditions, fuel, project load service, and environmental constraints. Steam conditions identify the amount of steam required, the temperature and pressure of the main and reheat steam, and the feedwater temperature. Of equal importance is the type and chemical composition of the fuel, the ash characteristics, and the emissions control requirements for the specified plant site.

The boiler designer needs a complete set of data pertinent to steam generation to produce the most economical steam generating equipment and satisfy the needs of the user.

The requirements and conditions that form the basis for the designer's equipment selection can be outlined as follows:

1. Fuels – sources presently available or planned for future use; proximate, ultimate and ash analyses of each fuel as well as costs and future trends.
2. Steam requirements – ideally steam turbine heat balances should be provided for a more comprehensive understanding of the cycle design requirements. At a minimum the flow, pressure and temperature at each terminal location (main steam, feedwater, cold reheat, hot reheat, auxiliary steam, etc.) must be given for the various loads where performance is to be evaluated.
3. Boiler feedwater – source, chemical analysis and

temperature of the feedwater entering the steam generating unit.

4. Environmental requirements – site limitations; permissible levels for nitrogen oxides (NO_x), sulfur dioxide (SO_2), particulate and other atmospheric emissions; solid waste specifications; and all other regulatory and commercial requirements.
5. Dispatch requirements – turndown, rate of load change, and on/off cycling.
6. Space and geographical considerations – space limitations, relation of new equipment to existing equipment, earthquake and wind resistance requirements, elevation above sea level, foundation conditions, climate, and accessibility for service and construction.
7. Auxiliary power – medium used and evaluated cost of energy.
8. Operating personnel – experience level of operating and maintenance personnel as well as the cost of labor.
9. Guarantees.
10. Evaluation basis – for unit efficiency, auxiliary power required, building volume, and various fixed charges.

With this information, the boiler designer is able to analyze the user's specific needs. As a result, an economical, reliable steam generator can be built and initial costs can be balanced with long-term savings. Setting these requirements based on anticipated future needs will provide a flexible boiler design within the constraints of cost and technical criteria.

Design practice

Utility boiler design is a custom design process due to the uniqueness of each project. Variations in projects are a result of the following fundamental differences: steam cycles, types and range of fuels, site conditions, emissions requirements, and the user's operating plans. Such variations require custom design in the overall arrangement of boiler components. The boiler designer works with standardized component concepts which are assembled to provide the optimum design arrangement to satisfy the unique requirements of the project.

While the overall design is customized, component design concepts are highly standardized and make use of pre-engineered elements where possible (attachment clips, access doors, etc.). In addition, some components, such as pulverizers, are largely pre-engineered.

At the start of a project, the designer reviews the available database and past experience to determine which large shop-fabricated components, called *modules*, may be applied to the design. Reviewing shipping sizes, traffic methods and routing, and the general economic tradeoff of greater shop assembly versus reduced field erection time are standard project practices. Modularization is now common practice but needs to be assessed on each project to determine the optimum cost and schedule impact.

Fuels

The basic types of fuels used for U.S. electricity generation are shown in Fig. 1. The dominant fuel in

modern U.S. central stations is coal, either bituminous, subbituminous or lignite. A similar picture emerges for worldwide electric power production. (See Fig. 2.) While natural gas, and possibly fuel oil, used with gas turbine and combined cycle technology may be the fuel of choice for many new fossil fuel power plants, coal is expected to continue its important role in supplying energy to new, base-loaded utility power station boilers. The following material focuses primarily on coal-fired utility boilers but includes selected comments and discussion of other fossil fuels. General discussion of steam production as part of combined cycle and waste heat recovery applications is provided in Chapter 27. Specialized designs for unique, smaller power production facilities are also discussed.

Coal Coal is the most abundant fuel in the U.S. and in many parts of the world. The U.S. leads the world in coal production followed by China, India, South Africa and Australia. However, of the major fossil fuels, coal is also the most complicated and troublesome to burn. In the U.S., Europe, Japan, and increasingly in other parts of the world, there are also societal and political difficulties in locating, siting and permitting coal-fired power plants, especially considering the airborne, liquid and solid emissions compared to other fossil fuels. Coal use involves unloading, storage and handling facilities; preparation before firing using crushers and pulverizers; ash disposal equipment; emissions control equipment; and sootblowers. There is a wide variation in the properties of coal and its ash. As a result, while the design of the steam-producing unit must provide optimum performance when firing the intended coals, it must also accommodate reasonable alternate coals if necessary.

The coals selected for a prospective installation should be tabulated to indicate chemical analysis, heating value and grindability. In addition, each coal's ash analysis and ash temperature profile should be listed. The ash composition has a marked effect on a coal's slagging and fouling characteristics; the analysis must be provided to the boiler supplier for proper selection of unit geometry, features and surfaces. (See Chapter 21.)

Fig. 2 Worldwide electricity generation in 2001, by fuel.

Steam requirements

Modern turbines are designed for nominal conditions of 3500 psi/1050F/1100F (24.1 MPa/566C/593C) for supercritical systems and 2400 psi/1000F/1000F (16.5 MPa/538C/538C) for subcritical systems. For some very small units, lower steam conditions such as 1800 psi (12.4 MPa) pressure may be selected. As noted earlier, some advanced steam pressure and temperature conditions may also be applied.

The steam temperature specified at the superheater outlet is generally considered to be equal to that required at the turbine plus 5F (3C). While there is very little heat loss in the well-insulated steam lines, the pressure loss in the piping results in a temperature change at constant enthalpy. For optimum performance and turbine maintenance, the steam temperature should remain constant over a broad load range. Means for controlling steam temperatures are required in utility practice. Steam temperature variation and control are discussed in Chapters 19 and 41.

The steam pressure at the superheater outlet is normally specified by the plant designer after evaluating the economics of pressure drop versus pipe sizing. Typically, the allowance for the main steam line pressure loss is 5% of the throttle pressure and the total allowance for the hot and cold reheat line loss is 5% of cold reheat pressure.

It has been customary stationary-boiler practice in the U.S. to hold the main steam pressure constant for all loads, on the premise that this condition satisfies all pressure and quantity requirements of the steam-using equipment (constant pressure). This is particularly the case where the unit is base loaded and significant cycling operation is not anticipated. In addition, constant pressure operation permits more rapid load transients while minimizing transient stresses in the boiler. However, constant pressure operation assesses some heat rate penalty at partial load conditions

Fig. 1 U.S. electricity generation in 2001, by fuel.

and results in some additional stresses in the turbine during rapid load changes.

Alternately, the system can be operated so that steam pressure varies with boiler load (variable pressure). This is more energy efficient at reduced load conditions and permits better temperature control to the turbine under load transients. However, the system may be less responsive due to the need to change the thermal inventory of the boiler during load changing, and additional stress is placed on the unit under transient conditions due to the saturated water temperature change. The thermal transient response may be improved by operating with throttle valve reserve where, for partial arc turbines, the turbine is controlled with constant throttle pressure until the first valve is closed and then operated with variable pressure. This allows the turbine valve to be opened for rapid load increase, essentially borrowing energy from the boiler system. This mode of operation is sometimes called turbine hybrid variable pressure operation.

Another mode of operation is boiler hybrid variable pressure or split pressure operation. In this mode, the turbine is operated variable pressure while the boiler through the primary superheater is operated at constant pressure. Pressure is controlled by a reducing valve located between the primary and secondary superheaters. The boiler can be maintained at a constant pressure, thereby minimizing stress and maximizing response to load changes. The temperature of the steam entering the turbine can be separately maintained, minimizing stress and maximizing load response of the steam turbine. This mode of operation provides the maximum responsiveness to load transients. While this mode of operation has a thermodynamic advantage at reduced loads compared to constant pressure operation, it is not as efficient as variable pressure operation.

These control approaches and their implications are addressed in Chapters 19 and 41.

Central station units use the reheat cycle for increased station thermal efficiency. The reheater, located within the boiler enclosure, receives steam exhausted from an intermediate pressure stage of the turbine. The steam temperature is raised and the steam is returned to the low pressure section of the turbine. The cold reheat enthalpy is impacted by the mode of turbine operation (constant vs. variable pressure) and this must be considered in the boiler design. The cold reheat enthalpy is greater under variable pressure operation (due to the increased main steam enthalpy at constant temperature but lower pressure at the throttle and reduced throttling loss) and therefore the heat absorption required of the reheater is reduced with variable pressure operation.

The double reheat cycle, where steam is returned to the boiler twice for reheating and then delivered to low pressure sections of the turbine, results in even higher station thermal efficiency than the single reheat cycle. However, the gain in plant efficiency must be weighed against the cost of additional piping systems and turbine and boiler equipment used to accommodate the flow of low pressure steam.

Steam flow requirement

Steam producing equipment must be of sufficient capacity, range of output and responsiveness to ensure prompt response to the turbine steam demand. The demand may be steady, as in base loaded systems, or it may fluctuate widely and rapidly, as in cycling units. The steam flow requirements should therefore be accurately established for peak flow, maximum continuous flow (usually steady maximum flow), minimum flow, and rate of change in flow. The peak load establishes the capacity of the steam producing equipment and all its auxiliaries.

Often the turbine is designed for 5% overpressure operation (operation at a pressure 5% greater than the nominal throttle pressure). This permits a 5% higher steam flow through the turbine and results in greater unit output. This design concept will determine both the boiler maximum capacity and the boiler maximum operating and design pressures.

Occasionally, the specification will require that the system be capable of peaking by removing one or more of the top feedwater heaters from service. The steam normally supplied to this feedwater heater then flows through the turbine, thereby increasing its output. The source of that steam is from extraction on the high pressure turbine and potentially the intermediate pressure turbine depending on the heaters removed from service. This method results in higher than normal heat rates (i.e. lower efficiencies) while overpressure operation reduces heat rate. This condition impacts the boiler design in determining the maximum output and because the change in turbine extraction impacts both the feedwater temperature and the reheat flow, thereby changing the required heat absorption in various boiler components.

The range from minimum to maximum output is an important factor in selecting the boiler's firing equipment. To maintain stable ignition and optimal combustion, this range must also be considered in designing the furnace.

The required rate of change in turbine load (steam flow) may affect the entire design of the steam producing equipment. Within a specified load range, good response is easily obtained with well-designed firing equipment for pulverized coal, oil and natural gas. A multiplicity of burners (and pulverizers, where used) widens the available range, but if there is a frequent change in load, remote manual on/off operation of burners and pulverizers may be objectionable. It is therefore important that the designer, manufacturer and operator understand what can be done by full automatic firing and what is required beyond that.

In selecting equipment to produce steam at minimum total cost, it is also necessary to establish the probable capacity factor – the ratio of the average output to the rated output. This capacity factor serves as a basis for establishing the value of incremental increases in steam generating efficiency. For example, the initial cost necessary to achieve high efficiency in a plant operating continuously at high output may not be justified for a plant operating as a cycling unit where the average capacity factor is relatively low.

Boiler feedwater

The steam passing through the turbine is condensed in the condenser. This condensate is the primary source of feedwater for the boiler. Makeup water is also required to be added to the system due to cycle losses. High purity makeup water is supplied by a comprehensive water treatment system which removes troublesome compounds, and oxygen normally found in raw water from surface or subsurface sources.

Dissolved oxygen will attack steel and the rate of attack increases sharply with a rise in temperature. High chemical concentrations in the boiler water and feedwater cause furnace tube deposition and allow solids carryover into the superheater and turbine, resulting in tube failures and turbine blade deposition or erosion.

As steam plant operating pressures have increased, the water treatment system has become more critical. This has led to the installation of more complete and refined water treatment facilities. (See Chapter 42.)

Environmental considerations

Environmental protection is an integral part of the boiler and power system design process. As outlined in Chapters 1 and 32, boilers emit varying levels of NO_x , SO_2 , particulate, and other compounds into the air and they discharge ash. Government regulations tightly control these emissions in most parts of the world. The specific local regulations will govern the extent of back-end cleanup equipment required and many of the boiler design parameters. A new unit burning coal in the U.S. today might look like the unit shown in Fig. 3. The boiler is designed with low NO_x

burners, an enlarged furnace, staged combustion (with overfire air or NO_x ports) to minimize NO_x emissions, and a selective catalytic reduction (SCR) system for further NO_x control. (See Chapters 14 and 34.) An electrostatic precipitator or fabric filter collects particulate (Chapter 33), while either a wet flue gas desulfurization system (wet scrubber) or a spray dryer absorber (dry scrubber) removes most of the SO_2 (Chapter 35). Careful review and economic evaluation of all local regulations and permitting requirements are needed to achieve the required environmental protection in the most cost effective manner.

Space and geographical considerations

Space and geographical considerations are extremely site specific and can dictate the equipment arrangement and even the construction sequence. In some cases, a new boiler is added to an existing plant to maximize the use of existing equipment and plant infrastructure. The most extreme case involves *repowering* an existing plant, where the old boiler is removed and a newer unit is installed in the same space.

The boiler and its support structures must be designed to accommodate expected seismic forces and wind loadings, in accordance with local structural laws and regulations. The site elevation above sea level significantly affects the design and sizing of ducts, fans and the stack due to the impact of site barometric pressure on the air and flue gas specific volume. Fan power consumption is also influenced by site elevation. Finally, boilers can be designed for indoor or outdoor installation, depending upon the prevailing climate.

Fig. 3 Integrated pulverized coal-fired boiler power system with emissions control.

Power for driving auxiliaries

Modern practice in central stations generally calls for electric motor drives for rotating auxiliaries such as pumps, fans, pulverizers and crushers (although the boiler feed pump is usually turbine driven). The convenience and cost of the electrical drive substantiate this preference. The available plant voltage levels can determine the maximum motor size and may impact the number of forced draft and/or induced draft fans required.

Guarantees

It is common practice to obtain performance guarantees from component suppliers to provide a means to evaluate offerings and to validate the actual performance of the unit during operation.

The boiler manufacturer is usually requested to provide the following guarantees, depending on the arrangement, type of fuel and type of boiler.

1. For a given load point and fuel:
 - a. efficiency,
 - b. superheater steam temperature,
 - c. reheater steam temperature,
 - d. pressure drop from feedwater inlet to superheater outlet and from reheater inlet to reheater outlet,
 - f. solids in steam (for drum boilers),
 - g. auxiliary power consumption (fans, pulverizers and drives), and
 - h. air heater leakage.
2. Unit maximum capacity (which is often greater than the turbine maximum capacity).
3. Superheater and reheater temperature control ranges.
4. Pulverizer capacity and fineness (where applicable).
5. NO_x and other emissions depending on project requirements.

Pulverized coal firing

The size of large pulverized coal-fired boilers and turbine-generators has peaked at 1300 MW. The equipment can be designed to burn practically any bituminous coal, subbituminous coal or lignite commercially available. Anthracite can be successfully burned in pulverized form, but requires a specialized boiler arrangement. While the special attention and additional expenses associated with plants designed for this fuel preclude its use in North America, anthracite is used today in parts of China, Vietnam and Europe.

The overall aspects of pulverized coal firing, as applied to boiler units, are as follows:

1. is suitable for almost any coal mined throughout the world,
2. is economically suitable for a very wide range of boiler capacities,
3. provides wide flexibility in operation and high thermal efficiency,
4. must have proper coal preparation and handling equipment, including moisture removal,

5. must have proper means of handling the ash refuse, and
6. must have controls for atmospheric emissions arising from elements in the coal and from the combustion process.

Babcock & Wilcox pulverized coal-fired boiler types for electric power

Prior chapters provide information on steam generation and power plant design and include fundamentals that are applied by designers and manufacturers worldwide. In particular, Chapter 19 discusses general boiler design, while Chapters 13 and 14 address the preparation and combustion of pulverized coal. This chapter concentrates on The Babcock & Wilcox Company (B&W) design philosophy which integrates these technologies into large reheat steam generators for electric power generation.

B&W has a broad base of experience that can be applied to most owner needs. B&W's basic design philosophy focuses on the key operating issues of availability and reliability, and on incorporating technology advances into each new unit design. Examples of the company's strengths include rapid startup and load shedding features, extended control ranges for superheater and reheater outlet temperatures, and experience in burning a wide variety of coals.

Supercritical (once-through) boilers

The B&W boiler for supercritical applications is the Universal Pressure (UP[®]) boiler. Originally designed for both supercritical and subcritical applications, this design is now used for supercritical applications; the drum boiler is used for subcritical applications. The supercritical application is usually applied to systems with a capacity of 300 MW or larger due to steam turbine considerations.

The original UP boiler design dates back to the mid-1950s when the 125 MW advanced supercritical boiler was provided for American Electric Power's Philo station. This pioneering boiler/turbine system, with advanced steam conditions of 4500 psi/1150F/1050F/1000F (31 MPa/621C/566C/538C), was the first supercritical system. The boiler design rapidly evolved to units as large as 1300 MW in the late 1960s. These boilers, nine of which are in operation, are among the largest capacity fossil fuel boilers in the world.

In modern units, the furnace is completely fluid-cooled, designed for balanced draft operation, and usually features dry ash removal. Superheater and reheater components are of the vertical pendant and/or horizontal design. Superheat temperature is controlled by the firing rate to feedwater flow ratio with typically one or more stages of attemperation for transient control. Reheat temperature control is by gas proportioning dampers.

Range in capacity, steam output – from 2,000,000 lb/h (252 kg/s) steam output to more than 10,000,000 lb/h (1260 kg/s).

Operating pressure – usually at 3500 psi (24.1 MPa) throttle pressure with 5% overpressure; higher pressures available.

Superheater steam temperatures – as required, usually 1050F (566C).

The principle of operation is that of the once-through or Benson cycle. The water, pumped into the unit as a subcooled liquid, passes sequentially through all the pressure part heating surfaces where it is converted to superheated steam as it absorbs heat; it leaves as steam at the desired temperature. There is no recirculation of water within the unit and, for this reason, a conventional drum is not required to separate water from steam.

The furnace is completely fluid-cooled and is usually designed for balanced draft operation. Heat transfer surface for single or two-stage reheat may be incorporated in the design. (See Chapter 2.)

Firing rate, feedwater flow, and turbine throttle valves are coordinated to control steam flow, pressure, and superheater steam temperature. Reheater steam temperature is controlled by gas proportioning dampers at the outlet of the steam and water heating surfaces.

The UP boiler is designed to maintain a minimum flow inside the furnace circuits to prevent furnace tube overheating during all operating conditions. This flow must be established before boiler startup. A startup system (boiler bypass), integral with the boiler, turbine, condensate and feedwater system, is provided. This system assures that the minimum design flow is maintained through pressure parts that are exposed to high temperature combustion gases during the startup operations and at other times when the required minimum flow exceeds the turbine steam demand. (See Chapter 19.)

Two types of UP boilers are available. The original design (UP) features the vertical tube furnace arrangement with high mass flux within the furnace tubes. This boiler is designed for load cycling and base load operation; fluid pressure in the furnace is at supercritical pressure at all loads. More recently, there has been demand for supercritical boilers capable of variable pressure operation and on-off cycling, as well as load cycling and base load operation. This boiler is the SWUP™, or spiral wound tube geometry UP boiler.

Spiral wound UP boiler – variable pressure operation with pulverized coal

The steam generating unit shown in Fig. 4 is a balanced draft coal-fired B&W Spiral Wound Universal Pressure (SWUP™) boiler, comprising a water-cooled dry-bottom furnace, superheater, reheater, economizer, and air heater components. The unit is designed to fire coal usually pulverized to a fineness of at least 70% through a 200 mesh (75 micron) screen. The B&W SWUP unit is designed for both base load and variable pressure load cycling operation as well as on-off cycling operation.

The unique feature of this boiler, compared to other boilers, is that the tubes in the furnace, from the lower furnace inlet headers to a location near the furnace

arch, are wound around the furnace circumference rather than being vertical (see Fig. 5). With this arrangement, each tube in the furnace passes through similar heat absorbing areas so that the heat absorption from tube to tube is reasonably uniform. In addition, because the tubes are at an angle (typically 10 to 25 degrees from horizontal), the number of individual flow paths is reduced, compared to a vertical tube geometry. A high mass flux within the tube is obtained to maintain nucleate boiling during subcritical operation (Chapter 5).

Therefore, the water introduced from the economizer piping is heated at essentially the same rate to the same temperature, minimizing thermal upsets which restrain rapid load change. The capability of this design to operate at variable pressure is further enhanced by using a startup and bypass system specifically designed for rapid load change. (See Chapter 19.)

Fuel flow Raw coal is discharged from the feeders to the pulverizers. Pulverized coal is transported by the primary air to the burners through a system of pressurized fuel and air piping. The burners are located on the furnace walls with opposed firing (burners on the front and rear walls).

Air and gas flow Air from the forced draft fans is heated in the air heaters, then routed to the windbox where it is distributed to the burners as secondary air. In the arrangement shown in Fig. 4, high pressure fans provide air from the atmosphere to a separate section of the air heater known as the primary section. A portion of the air from the primary fans is passed unheated around the primary air heater as tempering primary air. Controlled quantities of preheated and tempering primary air are mixed before entering each pulverizer to obtain the desired pulverizer fuel-air mixture outlet temperature. The primary air is used for drying and transporting fuel from the pulverizer through the burners to the furnace.

Hot flue gas from the furnace passes successively across the finishing banks of the superheater and reheater. Before exiting the boiler, the gas stream is divided into two parallel paths, one gas stream passing over a portion of the reheater and the other stream passing over a portion of the superheater. Proportioning the gas flow between these two paths as unit load changes provides a tool for reheat steam temperature control. The flow quantities are adjusted by a set of dampers at the boiler exit. A controlled amount of gas passes over a portion of the reheater to obtain the reheater steam temperature set point, and the remaining gas travels a parallel path across the superheater surface. Attenuators are provided in the reheater and superheater systems. The reheater attenuator is used during transient loads and upset conditions, with reheater spray quantities held to a minimum to maximize cycle efficiency. The superheat attenuator spray is used to help control main steam temperatures during transient operation. This arrangement of convection surface and damper system provides extended capability to obtain design steam temperatures in the superheater and reheater over a broad load range.

The gases leaving the superheater and reheater sections of the convection pass cross the economizer, pass

to the air heater(s) and then travel to the appropriate environmental control equipment. In areas where tight NO_x emissions requirements have been established and post-combustion control is needed, selective catalytic reduction (SCR) NO_x removal systems are frequently installed between the economizer and air heater (see Chapter 34).

Water and steam flow Feedwater (Fig. 6) enters the bottom header of the economizer and passes upward through the economizer tube bank into support tubing located between tube rows of the primary superheater. The heated feedwater is collected in outlet headers at the top of the unit. It is then piped to the lower furnace area from which multiple connecting pipes

(supplies) are routed to the lower furnace headers.

From the lower furnace wall headers the fluid passes upward through the spiral furnace tubes to a transition section located below the furnace arch. From the transition section the tubes are routed vertically up the front and side walls and up the rear wall and furnace arch.

After discharging to the upper furnace wall headers, all of the fluid is piped to a fluid mix bottle, then to the front roof header, then through the roof tubes to the rear roof header. Pipes then convey the fluid to the vertical steam separators. The vertical steam separators are a part of the boiler startup system (see Chapter 19).

As illustrated in Fig. 7, steam from the vertical

Fig. 4 750 MW once-through spiral wound universal pressure (SWUP™) boiler for pulverized coal firing.

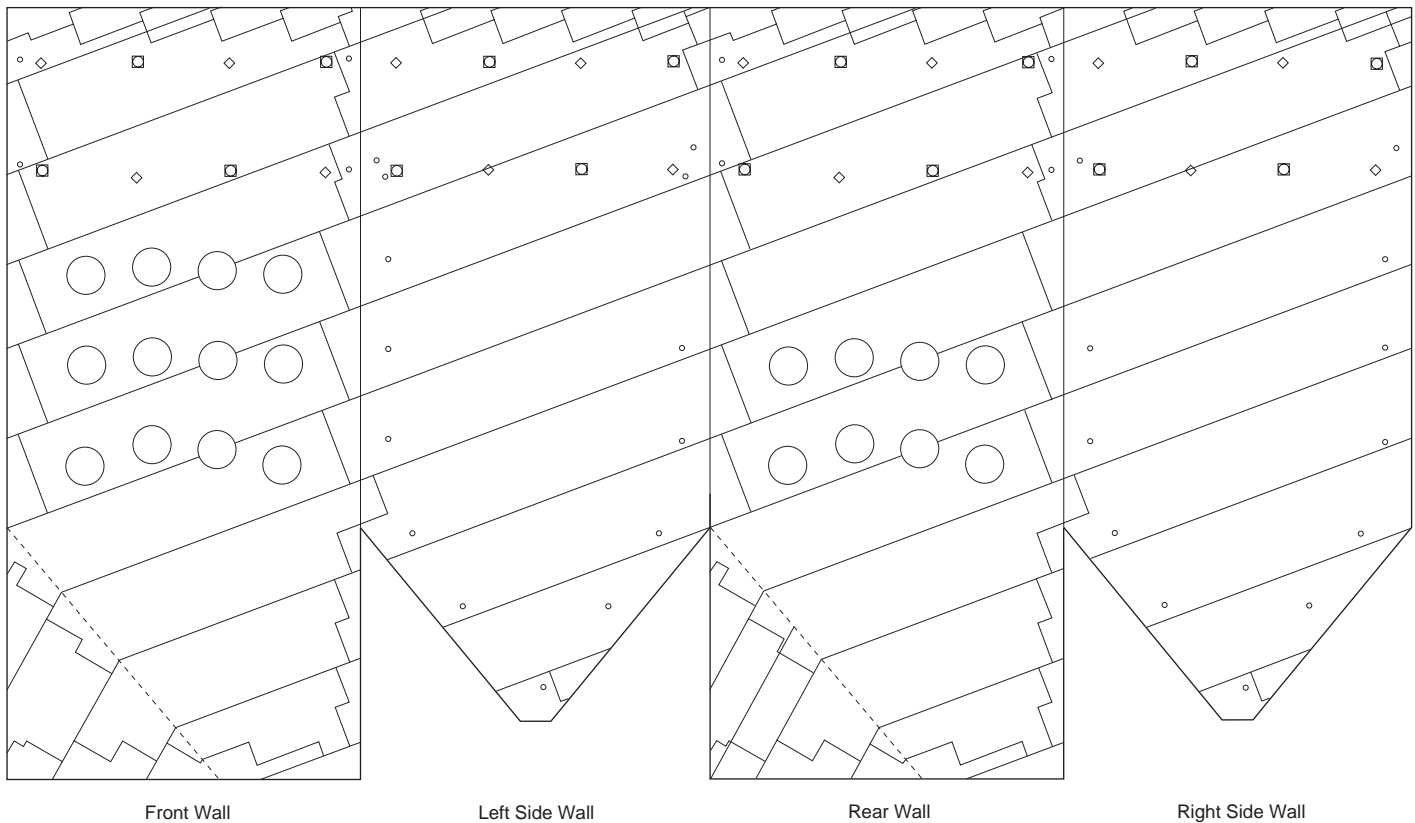

Fig. 5 Typical spiral wound tube arrangement for a 420 MW coal-fired boiler.

steam separator passes to the convection pass enclosure wall lower headers. The fluid flows up through the wall tubes and the baffle wall and is collected into the downcomer supplying the primary superheater inlet header. The steam rises through the primary superheater, discharges to its outlet header and flows through connecting piping equipped with a spray attemperator. The partially superheated steam then enters the platen secondary superheater and flows through the various superheater sections to its outlet headers. The steam flows through connecting pipes and the second set of spray attemperators to the finishing portion of the secondary superheater and finally to the outlet header and discharge pipes, which terminate at points outside of the unit penthouse. The superheated steam is directed to the high pressure section of the steam turbine. After partial expansion in the steam turbine (see Chapter 2), the low pressure steam is returned to the boiler for reheating.

The low pressure steam is reintroduced to the boiler at the reheater inlet header (RHSH inlet) and flows through the reheater tube bank to the reheater outlet header (RHSH outlet). Reheated steam is then routed to the intermediate pressure and then low pressure sections of the steam turbine-generator set.

Universal Pressure boiler for load cycling operation with pulverized coal

The steam generating unit shown in Fig. 8 is a balanced draft B&W Universal Pressure coal-fired Carolina-type boiler (UPC), comprising a water-cooled dry-bottom furnace and superheater, reheater, economizer

and air heater components. The unit is designed to fire coal, usually pulverized to a fineness of at least 70% through a 200 mesh (75 micron) screen. The B&W UPC unit is particularly suited for base load duty and constant boiler pressure, load cycling operation.

Fuel flow Raw coal is discharged from the feeders to the pulverizers, which can be located at the front or sides of the unit. Pulverized coal is transported by the primary air to the burners through a system of pressurized fuel and air piping.

Air and gas flow The air flow arrangement and routing are similar to that used on the SWUP design previously discussed.

As indicated in Fig. 8, hot flue gases leaving the furnace pass successively across the fluid-cooled surface at the top of the furnace (wing walls), the secondary superheater and the pendant reheater, which are located in the convection pass out of the high radiant heat transfer zone of the furnace. The gas turns downward (convection pass) and crosses the horizontal primary superheater, horizontal reheater and economizer before passing to the air heaters. In areas where tight NO_x emissions requirements have been established and post-combustion control is needed, SCR NO_x control systems are frequently installed between the economizer and the air heater (see Chapter 34).

Water and steam flow Feedwater enters the bottom header of the economizer and passes upward through the economizer to the outlet header. It is then piped to the lower furnace area from which multiple connecting pipes (*supplies*) are routed to the lower furnace headers.

Fig. 6 Typical fluid flow for a SWUP™ boiler.

From the furnace wall headers the fluid is then passed upward through the first pass of vertical furnace tubes (Fig. 8). A transition section (Fig. 9) is provided some distance below the furnace arch and the first pass tubes exit the furnace enclosure and connect to headers at this location. The fluid from the various headers around the furnace circumference is mixed together in common piping. This equalizes the temperature of the fluid before it passes down to the second set of lower furnace inlet headers and flows upward through the second pass of vertical furnace tubes. The second pass tubes exit the furnace enclosure at the transition section and connect to another set of headers. The first and second pass are alternated around the furnace circumference to maintain uniform wall temperatures.

From the second pass outlet headers, the fluid flows through mix piping and on to the third pass inlet headers. The third pass furnace tubes form the furnace enclosure from the transition section to the furnace roof. In addition, furnace wing walls may be in a parallel flow circuit with the third pass tubes. This com-

pletes the furnace tube pass and the fluid exits to the upper furnace wall headers.

After discharging to the upper furnace wall headers, the fluid is piped to the front roof header, then through the roof tubes to the rear roof headers where mixing again takes place. It is then passed through a pipe distribution system to the convection pass enclosure wall lower headers. The fluid flows up through the wall tubes and the superheater screen. Pipes then convey the fluid to a common header and then to the primary superheater inlet header.

The fluid is collected and partially mixed before entering the primary superheater, then partially mixed again as it flows from the primary superheater through connecting piping to the secondary superheater. The furnace pressure control valves and connections to the boiler startup system (Chapter 19) and the spray attemperator are contained in this connecting piping. The steam flows through connecting piping to the secondary superheater and finally to the outlet header and discharge pipes, which terminate at points outside of the unit penthouse. The superheated steam is directed to the high pressure section of the steam turbine. After partial expansion in the steam turbine (see Chapter 2), the low pressure steam is returned to the boiler for reheating.

Advanced supercritical boiler designs

Vertical tube variable pressure boiler While the spiral wound furnace (SWUP) meets today's market needs for variable pressure operation, B&W is continuing the research and development of advanced supercritical boiler designs.

The ideal furnace design would have vertical tubes and be capable of variable pressure operation over the load range while exhibiting natural circulation flow characteristics (flow increasing as heat absorption increases), thus protecting the tubes from overheating. The high mass fluxes required by the ribbed tubes used

Fig. 7 Typical steam flow for a SWUP™ boiler.

Fig. 8 1300 MW Universal Pressure (UPC) boiler for pulverized coal firing.

in the current UP boilers do not provide this characteristic. Instead, a ribbed tube design (Fig. 10) capable of preserving the desirable departure from nucleate boiling (DNB) characteristics (Chapter 5) at low mass fluxes in the high heat flux zones is necessary. The low mass flux is required to achieve the low dynamic pressure loss necessary to achieve the self-compensating, natural circulation characteristic. A secondary benefit is a reduction in pressure loss through the boiler so that the feed pump power is reduced and cycle efficiency is slightly increased. Research continues in ribbed tube development and the application of the advanced ribbed tube designs to the boiler. (See Chapter 19.)

Higher temperature and pressure The supercritical steam cycle provides an improvement in heat rate (efficiency) as compared to the subcritical steam cycle.

Additional gains in efficiency are possible as the cycle temperature and pressure are further increased. Research continues in tube materials to develop higher efficiency boiler and turbine systems.

Subcritical (drum) boilers

The B&W boiler for subcritical applications is the Radiant boiler (RB), so named because the steam generation is by radiant heat transfer to the furnace enclosure tubes. Its components are pre-engineered with sufficient flexibility to adapt the design to various fuels and a broad range of steam conditions.

In modern units, the furnace is a natural circulation, water-cooled, balanced draft design and usually features dry ash removal. Superheater and reheater surfaces are of the vertical pendant and/or horizon-

Fig. 9 UP boiler furnace tube arrangement.

tal designs. Superheat temperature control is accomplished by an attemperator. Reheat temperature control is by gas proportioning dampers.

Range in capacity, steam output – about 700,000 lb/h (90 kg/s) to a maximum that may exceed 7,000,000 lb/h (880 kg/s).

Pressure – subcritical, usually 1800 to 2400 psi (12.4 to 16.5 MPa) throttle pressure with 5% overpressure capability.

Superheater and reheater outlet temperatures – as required, usually in the range of 1000 to 1050F (538 to 566C).

Radiant boiler for pulverized coal – Carolina

The steam generating unit shown in Fig. 11 is a balanced-draft Carolina-type Radiant boiler (RBC). It is arranged with a natural circulation, water-cooled dry-bottom furnace, and superheater, reheater, economizer and air heater components. The unit is designed to burn coal, usually pulverized to a fineness of which at least 70% passes through a 200 mesh (75 micron) screen. The horizontal convection pass and vertical pendant heat transfer surfaces provide the benefits of: 1) high temperature supports outside of the flue gas stream, 2) minimal motion between the boiler roof penetrations, and 3) more control over pendant section spacing in the design. The lower furnace height compared to other pulverized coal designs also reduces structural steel and erection costs.

Fuel flow Raw coal is discharged from the feeders

to the pulverizers. The pulverized coal is transported by the primary air to the burners through a system of pressurized fuel and air piping. The burners are located on the furnace walls with opposed firing (burners on the front and rear walls) being used for all but the smallest units.

Air and gas flow Air from the forced draft fans is heated in the air heaters, then routed to the windbox where it is distributed to the burners as secondary air. In the arrangement shown in Fig. 11, high pressure fans provide air from the atmosphere to a separate section of the air heater known as the primary section. A portion of the air from the primary fans is passed unheated around the primary air heater as tempering primary air. Controlled quantities of preheated and tempering primary air are mixed before entering each pulverizer to obtain the desired pulverizer fuel-air mixture outlet temperature. The primary air is used for drying and transporting fuel from the pulverizer through the burners to the furnace.

Hot gases from the furnace pass successively across the finishing banks of the superheater and reheater. Before exiting the boiler, the flue gas stream is divided into two parallel paths – one gas stream passing over a portion of the reheater and the other stream passing over a portion of the superheater. Proportioning the gas flow between these two paths as unit load changes provides a tool for reheat steam temperature control. The flow quantities are adjusted by a set of dampers at the boiler exit. A controlled amount of gas passes over a portion of the reheater to obtain the reheater steam temperature set point and the remain-

Fig. 10a Single-lead ribbed tube.

Fig. 10b Multi-lead ribbed tube.

Fig. 10c Optimized multi-lead ribbed tube.

ing gas travels a parallel path across the superheater surface. Attemperators are provided in the reheater and superheater systems. The reheater attemperator is used during transient loads and upset conditions, with reheater spray quantities held to a minimum to maximize cycle efficiency. Superheater spray is used to maintain main steam temperatures. This arrangement of convection surface and damper system pro-

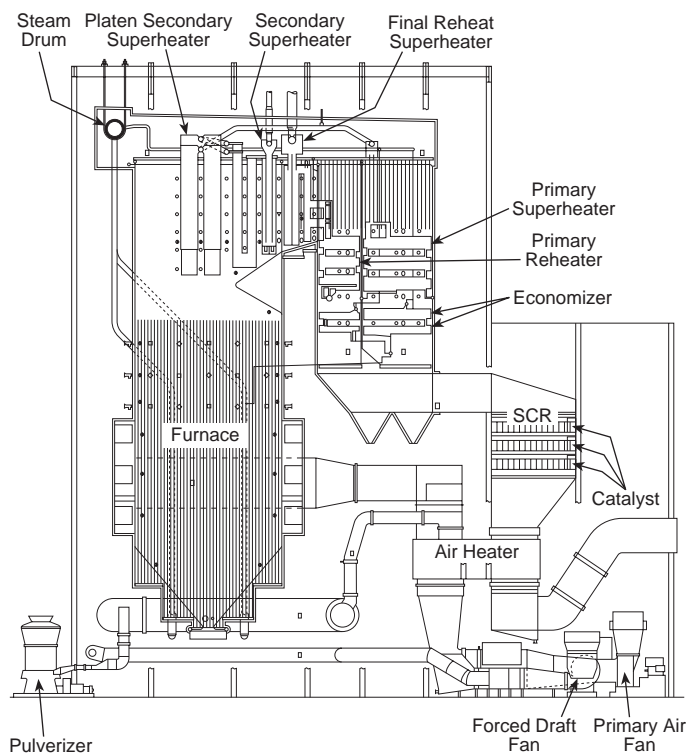

Fig. 11 Carolina-type Radiant boiler (RBC) for pulverized coal firing.

vides extended capability to obtain design steam temperatures in the superheater and reheater over a broad load range.

The flue gases leaving the superheater and reheater sections of the convection pass cross the economizer. In new or recently retrofitted units, the gas leaves the economizer and passes through an SCR system to reduce NO_x emissions before the gas travels to the air heater. After the air heater, the gas passes to the appropriate environmental control equipment.

Water and steam flow Feedwater enters the bottom header of the economizer. The water passes upward through the economizer tube bank into support tubing that is located between tube rows of the primary superheater. The heated feedwater is collected in outlet headers at the top of the unit, then routed into the steam drum. As shown in Fig. 12, natural circulation provides water flow from the steam drum down through large diameter downcomer pipes to multiple supply distributor tubes or *supplies* connecting to the individual lower furnace headers. The fluid rises as it is heated in the furnace tubes and passes through riser tubes back into the steam drum.

The mixture entering the steam drum is separated into steam and water flows by cyclone separators. These provide essentially steam-free water to the downcomer inlets. The steam is further purified by passing it through the primary and secondary steam scrubbers as discussed in Chapter 5.

As illustrated in Fig. 13, steam from the steam drum passes through multiple connections to a header supplying the furnace roof and convection pass rear

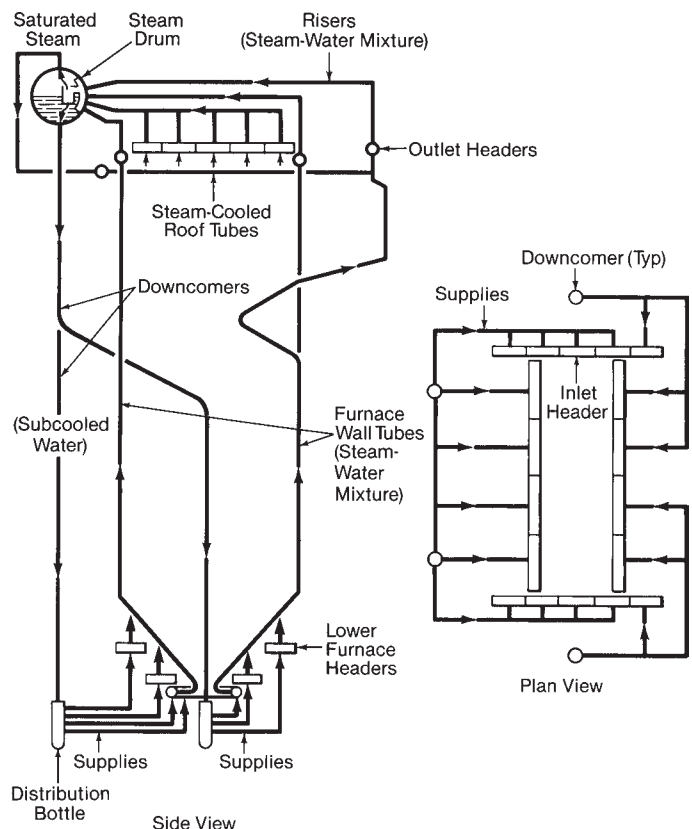

Fig. 12 Typical furnace circulation diagram for a Radiant boiler (RB).

Fig. 13 Typical steam-cooled roof and convection pass enclosure wall circuits for a Radiant boiler (RB).

wall tubes, which directly connect to the primary superheater inlet header. Steam leaving the drum is also routed to a series of headers, which provide cooling steam for the convection pass side walls, before being directed to the primary superheater inlet header.

As shown in Fig. 14, the steam rises through the primary superheater, discharges to its outlet header and flows through connecting piping equipped with a spray attemperator. The partially superheated steam then enters the secondary superheater and flows through the various superheater sections to its outlet headers and discharge pipes, which terminate at points outside of the unit penthouse. The superheated steam is directed to the high pressure section of the steam turbine. After partial expansion in the steam turbine (see Chapter 2), the low pressure steam is returned to the boiler for reheating.

The low pressure steam is re-introduced to the boiler at the reheater inlet header (RHSH inlet) and

Fig. 14 Superheater, reheater and economizer circuits for a Radiant boiler (RB).

flows through the reheater tube bank to the reheater outlet header (RHSH outlet). Reheated steam is then routed to the intermediate pressure and then low pressure sections of the steam turbine-generator set.

Radiant boiler for pulverized coal – Tower

An alternate configuration of the Radiant boiler is the Tower design (RBT) shown in Figs. 15 and 16. A special feature of this design is that all surfaces are drainable. This feature was initially designed for service in northern latitudes to provide freeze protection by arranging the superheater, reheater and economizer sections so that they are drainable. The Tower design is a single gas path, as compared to the parallel gas path of the RBC, and therefore, has no inherent provision for steam temperature control other than spray attemperation. The Tower design may be equipped with gas recirculation and tempering for extended superheater and reheater temperature control range. Additional advantages of the Tower design include more uniform gas flow entering all convection sections, minimum tube bend erosion potential because of no convection pass turns, and removal of most of the ash and slag through the main furnace hopper. However, the Tower design requires a much taller structure and generally results in a longer erection schedule due to the single erection path as compared to the RBC design.

General characteristics of the design are water-cooled furnace, balanced draft, natural circulation, top supported and drainable. The draining feature is accomplished by placing all steam- and water-contained

Fig. 15 400 MW Tower-type Radiant boiler (RBT) for pulverized coal firing.

Fig. 16 Four 400 MW RBT boilers and three 600 MW RBC boilers in Southeast Asia.

surfaces in the horizontal position so that they may be completely drained when the unit is taken out of service.

Fuel flow Similar to the RBC, the RBT is arranged so that raw coal is discharged from the feeders to the pulverizers. Primary air is used to transport the pulverized coal from the pulverizers to the burners through a system of pressurized fuel and air piping.

Air and gas flow Air is introduced to the RBT in the same pattern as the RBC. The geometric differences of the two units create varying paths for gas flow. The hot gases from the furnace pass vertically up and over the superheater and reheater banks located in the upper section of the boiler. The flue gas is then directed down to the economizer located outside of the boiler setting, finally passing to the SCR (if required) and air heater system, and then to the environmental control equipment for cleanup.

Water and steam flow Feedwater is introduced to the boiler system through the economizer where it is heated and discharged through a header/piping system to the steam drum. With this natural circulation system, the furnace circuitry follows the same general flow patterns as the RBC described above.

Saturated steam from the steam drum is directed through a series of pipes down to the outlet of the furnace, where a small bank of primary superheater tubes (primary superheater 1) is placed with its outlet tubing forming the internal steam-cooled support structure for the other banks of surface located farther up in the gas stream.

Steam from the support tubing is collected and directed to the finishing banks of primary superheater 2. The primary and secondary superheaters are connected with piping that contains a spray attemperator

for superheater steam temperature control. Steam enters the secondary superheater and flows through the tube sections to the outlet header, which discharges to a terminal located outside of the unit. The superheated steam is directed to the high pressure section of the steam turbine. After partial expansion, low pressure steam is then returned to the boiler for reheating.

Steam returned to the boiler is introduced at the reheater inlet header. The steam flows through the reheater tube bank and is then routed to the outlet header and steam piping connection before being sent to the intermediate and low pressure sections of the steam turbine-generator.

Radiant boiler for anthracite – Downshot

The use of anthracite is limited to a relatively few locations in the world, mainly Spain and parts of Asia. Anthracite presents a special challenge for combustion due to its very low volatile matter content. As a result, a special furnace configuration is used to improve combustion. The furnace is arranged so that the burners fire downward into the lower furnace. The flame shape in this opposed-firing arrangement is in the form of a W, hence the name of the boiler style, the RBW. A typical steam generating unit is shown in Fig. 17.

Except for the lower furnace and the combustion system, this design is very similar to the RBC. The downshot firing arrangement provides increased residence time in the lower furnace. The lower furnace is refractory lined to minimize heat loss and to maintain peak flame temperature for high combustion efficiency. In addition, the anthracite fineness is increased, compared to normal coal, to 90% passing through a 200 mesh (75 micron) screen, to further enhance combustion efficiency.

The boiler is arranged with a water-cooled dry-bottom furnace, and superheater, reheater, economizer

Fig. 17 300 MW RBW boiler for pulverized anthracite (downshot).

and air heater components. The horizontal convection pass and vertical pendant heat transfer surfaces provide the benefits of: 1) high temperature supports outside of the flue gas stream, 2) minimal motion between the boiler roof penetrations, and 3) more control over pendant section spacing in the design. The lower furnace height compared to other pulverized coal designs also reduces structural steel and erection costs.

Fuel flow Raw coal is discharged from the feeders to the pulverizers. The pulverized coal is transported by the primary air to the burners through a system of pressurized fuel and air piping. The burners are located on the shelves of the furnace front and rear wall so that they fire downward giving a flame pattern in the shape of a W.

Air and gas flow Air from the forced draft fans is heated in the air heaters, then routed to the windbox where it is distributed to the burners as secondary air. In addition, a portion of the air is introduced to the lower portion of the lower furnace as staging air. The staging air both increases the peak flame temperature near the burners by decreasing the amount of excess air and helps to draw the flame path down into the furnace to increase residence time.

In the arrangement shown in Fig. 17, high pressure fans provide air from the atmosphere to a separate section of the air heater known as the primary section. A portion of the air from the primary fans is passed unheated around the primary air heater as tempering primary air. The primary air is used for drying and transporting fuel from the pulverizer through the burners to the furnace. Generally, it is desirable to achieve the maximum pulverizer fuel-air mixture temperature possible. However, provisions are included for mixing the preheated and tempering primary air before entering each pulverizer to provide control of pulverizer fuel-air mixture temperature during pulverizer start up and shut down. In addition, special provisions may be included for further increasing the temperature of the fuel/air mixture to further enhance combustion.

Hot gases from the furnace pass successively across the finishing banks of the superheater and reheater in the same manner as described for the RBC boiler.

Water and steam flow The water and steam flow arrangement is the same as for the RBC boiler discussed earlier.

Oil- and gas-fired utility boilers

The use of oil and gas as fuels for new utility boilers has declined except for selected locations and conditions, primarily the oil producing nations. This is due in part to the price of these premium fuels and their availability. At the same time, advancements in gas turbine and gas turbine combined cycle systems (Chapter 27) have made the use of oil and gas in these systems more cost effective.

However, in selected cases, the proposed boiler location, fuel availability, local price or existing facility constraints may make oil or gas the preferred fuel. In addition, low sulfur oil- and natural gas-fired new utility boilers have the distinct advantage of low environ-

mental emissions; NO_x, SO₂ and particulate emissions are less in these units.

Both the SWUP (and UP) and the RBC boiler designs can be used for oil and gas firing. However, for subcritical applications a design different than the RBC is normally used.

Fuels

Natural gas Natural gas (see Chapter 11) has the fewest design restrictions of the major fuels because it is relatively clean and easy to burn. If only natural gas is burned, fuel storage facilities, ash hoppers, ash pits and ash handling equipment are unnecessary. Sootblowers can be omitted and dust collectors are not needed. Control of heat input to the boiler furnace is simplified. Heating surfaces can be arranged for optimum heat transfer and gas resistance (draft loss) without consideration of ash deposits and erosion. The total enclosure volume is at a minimum and the adaptability for outdoor service is increased.

Fuel oil Fuel oil (see Chapter 11) has many of the desirable features of natural gas, including ease of handling and elimination of ash hoppers and ash pits. However, it requires storage, heating and pumping facilities. Oils with high sulfur and vanadium contents can cause troublesome deposits on surfaces throughout the unit. (See Chapter 21.) These deposits can be minimized by arranging the heating surfaces for optimum cleaning by sootblowing equipment. Provision should be made for water washing the furnace and all convection surfaces when the unit is shut down for maintenance. Air heater protection devices (a steam coil or hot water coil) should be installed to prevent gas condensation and acid attack on the gas side of the air heater surfaces (see Chapter 20) and in the equipment downstream of the air heater.

B&W Radiant boiler for natural gas and oil

The steam generator shown in Figs. 18 and 19 is an El Paso-type Radiant boiler (RBE) unit. It is arranged with a water-cooled hopper-bottom furnace and superheater, reheater, economizer and air heater components. The unit is designed to use natural gas and oil separately or in combination. The general characteristics of the Radiant boiler are discussed in *Pulverized coal firing*. The unique aspects of the El Paso design are the elimination of the pendant convection pass and the inclusion of the upflow and downflow convection passes within the footprint occupied by the boiler furnace. The flow rates and pressure ranges for the coal-fired Radiant boiler are also applicable here.

Air and gas flow Air from the forced draft fan is heated in the air heater and is distributed to the burner windbox. Hot gases from the furnace pass successively over the horizontal secondary superheater and reheater sections and one bank of the primary superheater. The gas then turns, flows downward and crosses the remainder of the primary superheater and economizer sections. It then travels out of the water-cooled enclosure to the air heater. In new or recently retrofitted units, the gas leaves the economizer and passes through an SCR system to reduce NO_x emissions before the gas travels to the air heater. After the

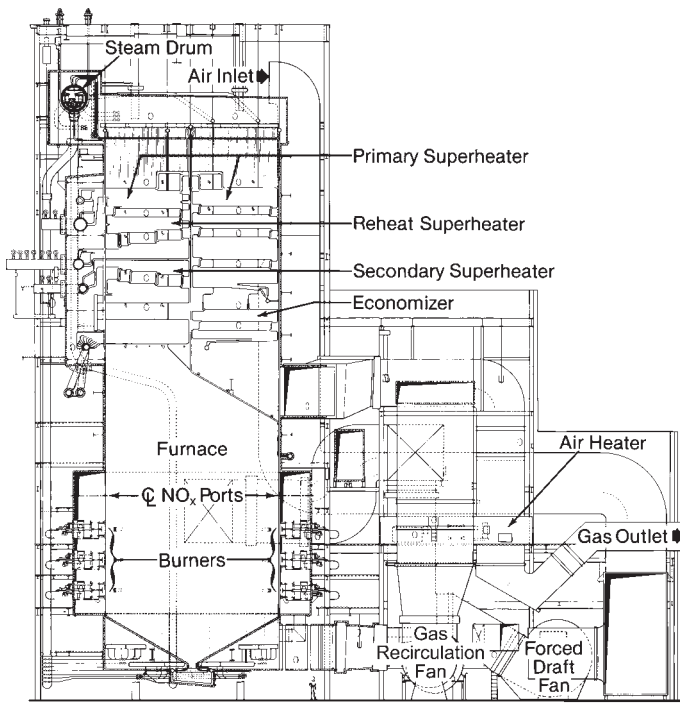

Fig. 18 El Paso-type Radiant (RBE) boiler for oil and gas firing.

air heater, the gas passes to the appropriate environmental control equipment.

Water and steam flow Feedwater enters the bottom header of the economizer. The water flows upward through the economizer and discharges through the outlet header into piping that directs it to the steam drum. By means of natural circulation, water flows downward through downcomer pipes, then through supply distributor tubes to the lower furnace headers. It then rises through the furnace tubes (which enclose the convection area) and flows to the upper headers and through connecting riser tubes into the steam drum.

The steam-water mixture in the steam drum is passed through cyclone separators, which provide essentially steam-free water for the downcomers. The

Fig. 19 Two 300 MW RBE boilers in Egypt.

steam is further purified by passing it through the primary and secondary steam scrubbers within the drum.

Steam from the drum passes through multiple connections at the rear of the convection enclosure into the primary superheater inlet header.

The steam rises through part of the primary superheater and, by means of connecting tubes, is directed into the remainder of the primary superheater in the first gas pass. The flow discharges through the primary superheater outlet header into connecting piping equipped with a spray attenuator. The steam enters the secondary superheater inlet header and flows through the secondary superheater sections to the outlet header and to a discharge pipe, which terminates outside the casing at the front of the unit.

Low pressure steam, introduced to the reheater inlet header, flows through the reheater sections and out through the reheater outlet header to a connection terminating outside the casing, also at the front of the unit.

This power plant features two B&W 420 MW variable pressure, supercritical boilers burning pulverized coal.

Chapter 27

Boilers for Industry and Small Power

Most manufacturing industries require steam for a variety of uses. Basic plant heating and air conditioning, prime movers such as turbine drives for blowers and compressors, drying, constant temperature reaction processes, large presses, soaking pits, water heating, cooking and cleaning are all examples of how steam is used.

Steam produced by industrial boilers can also be used to generate electricity in a cogeneration mode which uses a conventional steam turbine for electric power generation and low pressure extraction steam for the process. The electricity is then used by the plant or sold to a local electric utility company. As an alternate cogenerating system, a gas turbine can be used for power generation with a heat recovery steam generator for steam.

Thousands of boilers are installed in industrial and municipal plants, providing lower pressure and temperature steam than utility boilers dedicated to large, central station electric power generation. In an industrial plant, the dependability of steam generating equipment is critical. Most often, the industrial operation has a single steam plant with one or more boilers. If the steam flow is interrupted, production can be seriously impacted. Accordingly, industrial boilers must be very reliable because plant productivity relies so heavily on their availability. Loss of a boiler for a short time can stop production for days if, for example, materials cool and solidify in process lines. For this reason, some industries prefer multiple smaller units.

The principles governing the selection of boilers and related equipment are discussed in Chapter 37. Proper equipment selection can be accomplished only in the framework of a sound technical and cost evaluation. This requires a working knowledge and understanding of the performance of the different steam generating unit components under various conditions, including the significance of the many different arrangements of heat absorbing surfaces, the characteristics of available fuels, combustion methods and ash handling. The owner must also establish the present and future steam conditions and requirements. All pertinent environmental regulations must also be considered. A brief summary of boiler specifications is provided in Table 1.

Industrial boiler design

Industrial boilers generally have different performance characteristics than utility boilers. These are most apparent in steam pressures and temperatures as well as the fuel burning equipment.

Industrial units are built in a wide range of sizes, pressures and temperatures – from 2 psig (13.8 kPa) and 218F (103C) saturated steam for heating to 1800 psig (12.4 MPa) and 1000F (538C) steam for plant power production.

In addition, industrial units often supply steam for more than one application. For some applications, steam demand may be cyclic or fluctuating, thereby complicating unit operation and control of the equipment.

The Babcock & Wilcox Company (B&W) industrial boilers, such as the unit shown in Fig. 1, are water tube design and generally rely upon natural circulation for steam-water circulation.

Most utility boilers are designed to burn pulverized or crushed coal, oil, gas, or a combination of oil or gas with a solid fuel. Industrial boilers can be designed for the above fuels as well as coarsely crushed coal for stoker firing and a wide range of biomass or byproduct fuels.

13. Evaluation basis

Many industrial processes generate byproducts which can serve as boiler fuels, significantly contributing to the plant operating efficiency and effectively reducing product cost. Examples of these are gas products from the steel industry (blast furnace and coke oven gas), products from the petroleum industry (carbon monoxide (CO), refinery gas, petroleum coke), products from agriculture (sugar mill bagasse, peanut hulls, coffee grounds), waste from the pulp and paper industry (wood, bark, process chemicals, sludge) and municipal solid waste. Steam generation and fuel handling for some of these fuels and applications have become quite specialized. This chapter and the following chapters are devoted to these units:

- Chapter 28 – Chemical and Heat Recovery in the Paper Industry
- Chapter 29 – Waste-to-Energy Installations
- Chapter 30 – Wood and Biomass Installations
- Chapter 31 – Marine Applications

One of the distinguishable features of most industrial boilers is a large saturated water *boiler bank* between the steam drum and lower drum. (See Figs. 1 and 2.) The boiler bank serves the purpose of preheating the inlet feedwater to the saturation temperature and then evaporating the water (generating steam) while cooling the flue gas to a cost effective exit temperature.

In lower pressure boilers, insufficient heating surface is available in the furnace enclosure to absorb all of the energy needed to accomplish this function. Therefore, a boiler bank located downstream of the furnace

and superheater (if included) in the flue gas stream provides the rest of the necessary heat transfer surface.

As shown in Fig. 3, as pressure increases, the amount of heat absorption required to evaporate water declines rapidly, and the absorption required for superheating and water preheating increases. In some modern very high pressure industrial units, a smaller boiler module separate from the steam drum provides the same function as the traditional boiler bank (see Fig. 4), but at a lower cost.

A separate economizer and/or air heater can be used downstream of the boiler bank to further reduce the flue gas exit temperature to a more economic value.

Steam requirements

To assure prompt fulfillment of all steam demands, i.e., the delivery of heat to all points of use at the required rates, it is necessary to select steam producing equipment of sufficient capacity, range of output and responsiveness. The demand may be steady, as in most space heating systems, or it may fluctuate widely and rapidly, as in a heavy forging plant. Many steam heated processes, as in the initial heating of a liquid batch, require high peak flows of short duration. Rapidly changing rates of steam flow characterize requirements to produce the electrical power to drive a steel rolling mill. Combined cycle systems often require rapid steam load responses during cycle transients. The steam flow requirements should, therefore, be accurately established for a number of conditions to ensure that the boiler system selected will meet all of

Fig. 1 Two drum Stirling® power boiler system for pulverized coal with environmental control equipment.

Fig. 2 Two drum Stirling® boiler for spreader-stoker firing.

its demand conditions, i.e., peak flow, maximum continuous flow (the usual steady maximum flow), minimum flow, and rate of change in flow.

The peak load will, of course, establish the top capacity for the steam producing equipment and all of its auxiliaries. For widely fluctuating loads, it is advisable to establish the 15 minute peak. In most systems, peaks of shorter duration can be met by the storage of heat inherent in the steam generating equipment.

Steam for process and heating The pressure of saturated steam (no superheat) used for process heating is such that the corresponding condensing steam temperature is somewhat above the required temperature of the materials to be heated. Generally, superheat is of no value for this kind of service and is often undesirable because of its interference with temperature control. Reclaiming or devulcanizing rubber, where the rubber in a caustic solution is heated to 400F (204C) by condensing saturated steam at 250 psig (1724 kPa) and 407F (208C) in the jacket of the devulcanizer, is a typical example of process heating with steam.

Pressures of saturated steam for comfort heating of buildings range from 2 psig (13.8 kPa) to as high as

Fig. 3 Effect of steam pressure on evaporation in industrial boilers – 100F (56C) constant superheat.

80 psig (0.55 MPa) in the case of space heaters. It is seldom economical to distribute steam through long lines at pressures below 150 psig (1.0 MPa) because of piping costs. Furthermore, the usual requirements for steam within the boiler house for sootblowers, feed pumps and other auxiliaries make it desirable to operate boilers at a minimum of 125 psig (0.86 MPa). Consequently, few steam plants of any size are operated below this pressure. If the pressure required at points of use is lower, it is common practice to use pressure reducing stations at or near these locations.

The pressure required at the outlet of steam produc-

Fig. 4 Single drum Stirling® boiler for spreader-stoker firing.

ing equipment for process heating service usually ranges from 125 to 250 psig (0.86 to 1.7 MPa) and superheat is usually not required. For this service, boiler manufacturers have generally standardized on a pressure of 250 psig (1.7 MPa) for small water-tube boilers.

It is customary American stationary boiler practice to hold the main steam line pressure practically constant for all loads, on the premise that this condition satisfies all pressure and quantity requirements of the steam-using equipment. Automatic combustion control apparatuses are accordingly designed to function on this basis.

Cogeneration Many manufacturing operations, such as in paper and textile mills, in the production of chemicals and in processing rubber, require mechanical or electrical power as well as steam for process heating. For such cogeneration applications, studies are made of the relative merits and costs of: 1) a plant where the power is purchased and steam is generated to supply the heating requirements only, and 2) a plant where steam and power are generated in the same system. A sound appraisal of the relative merits of the two alternatives requires knowledge of the steam and power requirements, ability to correlate these requirements, economic studies and good judgement. The following general summary may be of assistance.

1. The basic economic advantage in generating steam and power in the same system arises from the use of a much larger portion of the heat supplied in the fuel. When generating electricity alone, as much as 60% of the heat supplied in the fuel is lost to the condensing system, even in a modern central station. (See Chapter 2.)
2. Despite this fundamental thermodynamic advantage, it is frequently more economical to purchase power when it is available at reasonable rates from a dependable source, except where:
 - a. blast fuels and waste heat, such as bagasse, blast furnace gas, sawdust or hogged wood, and hot gases are available at low cost from the plant process, and
 - b. the steam heating and power demands are reasonably parallel and relatively large, i.e., 50,000 lb/h (6.3 kg/s) of steam or more.
3. Two approaches are used for cogeneration. Where natural gas is available on site, a gas turbine can be used to generate power, with the waste heat in the turbine exhaust gas used to produce steam in a heat recovery steam generator (HRSG). HRSGs are discussed in more detail later in this chapter. Where a waste fuel such as petroleum coke, bark, biomass, tires or other fossil fuel such as coal is the economic fuel of choice, a steam turbine topping cycle is used. Here, high pressure high temperature steam is produced in the boiler system and is first passed through a steam turbine to generate power. The exhaust steam is then conditioned (brought to appropriate temperature and pressure) and sent to the process.
4. Variations in process heat and power demands usually do not coincide. To compensate for the differences, a variety of options can be used depending upon the economic evaluation:

- a. for a gas turbine-based system
 1. If steam demand typically exceeds power demand, auxiliary burners are supplied with the HRSG.
 2. If electrical load demand typically exceeds the steam demand requirements, the remainder of the power may be purchased outside.
- b. for a steam-based power system
 1. If steam demand typically exceeds power demand, the turbine exhaust steam flow can be supplemented with boiler auxiliary firing, and then the additional steam can be passed through a pressure reducing and attemperating system.
 2. If power demand is typically higher, either an extraction condensing turbine system can be used or the incremental power can be purchased outside.

If the process requirements for steam and power are reasonably parallel and steady, cogeneration, including capital, operating and maintenance costs, can be beneficial. Where discontinuous service, low capacity factor or significantly different steam and power requirements exist, electrical supply from the local power grid and on-site steam generation is frequently more cost effective.

Power generation Except for small isolated installations, the high speed turbine is the prime mover of choice for steam power generation because of its efficiency, compactness and low cost. Continued improvement in reliability, reduction in cost, and availability of packaged systems have made on-site power generation more popular. Where natural gas is available and cost effective, simple gas turbines, especially package units, have tended to dominate on-site power production needs. Where a waste fuel (or low cost coal) is available, a boiler and steam turbine system can prove to be the most economic system to supply on-site power. The selection of steam pressure and temperature for such systems depends upon an economic evaluation along the guidelines presented in Chapter 37. Steam temperature control using one or more of the methods outlined in Chapter 19 is usually provided when electrical output exceeds 25 MW. Steam temperature control is also very important where variations in the flow of the fuel and the fuel quality would otherwise lead to wide swings in power output.

Combined cycles

The concept of using waste energy for increased steam generation in industry has been around for many years. The progressive increase in fuel costs, the need to capture heat from various industrial processes, and the increasingly stringent environmental regulations have created the need for using waste heat to its fullest potential.

In the power industry, the waste heat from one power system such as a gas turbine can serve as the heat source for a steam turbine cycle. Such *combined cycles* can push overall electrical power cycle efficiency to nearly 50%. Overall energy use can substantially

exceed even this level when electrical generation is combined with process steam use.

Industries such as steel making, oil refining, pulp and paper, and food processing have used many unique steam generating systems to get the most out of their waste heat. These systems allow reduced consumption of traditional fuels, recovery of waste heat for safety and economy, and elimination of process byproducts.

In its broadest terms, a *combined cycle* plant consists of the integration of two or more thermodynamic power cycles to more fully and efficiently convert input energy into work or power. With the advancements in reliability and availability of gas turbines, the term combined cycle plant today usually refers to a system composed of a gas turbine, heat recovery steam generator and a steam turbine. Thermodynamically, this implies the joining of a high temperature Brayton gas turbine cycle with a moderate and low temperature Rankine cycle – the waste heat from the Brayton cycle exhaust serves as the heat input to the Rankine cycle. The challenge in such systems is the degree of integration needed to maximize efficiency at an economic cost. Chapter 2 discusses the thermodynamic processes and benefits of this application.

The following brief discussion focuses on the combination of a gas turbine with a heat recovery steam generator and steam turbine.

Simple combined cycle system

As shown schematically in Figs. 5a and 5b, the simple combined cycle system can consist of a single gas turbine-generator, HRSG, single steam turbine-generator, condenser, and auxiliary systems. In addition, if the environmental regulations require, a selective catalytic reduction (SCR) system to control emissions of nitrogen oxides (NO_x) can be directly integrated within the steam generator. (See Chapter 34.) This is particularly attractive because the SCR catalyst can be positioned in an optimal temperature window within the HRSG. The gas temperature leaving

the gas turbine is usually in the range of 950 to 1050F (510 to 566C) while the optimal SCR catalyst temperature is 650 to 750F (343 to 399C).

A variety of more complex configurations are possible. A key improvement in the steam cycle efficiency can be obtained by adding multiple separate pressure circuits to the HRSG to supply low pressure steam for deaeration and feedwater heating. This replaces the steam extraction regenerative feedwater heating used in conventional steam power cycles.

Commercial combined cycle systems

Actual configurations are typically more complex because of application requirements and the degree of integration. The gas turbine-generators and steam turbine-generators are commercially available in a number of specific sizes and arrangements. HRSGs are built from standardized components to suit a wide variety of steam uses and turbine exhaust conditions. Frequently, multiple gas turbines with HRSGs may feed a single steam turbine system. A gas bypass stack and silencer are typically installed downstream of the gas turbine so that it can be operated independently of the steam cycle. With the high levels of oxygen remaining in the gas turbine exhaust, supplemental firing systems can be installed upstream of the HRSG. This permits greater operating flexibility, improved steam temperature control, and higher overall power capacity. The HRSG can be designed with one to four separate operating pressure circuits to optimize heat recovery and cycle efficiency. In selected cases, further cycle efficiency gains are possible with the addition of steam reheat.

A range of cycle efficiencies is possible depending upon the complexity of the system and components. Sample overall electrical power generation cycle efficiencies for a system using a gas turbine with a 2200F (1204C) turbine inlet temperature are provided in Table 2. These are based upon the fuel higher heating value.

The environmental emissions from combined cycle systems are generally low. If natural gas is fired, sul-

Fig. 5 Simplified combined cycle system schematics.

Table 2
Sample Cycle Efficiencies and Heat Rates

System	Efficiency (%)	Heat Rate (Btu/kWh)
Simple gas turbine	32	10,700
Gas turbine plus unfired single pressure steam cycle	42	8200
Advanced gas turbine plus unfired multiple pressure steam system	48	7100
Gas turbine plus dual pressure steam system plus process steam use (cogeneration)	61	—

Note: All values are calculated using the higher heating value (HHV) of the fuel. Use of the lower heating value (LHV) of the fuel would increase the efficiencies listed.

fur dioxide (SO₂) and particulate emissions will be negligible. With current gas turbine combustor designs, NO_x emissions from the gas turbine will be low, ranging generally between < 9 and 70 ppm. The final NO_x emissions then depend upon the supplemental firing system used (if any) and the potential incorporation of an SCR NO_x control system.

Beyond thermal efficiency and low environmental emissions, potential benefits of a gas turbine combined cycle plant include:

- Schedule** Depending upon equipment size and complexity, delivery and construction of the gas turbine can take about one year. The steam turbine cycle system delivery and erection can frequently be completed in an additional year. (See Fig. 6.)
- Flexibility** The gas turbine can be used alone for rapid startup and peaking service. The HRSG boiler system can usually be brought from a cold start to full load steam generation in about 60 minutes.
- Capital** The system capital cost is typically low as a result of smaller standardized components, modular construction, prompt delivery, rapid erection, and minimum support system costs.

In the system selection, these benefits must be weighed against the usually higher cost of the cleaner premium fuels needed for the gas turbine, potential maintenance and availability issues, and load requirements.

Water treatment

Industry today is intensely competitive, and a company's survival may often depend on uninterrupted production. When industrial plants generate their own power or when steam is required for the manufacturing process, the availability of the boiler becomes a very important consideration.

Boiler reliability is directly related to water quality, as discussed in Chapter 42. The lack of proper water quality is frequently the cause of failure and lack of availability in industrial boilers. As pressures and temperatures have increased, so has the required level of water quality. However, the need for water quality is often underestimated and the result is expensive downtime for pressure part replacement. Higher water quality translates to higher steam quality, which is needed to protect superheaters and turbines.

The use of a spray water condenser (see Chapter 25) was a step taken to produce higher quality spray water to minimize the steam contamination that is often prevalent when using feedwater for spray attemperation. A sample condenser installation is shown in Fig. 7.

The maximum allowable boiler-water concentration (total solids in boiler water) in relation to the pressure at the outlet of a steam generating unit (applicable to the boiler types in the following descriptive outlines) is given in Table 3.

It is evident that good water treatment practice requires the proper attention be given to water quality throughout the boiler system. This includes makeup water, steam condensate, feedwater and boiler water. One of the major concerns in boiler operation is the prevention of fouling, regardless of operating pressure. This becomes more severe as operating pressures increase; conditions which are not regarded as troublesome at lower pressures may be entirely unsatisfactory at higher pressures.

Other design requirements

The other factors affecting industrial boiler evaluation and selection as outlined in Table 1 are addressed in depth in Chapter 37. Key among these are fuel and ash identification and evaluation. Chapters 9 and 21 address the characterization of fuels and the effect of the noncombustible residue or ash on boiler design. Chapters 11 through 17 discuss the various fuel preparation and combustion systems which may be used. The designs of the boiler, superheater, economizer and air heater systems are covered in Chapters 19 and 20 while auxiliaries are addressed in Chapters 24 and 25.

Fig. 6 Rapid installation of modular components minimizes schedules.

Fig. 7 B&W condenser-attemperator system supplies pure attemperator spray water by condensing steam from the steam drum with incoming boiler feedwater.

Environmental control

Atmospheric emissions from industrial boilers and other combustion sources have come under increasingly stringent regulation over the past 30 years. Pollutants emitted from fossil fuel fired industrial boilers can include particulate matter (PM), nitrogen oxides (NO_x), sulfur oxides (SO_x), carbon monoxide (CO), volatile organic compounds (VOCs), and other compounds commonly referred to as HAPs (hazardous air pollutants). These include hydrogen chloride and hydrogen fluorides (HCl and HF), mercury and other trace metals, and trace organic compounds. The emissions characteristics of industrial boilers are largely dependent on the type of fuel(s) combusted and the use of selected air pollution control systems and technologies.

The United States (U.S.) Environmental Protection Agency (EPA) has promulgated various environmental performance standards that apply to different sizes and classes of boilers firing both fossil and non-fossil fuels. The Federal New Source Performance Standards (NSPS), codified under Title 40, Part 60 of the Code of Federal Regulations (CFR), establish minimum requirements for many air emission sources

throughout the U.S. In 40 CFR Part 60, Subparts Db and Dc specifically apply to fossil-fuel fired industrial steam generating units with heat input capacities greater than 100 million Btu per hour and greater than 10 million Btu per hour respectively (2.9 and 29.3 MW_t). The industrial boiler NSPS set minimum requirements governing allowable emissions of PM, SO₂, and NO_x from units constructed or substantially modified after June 19, 1984. Additional subparts under 40 CFR 60 set emissions standards for other classes of boilers including, but not limited to, electric steam generating units (40 CFR 60, Subpart Da), municipal waste combustors (40 CFR 60 Subpart(s) Eb, Cb, AAAA and BBBB), and chemical recovery boilers used in the pulp and paper industry (40 CFR 60, Subpart BB).

A large industrial power boiler with environmental control equipment is shown in Fig. 1. This pulverized coal-fired Stirling® power boiler (SPB), discussed below, is equipped with low NO_x burners to reduce NO_x emissions, an electrostatic precipitator (ESP) to control particulate emissions, and a wet flue gas desulfurization (FGD) system to control emissions of SO₂.

The most common methods employed to control NO_x emissions from industrial boilers involve combustion modifications using low NO_x burner designs, staged combustion with overfire air ports, and flue gas recirculation techniques (see Chapters 11 and 14). Fluidized bed boilers, discussed in Chapter 17, can achieve very low NO_x emission rates due, in part, to the inherently low furnace combustion temperatures. If needed, post-combustion control technologies, including selective noncatalytic reduction (SNCR) and selective catalytic reduction (SCR) systems (see Chapter 34), can be used to achieve additional NO_x reductions on many industrial boiler applications.

CO and VOC emissions are best controlled by employing prudent combustion system design and operating practices. The combustion system should facilitate good air/fuel mixing and allow for adequate residence time at required temperatures. Traditionally this has been referred to as the three Ts of combustion: time, temperature, and turbulence. Any combustion technique used to achieve low NO_x levels must be balanced to account for associated (negative) impacts on CO and VOC emissions.

To achieve compliance with current day particulate emission standards, most industrial boilers firing fuels other than a *clean* gas must utilize high efficiency particulate control equipment; typically a fabric filter (baghouse) or an electrostatic precipitator (ESP). (See Chapter 33.) Baghouses and ESPs can also effectively control HAPs (trace organic and metal compounds) that are affixed to the particulate matter.

The required levels and methods of SO₂ control are primarily driven by fuel choice. SO₂ controls are generally not needed if an industrial unit burns a clean fuel such as natural gas or a low sulfur fuel oil. While the use of low sulfur coal is still feasible for many older or smaller industrial boilers, the current NSPS regulation applicable to large industrial coal-fired boilers mandate the use of SO₂ control technologies capable of achieving 90% removal efficiency. Available post-combustion SO₂ controls include both dry and wet

Table 3
Limits for Solids Content of Boiler
Water in Drum Boilers, ppm

Pressure at Outlet of Steam Generating Unit, psi	Total Solids	Total Alkalinity	Suspended Solids
51 to 325	3500	700	15
326 to 450	3000	600	10
451 to 600	2500	500	8
601 to 750	2000	400	6
750 to 900	1500	300	4
900 to 1000	1250	250	2
1000 to 1500	100	20	1
1501 to 2000	50	10	1

FGD systems. (See Chapter 35.) Fluidized-bed boilers, discussed in Chapter 17, offer an alternative to FGD systems. These boilers are capable of achieving very high SO₂ removal rates via limestone addition directly into the combustion process (bed).

The combination of FGD systems with efficient particulate control has shown the potential for effective control of many HAPs. It is anticipated that the EPA's future HAP regulations may require retrofits of these combined controls on most large (new and existing) coal-fired industrial boilers.

B&W boilers for solid and multi-fuel applications

Brief descriptions of the boiler types that follow are intended to introduce the types of steam generating units that meet the wide range of fuel and performance requirements of the industrial sector.

Stirling® power boilers

Description The Stirling Power Boiler (SPB) is a top supported, two drum, single gas pass unit. (See Figs. 1 and 2.) In some cases, it is cost effective to replace the two drum design with a single drum and a smaller shop-assembled boiler module. (See Fig. 4.)

The furnace is completely water cooled using membrane wall construction [normally 3 in. (76.2 mm) tubes on 4 in. (101.6 mm) centers] and is satisfactory for either pressurized or balanced draft operation. Shop assembly of wall panels is maximized to facilitate field erection. Wall panels always come with the headers attached, regardless of the number of shipping pieces.

Cyclone steam-water separators, discussed in Chapter 5, along with primary and secondary steam scrubbers, are included in the steam drum to provide the high quality dry steam needed for present day superheater and turbine designs.

Furnaces include a nose arch which serves to direct gas flow over the superheater section and to shield the superheater.

SPBs are capable of firing solid, liquid or gaseous fuels. There are several furnace configurations to complement the type of fuel fired, as shown in Fig. 8. A hopper-bottom furnace is used for pulverized coal firing; a flat floor for gas or oil firing; and an open bottom to receive a stoker for stoker coal, wood, bagasse, biomass, refuse-derived fuel (RDF) and as-received municipal solid waste (MSW).

Furnaces for fuels having a significant amount of fines and/or high moisture such as wood, biomass, bagasse and RDF are arranged with an overfire air system consisting of multiple rows of nozzles. These nozzles inject air at various locations above the grate to provide the turbulence necessary for combustion.

The SPB is equipped with an economizer and/or air heater to provide economical heat recovery. For many fuels, air heating is important for combustion. Pulverized coal requires hot air to dry the fuel, and hot air is required to promote combustion of moist fuels such as wood, bagasse and biomass.

Because of the design features, the SPB is the preferred industrial boiler for many applications. There

are some other designs that serve special fuels, capacities, pressures and temperatures, making them a good alternative under special conditions.

Pre-engineering While the SPB is custom designed to meet specific steam and fuel conditions, the design is done within a framework of pre-engineered components to minimize engineering costs and delivery time.

The furnace width and depth are pre-engineered in 1 ft (0.3 m) increments so that all of the closures at the corners are established. Drum centerlines, in 2 ft (0.6 m) increments between 16 and 32 ft (4.9 and 9.8 m), have been pre-engineered to locate all of the access doors, sootblower openings, buckstays and platforms. Combinations of steam and lower drum sizes are designed so that all of the bend angles for drum entry are established.

These pre-engineered increments allow flexibility in the design to satisfy the job-specific requirements of furnace exit gas temperature, burner clearances, residence time, grate size, gas velocity, convection surface spacing, etc.

SPB design range

Steam capacity	
pulverized coal, oil, gas	up to 1,200,000 lb/h (151.2 kg/s)
stoker coal	150,000 to 400,000 lb/h (18.9 to 50.4 kg/s)
stoker wood, bagasse, and biomass	180,000 to 600,000 lb/h (22.7 to 75.6 kg/s)
Steam pressure to	2200 psig (15.2 MPa) design
Steam temperature to	1000F (538C)

Towerpak® boiler

Description The Towerpak is a version of the SPB designed for lower capacities that are often required by smaller industrial plants. (See Fig. 9.) It incorporates many of the features of the SPB including membrane walls, cyclone steam-water separators, and stokers for wood or biomass combustion.

Towerpak boilers are one drum or two drum bottom supported units. For the smaller sizes, they can be shipped in a single unit or in modules for ease of field assembly (see Fig. 10). Larger units follow the SPB format of maximum subassembly of wall panels, again for ease of field assembly. This unit is a preferred design at low steam capacity for hard to burn solid fuels such as wood, biomass and stoker coal.

Pre-engineering Like the SPB, these units are custom designed to meet specific conditions for each application, but within the framework of pre-engineered components.

Towerpak design range

Steam capacity	40,000 to 300,000 lb/h (5.0 to 37.8 kg/s)
Steam pressure to	1800 psig (12.4 MPa) design
Steam temperature to	1000F (538C)

Circulating fluidized-bed boiler

Description Fluidized-bed boilers feature a unique concept of burning fuel in a bed of particles to control the combustion process and, when required, control

SO₂ and NO_x emissions. Two options are offered – the circulating fluidized-bed boiler (CFB) and the bubbling fluidized-bed boiler (BFB). (See Figs. 11 and 12.) Both options can be used in new as well as in retrofit applications. Fluidized-bed technologies are discussed in depth in Chapter 17.

The CFB is a top supported boiler. (See Fig. 11.) One or two drums are used depending on the need for a generating bank to absorb heat. Fuel is admitted to the lower part of the furnace by screws, air-assisted gravity chutes or pneumatic feed, depending on fuels fired and plant design.

The bed medium is typically composed of fuel ash

and sulfated limestone particles (limestone is used as a sorbent for SO₂ removal). When firing low-ash and low-sulfur fuel, additional inert bed material (typically sand) may be introduced into the furnace. Compared to the fuel quantity present in the unit, the circulating bed material is many times greater. Total solids in the flue gas passing upwards through the furnace are a function of how much heat must be absorbed by the waterwalls.

Varying the bed density maintains the desired constant temperature necessary for maximum SO₂ removal [about 1550F (843C)]. The B&W Internal Recirculation CFB (IR-CFB) design features a two-stage

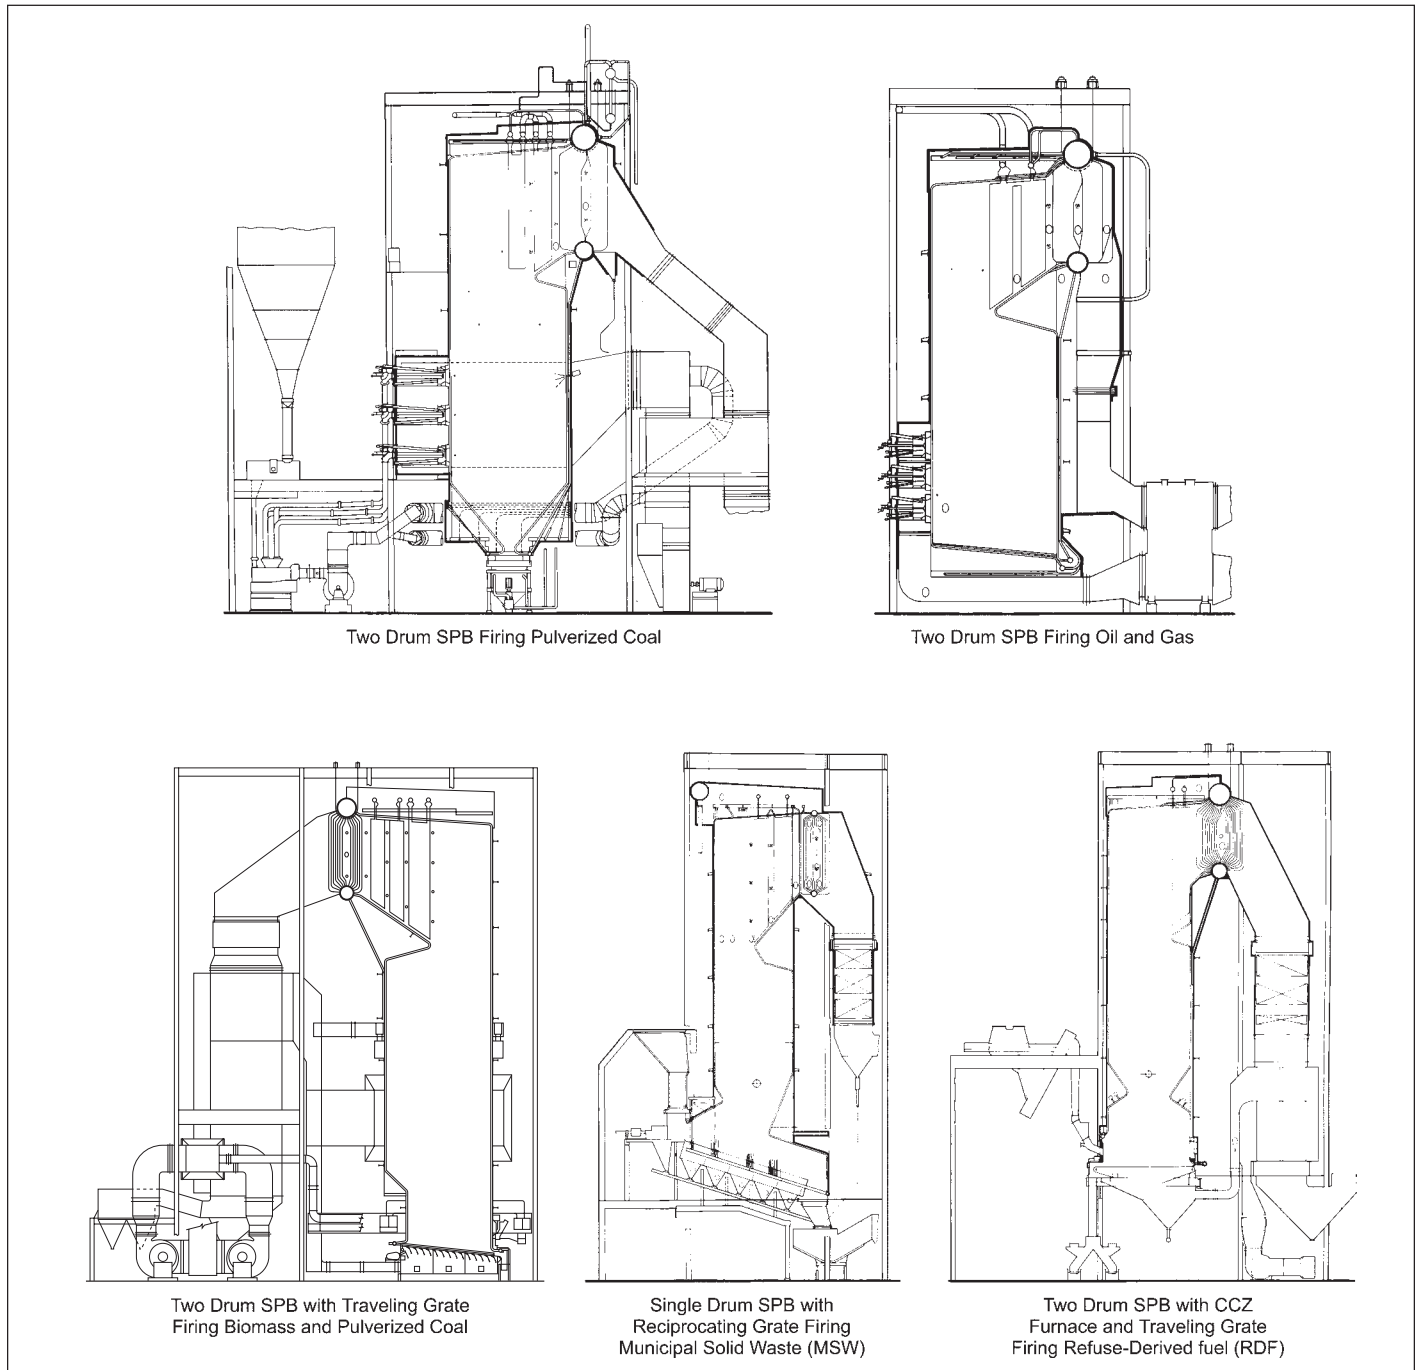

Fig. 8 Typical Stirling® power boiler furnace configurations.

solids collection system comprising U-beam particle separators (U-beams) at the furnace exit and a multi-cyclone dust collector (MDC) at the top of the convection downpass. Solids laden flue gas exits the furnace to U-beams where 90 to 95% of the solids are collected and directly (internally) returned to the furnace. Flue gas exiting the U-beams proceeds over convection surfaces, similar to other boiler designs. About 90% of the solids passing the U-beams are further collected by the MDC. The recirculation rate from the MDC is controlled to provide the flow necessary to maintain the required bed temperature and density.

The CFB has been selected for application with high-sulfur, high-ash and various waste fuels such as petroleum coke, waste coal, sludge, oil pitches, etc. It is also used for wood and other biomass fuels, how-

Fig. 10 Field assembly of a Towerpak® boiler.

Fig. 9 Towerpak® boiler.

ever the bubbling fluidized bed is often a more economical choice for these fuels. The CFB, because it operates at a reduced combustion temperature, inherently generates about one half the NO_x as the other solid fuel-fired industrial boilers previously described.

The CFB is an alternative to the pulverized coal or stoker coal-fired SPB which frequently must be equipped with a wet or dry scrubber (for SO_2 removal) and ammonia injection, catalytic or non-catalytic reduction (NO_x removal) equipment. The choice of technologies requires in depth evaluation of a number of factors including required amount of emissions removal, fuel cost, reagent cost and capital cost.

Pre-engineering The CFB is custom designed to meet each specific application, but like the SPB, it is designed within a framework of pre-engineered components to minimize engineering costs and delivery time.

Fig. 11 Top supported circulating fluidized-bed boiler.

Fig. 12 Bottom supported bubbling fluidized-bed boiler.

CFB design range

Steam capacity	up to 1,500,000 lb/h (189 kg/s) or greater
Steam pressure to	2850 psig (19.7 MPa) design
Steam temperature to	1040F (560C)

Bubbling fluidized-bed boiler

Description The bubbling fluidized-bed (BFB) boiler is also a version of the Stirling power boiler in many ways. The unit can be top supported or bottom supported, can be a one or two drum design, and can burn a wide variety of fuels cleanly and efficiently. A bottom supported design similar to a Towerpak boiler (see Fig. 12) can be supplied for steam flow capacities up to 300,000 lb/h (37.8 kg/s). BFB technology is ideal for repowering an existing facility, recovery boiler conversion (Fig. 13), or when changing fuel or firing techniques of an existing boiler. It is particularly attractive in retrofit applications where the bottom of an existing furnace (including a stoker) can be removed and replaced with a bubbling fluidized-bed without major modifications to the balance of the furnace, convection pass enclosures and heat transfer surfaces. Such conversions have been effective in regaining boiler capacity lost because of a fuel change or a change in ash characteristics which are not compatible with the original boiler furnace design. Such retrofits also provide one option to reduce sulfur dioxide and nitrogen oxides emissions from industrial and small utility boilers.

The combustion process uses an inert material, typically sand, and fuel to form a bed in the bottom of the furnace. This bed is suspended by a stream of upwardly flowing fluidizing air. Fuel introduced to the bed is quickly volatilized. A significant amount of volatiles escape the bed and are burned in the freeboard area above the bed using overfire air. The remaining volatiles and fixed carbon burn in the bed. To achieve efficient combustion and low emissions, the bed temperature is controlled in the range of 1350 to 1650F (732 to 899C).

The BFB is particularly well suited for high moisture waste fuels such as sewage sludge, and various sludges produced in pulp and paper mills and recycle paper plants, but can also burn a variety of other fuels including wood wastes, bark, coal, tire derived fuel, oil and natural gas.

Pre-engineering The BFB is custom designed to meet each specific application, but like the SPB and Towerpak, this is done within a framework of pre-engineered components.

Fig. 13 Bubbling fluidized-bed retrofit of a recovery boiler.

BFB design range

Steam capacity	60,000 to 700,000 lb/h (7.5 to 88.2 kg/s)
Steam pressure to	2400 psig (16.5 MPa)
Steam temperature to	950F (510C)

B&W boilers for oil and gas applications

Boilers in this category have several similarities attributable to the fuel characteristics of oil and natural gas. Unlike coal-fired boilers, distillate oil and gas units do not have to consider slagging and fouling issues. Furnaces and convection banks can be arranged for optimum heat transfer. Some residual oils can be erosive and can contribute to fouling which is addressed in unit selection. The boilers in this section are all bottom supported.

FM boiler

Description The FM is a shop-assembled (package), two drum, bottom supported boiler. (See Fig. 14.) Package boilers can be shipped by rail, truck or barge. Most FM units are a D-type boiler design and have the furnace on one side and boiler bank on the other, separated by a baffle wall. In a D-type unit, firing is parallel to the drums toward the rear wall where the gas turns 180 degrees and flows frontward to the gas outlet.

B&W also provides an O-type FM boiler design where the furnace is located between the two drums. (See Fig. 15.) The flue gas splits at the rear of the furnace and flows forward through generating tube sections on each side of the furnace. Compared to the D-type boiler layout, the O-type boiler has a center of gravity that is on the unit centerline, which provides advantages for shipping.

Gas-tight furnaces, using membrane construction, are features of both the O and D boilers for pressure-fired (forced draft fan only) operation. With today's advanced low NO_x burner designs and steam separation technology, B&W offers rail-shippable units to 230,000 lb/h (29 kg/s).

In addition to burning oil and natural gas, these units can burn a variety of gaseous and liquid fuels such as landfill gas, refinery gas, and various waste liquid fuels. Emissions on natural gas are typically 30

Fig. 14 Type FM integral furnace boiler – membrane wall construction.

Fig. 15 FM O-type boiler.

ppm NO_x (0.036 lb/10⁶ Btu), and 80 ppm NO_x (0.1 lb/10⁶ Btu) on distillate oil. When required, 9 ppm NO_x is achievable on gas with advanced burners.

Pre-engineering The FM is totally pre-engineered in frame sizes to satisfy the capacity range of this package design. Series available are FM9, FM10, FM103, FM106, FM117 and FM120. Pre-engineered set furnace depths are the only variables in this series.

FM design range

Steam capacity	10,000 to 230,000 lb/h (1.3 to 29.0 kg/s)
Steam pressure to	1250 psig (8.62 MPa)
Steam temperature to	800F (427C) on oil 850F (454C) on natural gas (higher pressures and temperatures available)

High Capacity FM boiler

Description The High Capacity FM (HCFM) boilers are extensions of the FM D-type boiler design. (See Fig. 16.) High capacity boilers can be assembled in the shop, at a barge dock or in the field. Shipping dimensions of these units require that they be shipped by barge or ocean vessel.

The design is for oil and gas firing and uses membrane furnace walls for pressurized operation. Multiple burners are used for the increased capacity.

Pre-engineering Like the FM, these boilers are completely pre-engineered and set furnace depths are the only variable.

HCFM design range

Steam capacity	
HCFM	200,000 to 350,000 lb/h (25.2 to 44.1 kg/s)
Steam pressure to	1050 psig (7.24 MPa) design
Steam temperature to	825F (441C)

PFM boiler

Description Another higher capacity and design pressure D-type boiler, the Power for Manufacturing (PFM), is also designed for dock or field assembly. If

Fig. 16 High Capacity FM boiler.

shipped assembled, the size of these units requires special handling at the installation site. (See Fig. 17.) This design is also for gas and oil firing and uses a membrane furnace for pressure operation. Again, multiple burners are used for the increased capacity.

Pre-engineering Like the FM and HCFM, this boiler series, which includes PFM 140, 180, 220, 250 and 280, is completely pre-engineered and set furnace depths are the only variable.

PFM design range

Steam capacity	200,000 to 600,000 lb/h (25.2 to 75.6 kg/s)
Steam pressure to	1800 psig (12.4 MPa) design
Steam temperature to	1000F (538C)

PFI boiler

Description The Power for Industry (PFI) boiler is a two drum, bottom supported, multiple gas pass unit designed specifically to burn liquid and/or gaseous fuels. (See Fig. 18.) Due to the large furnace enclosure, the PFI is an excellent choice for harder to burn byproduct fuels such as blast furnace gas and refinery catalytic cracker CO gas.

The furnace is completely water cooled using membrane wall construction [2.5 in. (63.5 mm) tubes on 3 in. (76.2 mm) centers].

The PFI was developed for maximum shop assembly of components. For example, the furnace is shipped in as few as ten membrane wall panels with headers attached at the top and bottom. The panels include two for each side wall and two each for roof, front wall and floor. The burner throats are integral with the front wall panel. The unit is bottom supported on simple concrete piers and incorporates a drainable su-

perheater. A unique plenum encloses the upper front wall, roof and rear of the unit. This plenum serves as an integral air duct to the windbox and, with a division plate in the rear, a flue gas outlet. Either an air heater or economizer is used to reduce exit gas temperature and heat recovery.

This design features a gas pass extending the full length of the boiler bank. Flue gas flows horizontally and parallel to the drums through the bank. A gas baffle is used to direct the gas across the tubes in multiple passes to maximize heat transfer.

An inverted loop, drainable superheater is located behind a screen at the furnace outlet to protect it from direct furnace radiation. This superheater location gives a semi-radiant heat transfer characteristic that produces a relatively flat temperature curve across the load range. This temperature profile minimizes attemperation for steam temperature control.

Cyclone steam separators with primary and secondary scrubbers are included in the steam drum to produce the high quality steam needed for present day superheaters and turbines.

Pre-engineering The PFI unit is totally pre-engineered in a number of frame sizes to satisfy the capacity range of this boiler design. Several superheater arrangements are also pre-engineered for each frame size.

Units come in three different drum centerlines. Each centerline has a specific furnace depth and three or four furnace widths.

PFI design range

Steam capacity	100,000 to 700,000 lb/h (12.6 to 88.2 kg/s)
Steam pressure to	1150 psig (7.9 MPa) design
Steam temperature to	960F (516C)

PFT boiler

Description The Power for Turbine (PFT) boiler was developed as an extension of the PFI design to accommodate the development of higher pressure and temperature turbine cycles. This unit incorporates many of the PFI features including: two drum, bottom supported, modularized furnace membrane walls [3 in.

Fig. 17 PFM boiler in transit.

Fig. 18 Type PFI integral furnace boiler.

(76.2 mm) tubes on 3.75 in. (92.25 mm) centers], drum cyclones and a drainable superheater. (See Fig. 19.)

Some of the differences include an alternate pendant superheater (as shown in Fig. 19) and gas flow path the full width of the boiler bank with flow in vertical directions.

PFT units are particularly well suited to burn high ash liquid fuels, blast furnace gas and CO gas because cavities provide space for retractable sootblowers for cleaning requirements.

Pre-engineering The PFT, like the PFI, is totally pre-engineered in a number of frame sizes. The unit is designed with two drum centerlines and several furnace depths and widths to satisfy the capacity range of this design.

Fig. 19 PFT integral furnace boiler.

PFT design range

Steam capacity	300,000 to 800,000 lb/h (37.8 to 100.8 kg/s)
Steam pressure to	1800 psig (12.4 MPa) design
Steam temperature to	1000F (538C)

Enhanced Oil Recovery steam generator

Description The Enhanced Oil Recovery (EOR) steam generator (Fig. 20) was developed to meet a market need, as the name implies. High pressure, wet steam (approximately 80% quality) is produced by the unit and then injected into underground strata containing heavy oils. The steam enhances the recovery of oil by heating the heavy oil which reduces its viscosity and thereby aids in moving the oil to the producing wells.

A once-through steam water circuitry featuring all series flow coils is used for smaller units. Feedwater flows continuously in a single tube circuit through the convective (economizer) section to the radiant (furnace) section where the water is boiled to 80% (by weight) steam quality level. A multiple pass parallel flow design is used on larger units.

By maintaining wide flame clearances from the radiant walls (i.e., no direct flame impingement) and low heat releases, relatively poor feedwater (5000 ppm solids) can be tolerated. This permits minimal feedwater treatment and allows the water that is separated from the recovered oil to be recycled to the boiler with minimum cleanup. As stated, high solids content water is tolerable, however, near zero hardness is required to minimize the probability of solids depositing in the tubes. Only about 80% of the feedwater is vaporized to provide sufficient liquid at the steam outlet to keep water-soluble solids in solution.

Control of the process is achieved by pumping the required amount of feedwater at the specified pressure [up to 2500 psig (17.2 MPa)] into the convective section and by regulating the burner firing rate to maintain measured outlet steam quality.

Units are typically fired with natural gas or heavy oil.

Pre-engineering and design range Units come in pre-engineered sizes from 5 to 50 × 10⁶ Btu/h (1.5 to 14.7 MW_t) output. The units are shop-assembled with units through 40 × 10⁶ Btu/h (11.7 MW_t) trailer

Fig. 20 Enhanced oil recovery boiler on location.

mounted in one piece for shipment. Larger sizes are shop-assembled in several sections for final field assembly. Unit capacities are limited by shipping constraints and not because of design limitations.

EOR design range (oil and gas)

Steam capacity up to 250,000 lb/h (31.5 kg/s)
Steam pressure to 2500 psig (17.2 MPa) design

B&W boilers for specialty and waste heat applications

Heat recovery steam generator

The heat recovery steam generator (HRSG) is sometimes referred to as a waste heat recovery boiler (WHRB) or turbine exhaust gas (TEG) boiler. The latter designation indicates the main application for these units today – waste heat recovery and steam generation from gas turbine exhaust gas. The HRSG is a key element in a combined cycle plant affecting initial capital cost, operating cost, and overall cycle efficiency.

HRSGs are flexible in design depending upon the specific application. The gas flow through the unit can either be horizontal or vertical with a tradeoff being made between the cost of floor space for the horizontal flow unit and structural steel requirements of the vertical flow unit. The horizontal flow case is the most common in North America, while the vertical design is popular in Europe. The HRSG may be designed for operation with multiple, separate pressure steam-water loops to meet application requirements and maximize heat recovery. Superheater or reheater surface may also be employed to further increase cycle efficiency. Circulation may be forced or natural (see Chapter 5) with most horizontal gas flow units using natural circulation. HRSGs may be unfired, i.e., only use the sensible heat of the gas as supplied, or may include supplemental fuel firing to raise the gas temperature to reduce heat transfer surface requirements, increase steam production, control superheat steam temperature, or meet process steam temperature requirements. Finally, HRSGs may be designed to incorporate an SCR or CO catalyst. (SCR catalysts are discussed in Chapter 34.)

HRSGs are suitable for use with gas turbine sizes from a small 1 MW unit up to modern machines exceeding 250 MW. See Figs. 21 and 22 for typical arrangements.

Heat recovery steam generators are designed to handle the unique requirements of a variety of combined cycle systems. Depending on the cycle configuration, the HRSG may consist of one to four separate boiler circuits (high pressure, two types of intermediate pressure and low pressure) within the same casing. The high pressure boiler is used for power generation [up to 1005F (541C) superheat]. The intermediate pressure boilers can be used for power generation, steam injection for NO_x control (water or steam injected into the gas turbine combustor to limit NO_x formation) and/or process steam. The low pressure boiler is normally used for feedwater heating and/or deaeration. Operating pressures can range from 300

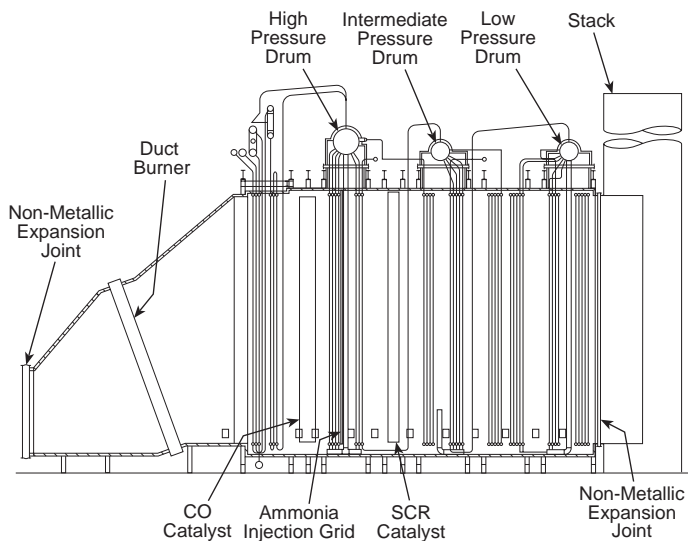

Fig. 21 Heat recovery steam generator (HRSG) arrangement.

to 1800 psig (2068 to 12,410 kPa) for the high pressure and intermediate pressure sections and 30 to 100 psig (206.8 to 689.5 kPa) for the low pressure section. To accommodate rapid startup, the design includes provisions for differential expansion between pressure parts and nonpressure parts. Expansion joints are used where a gas-tight seal is required.

HRSGs are designed to handle large gas flows with minimal pressure drop, resulting in greater gas turbine net electrical output. Special consideration is also given to the configuration of the interconnecting flue gas ductwork, transitions, and diverter valves to minimize pressure losses caused by changes in flow patterns or excessively high velocities. Heat losses through the boiler casing and ductwork are minimized through the use of an insulation system.

In the natural circulation design, the vertical tubes provide the pumping head necessary to develop sufficient circulation ratios for stable circulation. Circulation pumps are eliminated, therefore allowing plant efficiency to be maximized. The forced circulation design consists of horizontal tubes with gas flowing vertically. Floor space requirements are minimized. However, the additional load imposed by the circulation pumps reduces cycle efficiency.

Fig. 22 Large HRSG for enhanced oil recovery/cogeneration.

Once-through HRSG designs are also available. In a once-through design, feedwater is converted directly to superheated steam without the need for a drum. As a result, there is no distinction between economizer, evaporator or superheater surface. The water-to-steam transition point is variable within the unit and is dependant upon the heat input and mass flow of the water.

Most heat recovery steam generators are too large to permit shop assembly of an entire unit. Therefore, most HRSG components are shop fabricated to the maximum extent possible and delivered to the site as modules. Typically, each module is structurally independent and includes lifting lugs and temporary steel so that field transport and setting is readily accomplished. Some of the smaller HRSG units can be entirely shop-assembled and skid mounted.

Typical parameter ranges for HRSG units are summarized in Table 4.

Special HRSG designs are also available for enhanced oil recovery applications. The gas turbine exhaust gas is used in the HRSG to generate wet steam (approximately 80% quality) at pressures up to 2500 psig (17.2 MPa). The steam is injected into wells to enhance heavy oil recovery. A unique feature is that relatively dirty (up to 10,000 ppm dissolved solids) feedwater is used in a once-through steam generator design.

Technical considerations The HRSG is basically a counterflow heat exchanger composed of a series of superheater, reheater, boiler (or evaporator), and economizer sections positioned from gas inlet to gas outlet to maximize heat recovery and supply the rated steam flow at proper temperature and pressure. To provide the most economical and reliable design, it is necessary to evaluate the following:

1. Allowable back-pressure – Back-pressure is significantly influenced by the HRSG cross-sectional flow area. Higher back-pressures reduce HRSG cost but also reduce gas turbine efficiency. Back-pressures are typically 10 to 15 in. wg (2.5 to 3.7 kPa) in most units.

2. Steam pressure and temperature – The steam pressure and temperature are selected to provide an economical design. In general, higher steam pressures increase system efficiency but can limit total heat recovery from the flue gas in single pressure HRSGs due to the higher saturation temperature. To overcome this problem, multiple pressure HRSGs are offered. One to four separate pressure sections may be used. The superheater, reheater, boiler and economizer sections at each pressure are arranged to reduce overall cost and increase heat recovery.
3. Pinch point and approach temperatures – The pinch point temperature and approach temperatures have a significant impact on overall unit size. They are illustrated in Fig. 23 for a single pressure HRSG. Small pinch point and superheater approach temperatures result in larger heat transfer surfaces and higher capital costs, while the economizer approach temperature is typically set to avoid economizer steaming at the design point. Experience has generally indicated that the following ranges provide economical and technically satisfactory designs, although lower values may be appropriate in specific applications:

$$\text{Pinch point} = \Delta T_p = 20 \text{ to } 50\text{F} (11 \text{ to } 28\text{C})$$

$$\text{Superheater approach} = \Delta T_{SH} = 40 \text{ to } 60\text{F} (22 \text{ to } 33\text{C})$$

$$\text{Economizer approach} = \Delta T_E = 10 \text{ to } 30\text{F} (6 \text{ to } 17\text{C})$$

4. Stack outlet temperature – As with feedwater temperature, the minimum flue gas exit or stack temperature needs to be controlled to avoid corrosion due to acid condensation. Typical values are identified in Chapter 20.
5. Load response and cycling requirements – Many HRSGs today are cycled. That is, they are brought up and down in load on a daily basis, thus requiring frequent warm-ups and cool-downs. As a re-

Table 4
HRSG Parameters

Turbine application:	
Gas turbine sizes	1 MW to 220 MW
Gas flow	25,000 to 5,000,000 lb/h (0.32 to 630 kg/s)
Gas turbine outlet temperature	
≤ 1200F (≤ 649C)	
Supplemental firing temperature	
≤ 1650F (≤ 899C)	
Steam flow:	15,000 to 600,000 lb/h (1.9 to 76 kg/s)
Operating pressures:	
High	≥ 400 psig (2.76 MPa)
Intermediate	50 to 400 psig (0.34 to 2.76 MPa)
Low	15 to 50 psig (0.10 to 0.34 MPa)
Steam temperature	up to 1005F (541C)
Supplemental fuels	#2 oil, natural gas

Fig. 23 Temperature profile in single pressure HRSG.

sult, special consideration must be given to the thermal and mechanical stresses associated with this type of operation. Pressure parts and their attachments must be designed in a manner which allows them to expand freely. Steaming in the economizer is inevitable at off-design points. As a result, economizers must incorporate up-flow tube circuitry, recirculation lines, steam-water separation equipment in the drum, or gas bypasses. Stack dampers may also be necessary to keep the HRSG warm if it is to be brought off line for short periods of time.

6. Emissions – Emission requirements can have a physical impact on the design of an HRSG. Depending on permit requirements and the type of fuels fired in the duct burner, an SCR or CO catalyst may be required. In some instances, it may be necessary to have both. The location of either is driven by temperature (see Chapter 34). Therefore, tube banks must be arranged to accommodate the SCR and/or CO catalyst blocks which are sized to meet the removal efficiency required at the design conditions specified. It may also be necessary to install a distributor grid upstream of the catalyst section to distribute the flue gas evenly across the catalyst.

CO boiler

In the hydrocarbon processing industry, the operation of a fluid catalytic cracking (FCC) unit, depending on the FCC arrangement, produces gases rich in carbon monoxide (CO). To reclaim the thermal energy in these gases, the FCC unit can be designed to include a CO boiler to generate steam.

For refineries generating large quantities of CO, field-erected boilers such as the PFI boiler are used.

There are also many smaller refineries that have cracking units in the general range of 12,000 barrels (1908 m³) per day or less which produce from 75,000 to 175,000 lb/h (9.5 to 22.1 kg/s) of CO gas. CO boilers for this capacity are often small enough to be shop assembled. A shop-assembled boiler modified for CO firing is shown in Fig. 24. CO gas is admitted through ports in the side walls and front wall to promote mixing and rapid combustion. The burners, for firing supplementary fuel, are located in a refractory front wall and fire into a horizontal furnace.

The maximum steam requirements of the cracking unit may occur at normal, full load operation or during startup of the cracking unit, depending on the plant steam cycle. The supply of CO is normally not sufficient to generate the maximum amount of steam required; supplementary fuel is then needed.

Supplementary fuel is also required to raise the temperature of the CO gases to the ignition point and to assure complete burning of the combustibles in the CO gas stream. The following design criteria have been established:

1. The basic firing rate should produce a temperature of 1800F (982C) in the furnace for a suitable residence to provide safe and stable combustion of the fuels.
2. Air is supplied by the forced draft fan to provide 2% oxygen leaving the unit when burning CO gases and supplementary fuel.
3. Supplementary firing equipment is provided which is capable of raising the temperature of the CO gases to 1450F (788C), the temperature needed for ignition of the combustibles.

Because of possible variations in the combustible and oxygen content of the CO gases, the sensible heat of the CO gases and the amount of supplementary fir-

Fig. 24 Shop-assembled CO boiler.

ing, it is impractical to set up a fuel-air relationship. Consequently, it is necessary to directly determine the amount of excess oxygen leaving the unit. This may be determined intermittently by a portable oxygen analyzer, or continuously by an oxygen analyzer or combination oxygen-combustible recorder.

Water seal tanks are installed upstream of the CO boiler to act as shutoff valves in the large gas lines so that the CO gases from the catalyst regenerator may be passed through the boiler or sent directly to the stack. This permits independent operation of the CO boiler without interfering with the operation of the regenerator. Water seal tanks are preferred to mechanical shutoff dampers because of the high gas temperature, the size of the CO ducts, and the need for leak proof construction.

The operation of the CO boiler is coordinated with that of the catalytic cracker. Normally, the boiler will be required to supply steam for the operation of the catalytic cracking unit and will be started using supplementary fuel. The CO boiler should always be started using only the supplementary fuel burners and bypassing the gases from the regenerator to the atmosphere. CO gases should not be introduced into the boiler until it is brought up to temperature because these gases usually are at or below 1000F (538C) and, consequently, tend to cool the furnace. They ignite quite readily and burn with a non-luminous flame. As the CO is introduced to the boiler, it is necessary to reduce the supplementary fuel and the combustion air. This readjustment in the air requirement is determined from the oxygen recorder reading.

Because there are only slight variations in the operation of the catalytic cracking unit, the CO boiler is normally base loaded. It handles all the gases from the regenerator regardless of the carbon dioxide (CO₂) to CO ratio. A change in this ratio merely affects the quantity of supplementary fuel necessary to maintain the required furnace temperature of 1800F (982C). This temperature provides a reasonable operating margin for possible variation in the operation of the regenerator or the boiler. Stable operation can be maintained at a furnace temperature as low as 1500F (816C), but the margin above the ignition temperature of the CO gas is considerably reduced.

The economics of the CO boiler depend on the amount of available heat in the regenerator exhaust compared with an equivalent amount of heat from an alternate fuel. The heat from the CO gases is calculated by taking the sensible heat above an assumed boiler stack temperature plus all of the heat from the combustibles. The additional steam generated in the CO boiler by the supplementary fuel is comparable with the steam generated in a conventional power boiler. Normally, the supplementary fuel requirement will account for one fourth to one third of the output when the temperature of the entering CO gas is maintained at 1000F (538C).

Changes in FCC catalysts and in process conditions have permitted reductions in the CO content of the gases leaving the unit. These changes also result in the gas temperature to the CO boiler increasing from the 1000F (538C) level to as high as 1450F (788C).

Many existing CO boilers have been upgraded to handle the new conditions. Changes have included elimination of combustion zone refractory, use of membraned water walls, and resizing of heat transfer surface. (See Fig. 25.) New heat recovery boilers on FCC units are designed for these new process conditions.

General waste heat boiler

The progressive increase in the cost of fuel has fostered technical progress in the utilization of waste energy, including specialized designs and applications of boilers. There are many industries or processes that generate large quantities of high temperature gases from which the sensible heat may be extracted for steam generation. Such gases are produced in catalytic regenerators; blast furnaces; copper reverberatory furnaces; annealing, forge and billet heating furnaces; and fired kilns of many types.

The heat contained in these exhaust gases can often generate all the steam required for an industrial process via properly designed boiler equipment. Where the waste gases carry some of the noncombustible process material in suspension, suitable hoppers will collect a portion of the material, and the cooled gases leaving the boiler may be passed through dust collectors to recover the remaining particulate. Many types of boilers are necessary to meet the wide range of requirements in this field. Boiler design depends on the chemical nature of the gases and their temperature, pressure, quantity and dust loading.

Heat transfer from waste gases

The rate of heat transfer from the gas to the boiler water depends on the temperature and thermophysical properties of the gases, velocity and direction of flow over the absorbing surfaces, and the surface cleanliness, as discussed in Chapter 4. Temperatures of many process gases are relatively low as shown in Table 5.

To obtain the proper velocity of the gases over the surfaces, a sufficient pressure difference or draft must be provided, either by a stack or a fan. The draft must overcome the pressure losses caused by the flow of gases through the unit, with adequate allowance for normal heating surface fouling.

The radiation heat transfer component is low and the tendency is to design many waste heat boilers for higher gas velocities than prevail on fuel-fired units. However, high velocities with dust-laden gases can cause tube erosion, particularly where there are changes in gas flow direction. Therefore, process-specific velocity limits must be met.

Diagrams A and B, Fig. 26, show the approximate convection heating surface required for usual conditions in waste heat boilers.

A water-cooled furnace is a feature of some waste heat boiler applications where it is necessary to cool the furnace gases to the temperature required to prevent slagging in the following tightly spaced convection surfaces. The approximate amount of surface required for such furnace applications is given in Diagram C of Fig. 26.

Fig. 25 Circular CO boiler modernization.

Application factors

The design of a boiler for a particular application depends on many factors, most of which vary from process to process and even within an industry. The cost of equipment, auxiliary power and maintenance must be compared with the expected savings. The boiler design depends somewhat on the cost of power at the plant. A smaller unit with closely spaced tubes will cost less but will require more fan power, because of high draft loss. A larger unit will be more expensive but have a lower draft loss and therefore a lower fan power requirement. Other important factors are the available space, locations for the proper flue connections, the corrosive nature of the gases, the effect of dust loading on erosion, and the process operating pressure conditions, i.e., pressurized or induced draft.

If the gases carry dust, attention must be given to tube spacing and to removal of dust dislodged from the heating surfaces. The tubes must be spaced reasonably close for good heat transfer yet far enough apart to prevent bridging of deposits which can lead to excessive gas-side pressure loss. Often the boiler is arranged for wide tube spacing where the gases are hottest, with spacing reduced where the gases are cooler to maintain gas velocities and good heat transfer.

Sometimes the particulate or dust carried into the boiler from the process can be removed by mechanical cleaners or sootblowers (see Chapter 24). In other

cases, deposits from processes may require periodic manual cleaning with high pressure air, steam or water to keep the boiler passes open. In either case, suitable hoppers should be provided to collect the deposit material removed from the tubes.

Table 5
Temperature of Waste Heat Gases

Source of Gas	Temperature	
	F	C
Ammonia oxidation process	1350 to 1475	732 to 802
Annealing furnace	1100 to 2000	593 to 1093
Cement kiln (dry process)	1150 to 1500	621 to 816
Cement kiln (wet process)	800 to 1100	427 to 593
Copper reverberatory furnace	2000 to 2500	1093 to 1371
Diesel engine exhaust	1000 to 1200	538 to 649
Forge and billet heating furnaces	1700 to 2200	927 to 1204
Open hearth steel furnace, air blown	1000 to 1300	538 to 704
Open hearth steel furnace, oxygen blown	1300 to 2100	704 to 1149
Basic oxygen furnace	3000 to 3500	1649 to 1927
Petroleum refinery	1000 to 1400	538 to 760
Sulfur ore processing	1600 to 1900	871 to 1038

Fig. 26 Approximate surface required in convection tube bank and vestibule for various entering and leaving waste gas temperatures.

Gases from oil- or gas-fired process furnaces are relatively clean and, therefore, can be used in units with 1.0 in. (25.4 mm) clear spacing between bare tubes with little likelihood of deposit bridging and plugging.

Three-drum waste heat boiler An example of a simple three-drum waste heat boiler, specially designed to operate with dust-laden gases, is shown in Fig. 27. This type of unit is particularly well suited for use with high solids content waste gases from cement kilns. Maximum precipitation of solids is assured by the horizontal flow of the gases through the vertical tube banks and by the effective arrangement of baffles. With this tube arrangement, hand lancing is possible from both sides of the unit. Every space in the full width of the boiler can be lanced. Hand lancing can

also be done through the roof and above the lower drums, making all absorbing surfaces accessible with a short hand lance.

With high solids content gases, it is often possible to reduce the amount of hand lancing by using long retractable sootblowers. These are located at one or sometimes two elevations along the depth of tube banks at gaps formed by eliminating a single row of tubes.

To maintain optimum heat transfer conditions without changing the direction of gas flow, the tubes in the rear sections of the boiler are more closely spaced than those at the inlet.

Circulation in this boiler is simple, with the boiler tubes in the hot gas end acting as risers and the tubes in the cooler gas zones acting as downcomers or supply tubes. The boiler has a relatively long drum in which steam separation takes place without the use of baffles. The steam is collected in a dry pipe located in the quiet, cool gas end of the drum. Feedwater is thoroughly mixed with the boiler water rising into the steam drum.

Expansion and contraction of the drums and tubes have no effect on the steel casing, firebrick, or insulation. The most common source of brickwork trouble is therefore eliminated and air infiltration is reduced to a minimum. All pressure parts rest on supports located below the lower drums.

The location of the superheater can be altered for superheat temperature requirements. To increase heat absorption further, an economizer can be installed in the flue leaving the boiler. The economizer is arranged for downward flow of gases to aid in the collection of solids.

Solids collected in the hoppers under the boiler and economizer can be readily removed while the boiler is in service. In a single boiler behind a cement kiln, from 20 to 40 t (18.14 to 36.3 t_m) of cement dust may be recovered each day from these hoppers.

Basic oxygen furnace/oxygen converter hood

The basic oxygen furnace (BOF) used in the steel industry is blown with pure oxygen through a retractable water-cooled lance mounted vertically above the

Fig. 27 Three-drum waste heat boiler with lance ports and sootblowers.

furnace. After each charge of molten iron, scrap steel and fluxing material are loaded into the furnace, the oxygen lance is lowered into position above the charged material, and a blowing period of 15 to 20 minutes begins.

During the blowing time, the oxygen starts a chemical reaction which brings the charge up to temperature by burning out the silicon and phosphorous impurities and reducing the carbon content, as required, for high grade steel. Large amounts of carbon monoxide gas, at 3000 to 3500F (1649 to 1927C), are released in this conversion process. The gas is collected in a water-cooled hood and burned with air introduced at the mouth of the hood. The products of combustion are then cooled by adding excess air, injecting spray water, or water cooling of the hood. Combinations of these cooling methods may be used.

The high temperature of the gases discharged from the BOF and their high carbon monoxide content (about 70% by volume) make them ideal for burning in the water-cooled hood located above the BOF. While there are basic similarities to usual boiler service, there are also significant differences, particularly the carryover of iron-bearing slag from the BOF and the short, intermittent operating periods.

The basic oxygen furnace (BOF) hoods are fabricated from membrane wall panels (Fig. 28). The membrane wall can be formed into a variety of hood configurations depending on plant layout. The hood may be a long flue type used to transport the gases to an evaporation or quench chamber, or it may be a bonnet type that collects the gases and immediately discharges them into a spark box where the temperature is sufficiently reduced with spray water for use in the gas cleanup system.

Steam generator hood The oxygen converter hood, when equipped with a steam drum, boiler circulation pumps, boiler mountings and controls, is an effective steam generator during the oxygen blowing portion of the converter cycle. Steam generation is limited to the time of the oxygen blowing period, which is intermittent or cyclical in operation because of the steel-

Fig. 28 Oxygen converter hood arrangement.

making process. The rate of steam generation varies from zero to a maximum and back to zero during this period which is normally about 20 minutes for a converter cycle of 40 to 45 minutes. This cyclic operation, coupled with the outage time required for relining the converter vessel every few weeks, limits the steam production of a single hood to 12 to 15% of the life of the lining.

Type PFI Integral Furnace boiler installed in an industrial plant.

Chapter 28

Chemical and Heat Recovery in the Paper Industry

In the United States (U.S.), the forest products industry is the third largest industrial consumer of energy, accounting for more than 11% of the total U.S. manufacturing energy expenditures. In 2002, 57% of the pulp and paper industry relied on cogeneration for their electric power requirements.

Approximately one-half of the steam and power consumed by this industry is generated from fuels that are byproducts of the pulping process. The main source of self-generated fuel is the spent pulping liquor, followed by wood and bark. The energy required to produce pulp and paper products has been significantly reduced. Process improvements have allowed U.S. pulp and paper manufacturers to reduce energy consumption to 2.66×10^{12} Btu (2806.5×10^{12} J), a significant reduction.

Pulp and paper mill electric power requirements have increased disproportionately to process steam requirements. This factor, coupled with steadily rising fuel costs, has led to the greater cycle efficiencies afforded by higher steam pressures and temperatures in paper mill boilers. The increased value of steam has produced a demand for more reliable and efficient heat and chemical recovery boilers.

The heat value of the spent pulping liquor solids is a reliable fuel source for producing steam for power generation and process use. A large portion of the steam required for the pulp mills is produced in highly specialized heat and chemical recovery boilers. The balance of the steam demand is supplied by boilers designed to burn coal, oil, natural gas and biomass.

Major pulping processes

The U.S. and Canada have the highest combined consumption of paper and paperboard in the world (Fig. 1), consuming 105.6 million tons each year. With a base of more than 800 pulp, paper and paperboard mills, the U.S. and Canada are also the leader in the production of paper and paperboard. North America accounts for 32% of the total world output; pulp production is nearly 43%.

Total pulp production in the U.S. is divided among the following principal processes: 85% chemical, groundwood and thermomechanical; 6% semi-chemical; and 9% mechanical pulping. The dominant North America pulping process is the sulfate process, deriv-

ing its name from the use of sodium sulfate (Na_2SO_4) as the makeup chemical. The paper produced from this process was originally so strong in comparison with alternative processes that it was given the name *kraft*, which is the Swedish and German translation for strong. Kraft is an alkaline pulping process, as is the soda process which derives its name from the use of sodium carbonate, Na_2CO_3 (soda ash), as the makeup chemical. The soda process has limited use in the U.S. and is more prominent in countries pulping nonwood fiber. Recovery of chemicals and the production of steam from waste liquor are well established in the kraft and soda processes. The soda process accounts for less than 1% of alkaline pulp production and its importance is now largely historic.

Kraft pulping and recovery process

Kraft process

The kraft process flow diagram (Fig. 2) shows the typical relationship of the recovery boiler to the overall pulp and paper mill.¹ The kraft process starts with feeding wood chips, or alternatively a nonwood fibrous material, to the digester. Chips are cooked under pressure in a steam heated aqueous solution of

Fig. 1 World paper and board consumption by country, 2000.

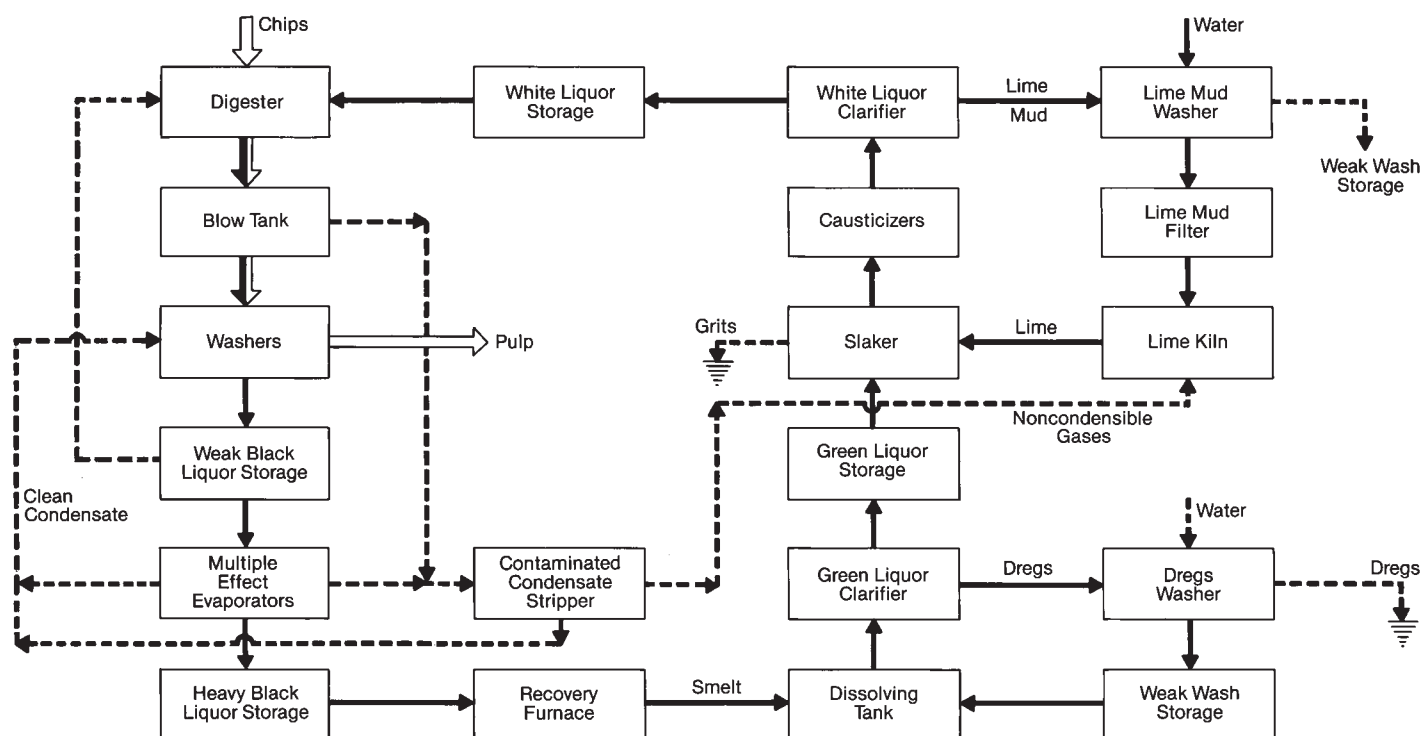

Fig. 2 Kraft process diagram.

sodium hydroxide (NaOH) and sodium sulfide (Na_2S) known as *white liquor* or cooking liquor. Cooking can take place in continuous or batch digesters.

After cooking, pulp is separated from the residual liquor in a process known as brown stock washing. The most common method features a countercurrent series of vacuum drum washers which displace the liquor with minimum dilution. Following washing, the pulp is screened and cleaned to remove knots and shives and to produce fiber for use in the final pulp and paper products.

The *black liquor* rinsed from the pulp in the washers is an aqueous solution containing wood lignins, organic material, and inorganic compounds oxidized in the cooking process. Typically, the combined organic and inorganic mixture is present at a 13 to 17% concentration of solids in weak black liquor. The kraft cycle processes this black liquor through a series of operations, including evaporation, combustion of organic materials, reduction of the spent inorganic compounds, and reconstitution of the white liquor. The physical and chemical changes in the unit operations are shown in Fig. 3.²

The unique recovery boiler furnace was developed for combusting the black liquor organic material while reducing the oxidized inorganic material in a pile, or bed, supported by the furnace floor. The molten inorganic chemicals or *smelt* in the bed are discharged to a tank and dissolved to form *green liquor*. Green liquor active chemicals are Na_2CO_3 and Na_2S .

Green liquor contains unburned carbon and inorganic impurities from the smelt, mostly calcium and iron compounds, and this insoluble material, or *dregs*, must be removed through clarification. This operation is basically settling of sediment and decantation of

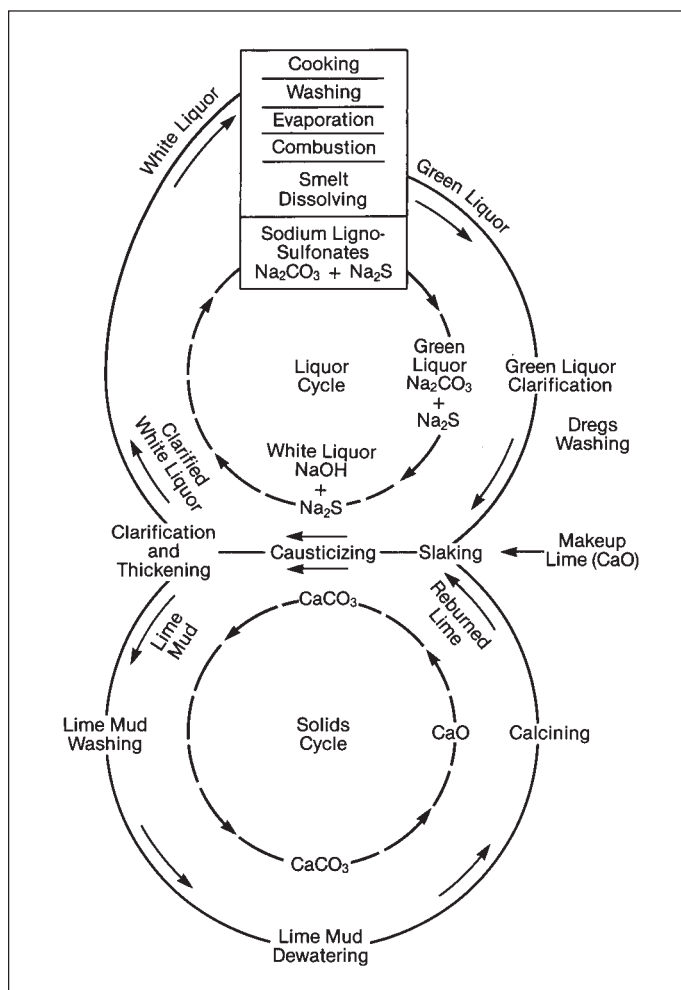

Fig. 3 Kraft process cycle.

clear green liquor that can be pumped to the slaker. The dregs are pumped out of the clarifier as a concentrated slurry. Normal operation is to water wash the dregs before landfill disposal. The water wash liquid containing the recovered sodium chemical is known as *weak wash*. The sodium chemicals are recovered by using the weak wash to dissolve the smelt in the dissolving tank.

Clarified green liquor and lime (CaO) are continuously fed to a slaker where high temperature and agitation promote rapid slaking of the CaO into calcium hydroxide (Ca(OH)₂). The liquor from the slaker flows to a series of agitated tanks that allow the relatively slow causticizing reaction to be carried to completion. The function of the causticizing plant is to convert sodium carbonate into active NaOH. The calcium carbonate (CaCO₃) formed in the conversion reaction precipitates in the causticizing operation to form a suspended *lime mud*.

The causticizing product must be clarified to remove the CaCO₃ precipitate and produce a clear white liquor for cooking. This clarification is carried out by either settling and decanting, in a manner similar to green liquor clarification, or by using pressure filters. In pressure filtration, the white liquor is filtered through a medium to provide a separation of clear white liquor from the lime mud. The lime mud is then washed to remove sodium chemicals that can lead to increased kiln emissions and clinkering, and further filtered to obtain the desired consistency for feed to the kiln.

The lime kiln calcines the washed lime mud feed into reburned lime. Calcination is the chemical breakdown with heat of the CaCO₃ into active lime and carbon dioxide (CO₂). The calcined lime is then slaked as previously described.

The reactions occurring in the solids cycle operations are as follows:

Slaking: $\text{CaO} + \text{water} = \text{Ca(OH)}_2 + \text{heat}$

Causticizing: $\text{Ca(OH)}_2 + \text{Na}_2\text{CO}_3 = \text{CaCO}_3 + 2\text{NaOH}$

Calcination: $\text{CaCO}_3 + \text{heat} = \text{CaO} + \text{CO}_2$

The combination of these process steps is referred to as *recausticization*.

In parallel with the reduction of sulfur compounds to form smelt, energy is released in the recovery furnace as the black liquor organic compounds are combusted. This combustion energy is used in the process recovery boiler to produce steam from feedwater. The steam can be introduced to a turbine generator to supply a large portion of the energy demand of the pulp and paper mill. Steam extracted from the turbine at low pressure is used for process requirements such as cooking wood chips, evaporation, recovery furnace air heating, and drying the pulp or paper products.

Rated capacity of a recovery unit

The capacity of a pulp mill is based on the daily tons of pulp produced. The primary objectives of a recovery boiler are to reclaim chemicals for reuse and to generate steam by burning the black liquor residue. Accordingly, the capacity of the recovery boiler should be based on its ability to burn or process the dry sol-

ids contained in the recovered liquor. Because the proper measure of recovery boiler capacity is the heat input to the furnace, The Babcock & Wilcox Company (B&W) has established a 24 hour heat input unit of 19,800,000 Btu (20,890 MJ). This unit, known as a B&W-Btu ton, corresponds to the heat input from 3000 lb (1361 kg) of solids (approximately equivalent to one ton of pulp produced) having a heating value of 6600 Btu/lb (15,352 kJ/kg) of solids. These were averages for the typical black liquor solids generated from a ton of kraft pulp production when this unit was originally defined. The black liquor solids produced from modern operations generally are characterized by considerable variation in the quantity of the solids per ton of pulp product and somewhat lower heating values. For this reason, a more common rating term applied to current recovery boilers is the amount of dry solids processed over a given period of time (hour or day). The recovery boiler is a heat input machine, and as such, The B&W-Btu rating recognizes the true indication of the unit's design capacity to process that energy input.

The nominal size of a B&W kraft recovery boiler can be determined by application of a simple formula as follows:

$$\text{Nominal size} = \frac{A \times B \times C}{19,800,000}, \text{ B\&W-Btu tons} \quad (1)$$

where

A = dry solids recovered, lb/t of pulp

B = pulp output of mill, t/24 h

C = heating value of dry solids, Btu/lb

and 19,800,000 is the product of 3000 lb/t and 6600 Btu/lb.

Today's recovery furnace is conservatively designed for a heat release rate (heat input rate divided by furnace plan area) of approximately 0.90×10^6 Btu/h ft² (2.84 MW/m²). This heat release has increased over time, but was always kept below 1.0×10^6 Btu/h ft² (3.15 MW/m²). Although new recovery boiler furnaces are sized for a low heat release rate, there are many recovery boilers that have experienced successful capacity increases at much higher heat release rates. Mills historically have increased pulp production making the recovery boiler a limiting factor at the mill. In order to maintain increased pulp production, the recovery boiler has been called upon to process an ever increasing amount of black liquor solids. Today it is common for a recovery boiler to successfully process solids that result in heat release rates up to 1.25×10^6 Btu/h ft² (3.94 MW/m²). This has been achieved through improvements to the combustion air and liquor delivery systems, sootblower systems, reduction of chlorine in the as-fired liquor, and changes to convection pass arrangements.

There are several criteria commonly used to evaluate the potential success of capacity increases for recovery boilers. In addition to the heat release rate, the furnace exit gas temperature, superheater exit gas temperature, flue gas velocity, and furnace volume are important criteria. Depending on the extent of the

capacity increase, most of these criteria can be met with changes to the original design. For example, flue gas temperatures can be reduced with furnace screen and superheater changes. Furnace volume has been modified by expanding the furnace forward, relocating the furnace front wall forward and making the side walls wider thus providing a greater furnace volume for higher rates of liquor solids.

The criteria B&W uses to predict recovery boiler performance is based on operating experience. Some of this has changed over time as equipment improvements have affected operation.

Process flows through the recovery boiler

The kraft process recovery boiler is similar in many respects to a conventional fossil fuel-fired boiler. The concentrated black liquor fuel is introduced into the furnace along with combustion air. Inside the furnace, the residual water is evaporated and the organic material is combusted. The inorganic portion of the black liquor solids is recovered as molten smelt. Most of the sulfur is in the reduced form of Na_2S and most of the remaining sodium is Na_2CO_3 . The requirement to recover sulfur in a reduced state is the most unique aspect of recovery boiler design. Fig. 4 illustrates a typical modern recovery boiler.

Combustion air is introduced into the furnace at staged elevations: primary, secondary, tertiary, and at times, quaternary. One-fourth to one-half of the air enters at the primary level near the furnace floor. The balance is staged at the secondary, tertiary and quaternary levels. Heavy black liquor (solids greater than 60%) is fed to the furnace through multiple burners between the secondary and tertiary air levels.

The gases generated by the black liquor combustion rise out of the furnace and flow across convection heat transfer surface. Superheater surface is arranged at the entrance to the convection pass, followed by steam generating surface and finally the economizer. In designs featuring direct contact evaporators, the flue gas may flow from the boiler bank to the evaporator with no economizer surface provided, or a relatively small economizer may be required.

Feedwater enters the recovery boiler at the bottom of the first pass economizer. Heated water from the second pass economizer is discharged into the steam drum. From the drum, saturated water is routed through pipe downcomers to lower furnace enclosure wall headers and the boiler bank. From these steam generating circuits, the steam-water mixture is returned by natural circulation to the steam drum where the mixture is separated. From the drum, steam-free water is again returned to the furnace and boiler bank circuits, and water-free steam is directed to the superheater. After flowing through the superheater sections, the steam leaves the recovery boiler and is typically piped to a turbine-generator.

Boiler thermal performance

The thermal efficiency of a recovery boiler is defined as the ratio of energy output to energy input. The boiler output is a measure of the energy transferred

to the feedwater in generating steam and can be expressed as:

$$\text{Output} = (H_s - H_{fw}) \dot{m}, \text{ Btu/h (J/s)} \quad (2)$$

where

H_s = enthalpy of steam leaving superheater, Btu/lb (J/kg)

H_{fw} = enthalpy of entering feedwater, Btu/lb (J/kg)

\dot{m} = steam or water flow rate, lb/h (kg/s)

Boiler water is frequently withdrawn from the steam drum as blowdown to maintain steam purity. Steam may also be withdrawn prior to the final superheater stage for use in sootblowing. In these instances, the output expression must be corrected to account for the energy leaving the boiler prior to the superheater outlet.

Fig. 4 Typical modern recovery boiler.

The portion of the input energy available to generate steam can be determined by calculating a steady-state heat and material balance around the boiler. Because steady-state output must equal the input less energy losses, boiler efficiency can also be expressed as:

$$\text{Boiler efficiency} = \frac{\text{Output}}{\text{Input}} = \frac{\text{Input} - \text{Losses}}{\text{Input}} \quad (3)$$

Fig. 5 illustrates the major streams crossing the heat and material balance boundaries. The total heat input can be calculated by summing the chemical and thermal energy contained in the streams entering the boundary. The total losses are then calculated by summing the heat losses due to endothermic reactions occurring within the boiler and the thermal energy losses of the exiting streams.

In practice, it is not feasible to precisely measure all streams entering and leaving the system boundaries. An unaccounted for heat loss and a manufacturer's margin are added to the total losses to correct the calculated efficiency for these limitations.

The gross heating value or chemical energy of black liquor is determined by combusting a black liquor sample with an excess of oxidant, under pressure, in a bomb calorimeter. Under these laboratory conditions, the combustion products predominantly exist as CO_2 , H_2O , Na_2CO_3 , Na_2SO_4 and sodium chloride (NaCl). A key process in black liquor combustion is the reclamation of sodium compounds in a reduced state. The reduction reactions occurring in the recovery furnace result in different combustion products than those resulting from the bomb calorimeter procedure. These endothermic reactions account for a portion of the black liquor heating value that is not available in the recovery furnace to generate steam. To accurately determine recovery boiler efficiency, the bomb calorimeter gross heating value must be corrected for the heats of reaction of these different combustion products.

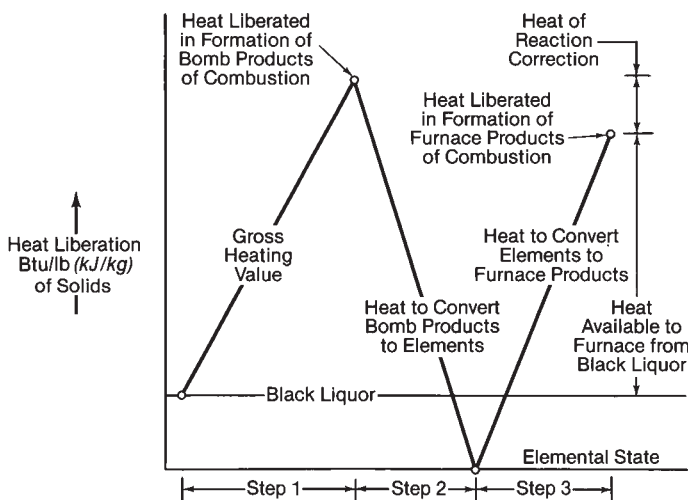

Fig. 6 Determination of black liquor heat of reaction correction.

The heat of reaction correction is the difference between the standard heat of formation of the bomb products and the heat of formation of the furnace products. Application of the heats of formation to determine a reaction correction is illustrated for kraft liquor in Fig. 6.

- Step 1 This is the gross heating value of the black liquor sample determined in the bomb calorimeter.
- Step 2 From the quantitative analysis of the fully oxidized bomb calorimeter compounds, the heat required to convert these products to their elemental state can be calculated from the standard heats of formation of the compounds from their elements.
- Step 3 Similarly, from the quantity of each chemical compound present in the furnace combustion products, the heat of formation for the actual furnace products can be calculated.

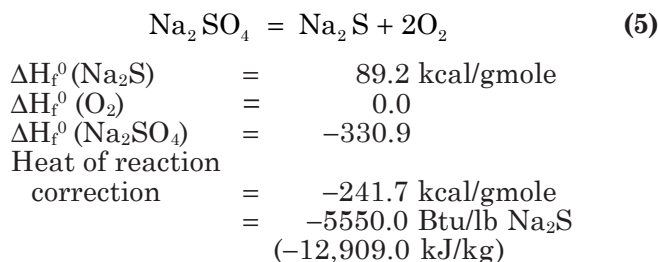

Fig. 5 Plant heat balance diagram. (See also Table 2.)

The difference between Step 2 and Step 3 is the heat of reaction correction.

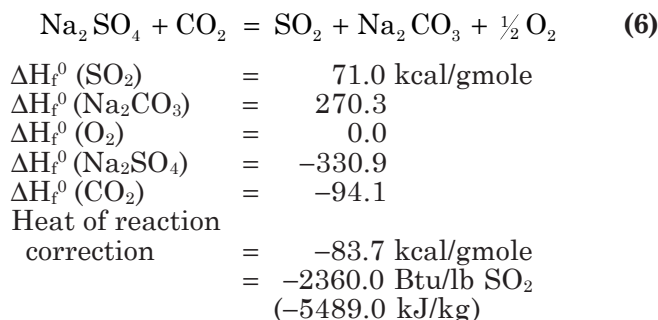

Sulfur dioxide (SO₂) and Na₂S are the most significant recovery furnace combustion products that differ from those formed under bomb calorimeter conditions. The heat of reaction correction for Na₂S is calculated as follows:

The calculation is simplified by combining Steps 2 and 3 and using standard heats of formation:

Similarly, the heat of reaction correction for sulfur dioxide can be determined from standard heats of formation from the bomb calorimeter combustion products:

In actual furnace operations, there is a variety of partially reduced, partially oxidized combustion products. However, accounting only for the presence of SO₂ and Na₂S in correcting the bomb calorimeter gross heating value closely approximates black liquor combustion in a recovery furnace.

Salt cake makeup and other additives to the black liquor are treated in a manner similar to the heat of reaction correction in calculating recovery boiler efficiency. The heat of formation or gross heating value of the Na₂SO₄ salt cake is accounted for as a contribution to the total system energy input. The subsequent reduction of Na₂SO₄ to Na₂S and O₂ is then taken as a heat loss.

The black liquor elemental analysis and gross heating value are used to determine the chemical and thermal performance of the recovery boiler. A typical black liquor analysis is presented in Table 1.

Table 2 lists the inputs and losses for a recovery unit firing 250,000 lb/h (31.5 kg/s) dry solids at 70% black liquor concentration based on the composition and heating value given in Table 1. Industry practice is to express the various heat losses as a percentage of the total heat input, also shown in Table 2. The system boundaries for the heat and material balance are shown diagrammatically in Fig. 5.

Table 1
Black Liquor Analysis

Dry solids, % by wt	
Nitrogen (N)	0.10
Sodium (Na)	19.77
Sulfur (S)	4.36
Hydrogen (H ₂)	3.86
Carbon (C)	35.14
Oxygen (O ₂)	34.74
Inerts	0.30
Potassium (K)	1.31
Chlorine (Cl)	0.42
Total solids	100.00

Solids gross heating value = 5985 Btu/lb (13,921 kJ/kg)

The black liquor gross heating value is the predominant energy input to the recovery boiler system. The balance of the input is the sum of the sensible heats contributed by those process streams entering the boiler above a base reference temperature. The black liquor is typically preheated to 230 to 270F (110 to 132C) prior to firing. The majority of the combustion air (primary and secondary) is also generally preheated to promote stable furnace conditions.

The heat of reaction correction is expressed as a heat loss due to the endothermic reduction reactions in calculating recovery boiler efficiency. To determine this heat loss, the fraction of sodium and sulfur converted to Na₂S, Na₂SO₄ and SO₂ must be calculated from the chemical analysis of the smelt and flue gas leaving the recovery boiler. For the example presented in Table 2, 0.099 lb of Na₂S is formed for each pound of black liquor solids entering the recovery boiler. The heat of reaction correction or heat loss associated with the formation of Na₂S is calculated as follows:

$$\begin{aligned}\frac{0.099 \text{ lb Na}_2\text{S}}{\text{lb solids}} \times \frac{5550 \text{ Btu}}{\text{lb Na}_2\text{S}} \times \frac{250,000 \text{ lb solids}}{\text{h}} \\ = 137.36 \times 10^6 \text{ Btu/h}\end{aligned}\quad (7)$$

In addition, 0.0017 lb of SO₂ is formed in the reduction of Na₂SO₄ to Na₂CO₃:

$$\begin{aligned}\frac{0.0017 \text{ lb SO}_2}{\text{lb solids}} \times \frac{2360 \text{ Btu}}{\text{lb SO}_2} \times \frac{250,000 \text{ lb solids}}{\text{h}} \\ = 1.0 \times 10^6 \text{ Btu/h}\end{aligned}\quad (8)$$

The heat loss due to the reduction reactions is the sum of these heat of reaction corrections:

$$\begin{aligned}\text{Reduction reaction heat loss} &= 137.36 \times 10^6 + 1.0 \times 10^6 \\ &= 138.36 \times 10^6 \text{ Btu/h}\end{aligned}$$

In addition to the heat of reaction correction and the heat loss attributed to reducing salt cake makeup, energy is lost from the boiler in the form of sensible heat. Heat is also lost through water vaporization and through the molten smelt. Typically, smelt leaving the recovery furnace represents 532 Btu/lb (1237 kJ/kg) of heat consumed to melt the smelt and raise its tem-

Table 2
Material and Energy Balances for a Recovery Boiler Firing 250,000 lb/h Dry Solids at 70% Liquor Concentration

Material balance:

Entering combustion air	=	1,176,620 lb/h

Boiler efficiency =

$$\frac{\text{Input} - \text{Losses}}{\text{Input}} = \frac{1583.31 - 568.04}{1583.31} = 64.12\%$$

Output = Efficiency x Input =

$$\frac{64.12}{100} \times 1583.31 \times 10^6 = 1015.22 \times 10^6 \text{ Btu/h}$$

Steam flow =

$$\frac{\text{Output}}{H_s - H_{fw}} = \frac{1015.22 \times 10^6}{(1444.16 - 246.93)} = 847,970 \text{ lb/h}$$

perature to a nominal 1550F (843C). The balance of the heat losses are determined in a manner similar to those for conventional power boilers. (See Chapter 22.)

The contribution to boiler efficiency offered by the remaining streams crossing the recovery unit heat and material balance is primarily established by their sensible heat content at the temperature at which they cross the system boundary. The minimum temperature of the flue gas leaving the boiler is selected to minimize corrosion. The heat transfer surface arrangement and thermodynamic considerations then dictate the economic limit for the flue gas exit temperature, typically 350 to 400F (177 to 204C).

The gross heating value of a given black liquor sample is strongly influenced by its carbon content. As this content increases, the heating value typically increases, as illustrated in Fig. 7. An increased liquor heating value also generally corresponds to an increased hydrogen content, with a corresponding decrease in inorganic sodium and sulfur contents. These

factors result in an increased quantity of theoretical air (see Chapter 10) required to combust the black liquor. The overall trends can be summarized as follows:

1. Carbon (and hydrogen) content increases with increasing heating value.
2. Inorganic sodium and sulfur contents decrease with increasing heating value.
3. Theoretical air increases with increasing carbon and hydrogen contents.
4. Theoretical air increases with increasing heating value.

These trends can be used as quick checks on laboratory results for a given black liquor sample chemical analysis and gross heating value.

Black liquor as a fuel

Black liquor

Black liquor is a complex mixture of inorganic and organic solids partially dissolved in an aqueous solution. Heavy or strong black liquor introduced to the recovery furnace ranges from 60 to 80% solids by weight. The organic fraction of the solids is principally derived from the hemicellulose and the lignin removed from the cellulose strands of the wood chips. The solids' inorganic fraction is primarily Na₂CO₃, sodium hydrosulfide (NaHS) and oxidized sulfur compounds. Black liquor also contains various chemical elements which enter the process with the wood, as impurities in makeup limestone and salt cake, and as contaminants in makeup water. These elements include potassium, chlorine, aluminum, iron, silicon, manganese, magnesium and phosphorous. The waste stream from a chlorine dioxide generator in a bleached mill can also contribute NaCl. Potassium and chlorine directly impact the recovery boiler design and operation if they are present in the black liquor in sufficient quantities.

It is not uncommon for many other waste streams and effluents from the mill to be added to the black liquor. This may include soap, various brines or other effluents from the bleach plant, or a variety of other streams. These may significantly affect the chemical composition or heating value of the black liquor fuel, which can have major impacts on performance, operations, emissions and/or cleanability of the recovery boiler.

Black liquor is sprayed into the furnace as coarse droplets which fall to the floor in a dry and partially combusted state to form a char bed. The mounded bed

Fig. 7 Black liquor high heating value as a function of carbon content in dry solids.

consists of a matrix of carbon and inorganic sodium chemicals rising 3 to 6 ft (0.9 to 1.8 m). The black liquor droplets sprayed into the furnace must be large enough to minimize droplet entrainment in the rising combustion gases, yet small enough so that they fall to the bed nearly dry. Wet liquor droplets reaching the bed can quench the burning char and cause a bed blackout, or can result in high sulfur emissions.

The design of the recovery furnace must promote combustion of the black liquor in parallel with the efficient reduction of sodium compounds. The absolute reduction efficiency is determined by the degree, on a weight percent, to which sulfur is present in the smelt in a reduced state, such as Na_2S and NaHS .

$$\text{Reduction efficiency} = \frac{\text{Na}_2\text{S} + \text{NaHS}}{\text{Total sodium sulfur compounds}} \times 100\%, \text{Na}_2\text{O} \quad (9)$$

A common industry simplification is as follows:

$$\text{Reduction efficiency} = \frac{\text{Na}_2\text{S}}{\text{Na}_2\text{S} + \text{Na}_2\text{SO}_4} \times 100\%, \text{Na}_2\text{O} \quad (10)$$

The industry practice is to express the compounds in the equations as the equivalent weight of Na_2O .

Emissions

The black liquor combustion process is never theoretically complete. This results in small concentrations of unburned combustibles, typically carbon monoxide (CO), organic and sulfur compounds, and hydrogen sulfide (H_2S), being discharged to the atmosphere. The volatile organic compounds, or VOC, are generally expressed in terms of equivalent methane (CH_4) and are sometimes more specifically referred to as nonmethane volatile organic compounds (NMVOC). H_2S and sulfur-bearing organic compounds such as mercaptans are grouped together as total reduced sulfur (TRS). Trace amounts of SO_2 also exist in addition to TRS-bound sulfur. As in most combustion processes, nitrogen oxides (NO_x) are present and are expressed in terms of equivalent nitrogen oxide (NO_2). Black liquor combustion also creates particulate matter.

The modern recovery boiler achieves effective NO_x control by staged air combustion, control of excess air, and a uniform distribution of the black liquor through multiple burners. A recovery furnace inherently produces lower NO_x emissions compared to fossil fuel boilers. Burning 68 to 75% solids concentration black liquor, NO_x levels would normally be expected to be below 100 ppm.

Recovery boilers can often be upgraded in capacity with little or no increase in NO_x emissions, as air port sizes and locations can be modified to allow adequate control of operations, and emissions, when increasing solids input. Numerical modeling of the existing air system using actual operating data provides the engineer with accurate predictions of NO_x and particulate emissions before hardware is installed.

SO_2 emissions are a function of the sulfidity of the smelt. Fig. 8 shows the general variation of SO_2 with

Fig. 8 Sulfur dioxide emissions.

sulfidity. An environmental benefit of increased black liquor concentrations fired in recovery boilers is a reduction in SO_2 emissions.

Concentrations of TRS in the combustion gases leaving a modern boiler are readily controlled below 5 ppm, as the H_2S and volatile organic sulfide compounds are oxidized in the high temperature furnace. VOC and CO emissions can be controlled by proper furnace design and operation. VOC can be maintained below approximately 80 ppm (current Environmental Protection Agency/EPA limit) while CO emissions are controllable to less than 500 ppm. A hot furnace and thorough mixing of combustion air with the generated volatiles are essential in minimizing VOC, TRS and CO emissions. Particulate is removed from the combustion gases in a high efficiency electrostatic precipitator, which can control the stack discharge particulate to the current EPA limit of 0.044 gr/dscf.

Ash

Ash accumulations on heat transfer surfaces create an insulating barrier that reduces heat transfer to the boiler tubes. Consequently, as the ash deposits build and heat transfer decreases, steam outlet temperatures decay and the flue gases retain higher temperatures as they pass through the boiler surfaces. Higher flue gas temperatures lead to more ash in its molten phase being carried further back in the boiler convection pass where it adds to already present accumulations. As ash deposits grow, they also begin restricting gas flow through the boiler, plugging the gas passes, and eventually increasing the furnace draft loss to inoperable levels.

The characteristics of ash from black liquor combustion impact the design of the process recovery boiler. Approximately 45% by weight of the dry, as-fired solids is inorganic ash. The majority of these inorganics are removed from the furnace as Na_2S and Na_2CO_3 in

the molten smelt. A significant amount of ash is present as particulate entrained in the existing flue gases. Generally, about 8% by weight of the entering black liquor dry solids leaves the furnace as ash.

Ash is generally categorized as *fume* or *carryover*. Carryover consists of char particles and black liquor droplets that are swept away from the char bed and liquor spray by the upward flue gas flow. Entrainment occurs when small particles caught in the furnace gases are not of sufficient size, shape or density to fall back into the furnace. Entrainment results in combustion of black liquor in the upper furnace which affects temperature and ash deposit properties. Entrainment of smelt and char materials is a major cause of convection surface plugging.

Once entrained, the black liquor carryover droplet follows the gas flow. When complete particle burnout occurs, the entrained droplet can settle out of the gas flow as a smelt bead. Otherwise, the partially combusted particles form sparklers that deposit on tubes as char, then continue to burn and yield a smelt deposit. At low loads with lower furnace gas flow rates, entrained droplets have time to burn out, and only small smelt droplets show up as carryover. As load is increased, larger drops can be entrained by the correspondingly increased gas flow. The particles can then include small smelt droplets and large char particles. Carryover can be controlled by furnace size and by proper design and operation of the firing and combustion air systems.

Fume consists of volatile sodium compounds and potassium compounds rising into the convection sections of recovery boilers. These volatiles condense into submicron particles that deposit onto the superheater, boiler bank and economizer surfaces. Fume particles in kraft recovery boilers are usually 0.25 to 1.0 microns in diameter and consist primarily of Na_2SO_4 and a lower content of Na_2CO_3 . Fume also contains potassium and chloride salts.

The much larger carryover particles, typically greater than 100 microns, are easily distinguishable from the submicron fume particles. Fume and carryover ash are also different in their chemical analyses. Carryover is similar in composition to the smelt (see comments above). Fume is mostly Na_2SO_4 and is enriched in potassium and chloride relative to their concentration in the smelt.

Fume can contribute to deposit formation and plugging in the convection heat transfer sections of the boiler, particularly if allowed to sinter and harden. Fume particles are also the predominant source of particulate emissions from recovery boiler stacks.

A third category of ash is represented by intermediate size particles (ISP), a class of particles between carryover (> 100 microns) and submicron fume, which are produced during combustion of black liquor droplets and the char bed. While ISPs are abundant, exist everywhere, and are potentially important to fouling in recovery boilers, the mechanisms by which these particles are formed are not yet well understood.

Char bed temperature controls the fuming rate. A rate just sufficient to capture the sulfur released during combustion should be established. This minimizes the dust load to the precipitator and the SO_2 to the

stack. More fuming than that sufficient to capture the sulfur causes the excess alkali to be converted to carbonate in the ash. Less fuming than that sufficient to capture sulfur causes excess sulfur to be released as SO_2 , and chlorine to be released as HCl in the stack gas, rather than being converted to chloride in the ash.

As potassium (K) has a higher vapor pressure than sodium (Na), the fume contains a higher ratio of K/Na than that found in smelt or black liquor. This is referred to as potassium enrichment. Chlorides are also found at higher concentrations in fume. Potassium and chlorides can contribute to severe plugging in the recovery boiler convection surfaces.

Ash fouling and gas path plugging within recovery boilers are directly related to the melting properties of the ash in the boiler. Chloride and potassium concentrations within the liquor cycle are the most significant factors affecting ash melting points. High chloride concentrations are the result of high chloride sources such as in the wood supply or makeup chemicals. Environmental improvements within the last decade have reduced chemical losses throughout the system, and increased various dead-load chemicals, including chlorides, within the liquor stream.

One of the main factors in determining ash deposition rates is the ash stickiness.³ Ash stickiness is a function of the amount of liquid phase present in the ash, that is dependent upon ash chloride content and temperature.

A simplified relationship between the ash chloride content and the sticky temperature is shown in Fig. 9. This graph may be used to illustrate the anticipated effects of elevated ash chloride levels in general terms. The conditions of this particular graph are at a 5% potassium molar ratio. Notice that the sticky band on this graph covers the widest temperature range from 5 to 10% molar chloride levels and would be in a narrow range at higher and lower chloride levels.

Ash enrichment by chloride reduces the ash melting point and increases the deposit sintering rate. The characteristic sticky temperature has been defined as the temperature where 15% of the alkali salt mixture is liquid. The presence of K in combination with chlorides further reduces the sticky temperature of depos-

Fig. 9 Sticky temperature.⁴

its. The recovery boiler should be designed to reduce the gas temperature entering the boiler bank to below the ash sticky temperature to avoid bank plugging. Decreasing the Cl level in the black liquor can also decrease the plugging tendency of the resulting ash. The successful reduction of chloride levels has been achieved by ash purging. When purging ash (see *Ash system*), ash is removed periodically to maintain chloride levels at a specified target. For the most part, maintaining a chloride level in the precipitator ash of 1.5% or less has proven to be successful in reducing fouling and plugging within recovery boilers.

Recovery boiler design evolution

The kraft recovery process evolved in Danzing, Germany approximately 25 years after the soda process was developed in the United Kingdom in 1853. In 1907, the kraft recovery process was introduced in North America. From its inception, a variety of furnace types competed for a successful commercial design, including rotary and stationary furnaces. During the late 1920s and early 1930s, significant design developments were achieved by G.H. Tomlinson, working in conjunction with B&W engineers.

The first Tomlinson recovery boiler was supplied by B&W Canada in 1929, at the Canada Paper Company's Windsor Mills, Quebec plant (Fig. 10). This black liquor recovery boiler had refractory furnace walls that proved costly to maintain. The steam generated with the refractory furnace was also much less than that theoretically possible. Tomlinson decided that the black liquor recovery furnace should be completely water-cooled, with tube sections forming an integral part of the furnace. This new concept boiler, designed

Fig. 10 First Tomlinson recovery boiler.

in cooperation with B&W, was installed at Windsor Mills in 1934. The water-cooled design was a complete success, and the boiler operated until 1988. The first Tomlinson recovery boilers in the U.S. were two 90 B&W-Btu t/day units sold to the Southern Kraft Corporation in Panama City, Florida in 1935.

The Tomlinson design evolved with a technique of spraying black liquor onto the furnace walls. The liquor is dehydrated in flight and on the furnace walls, where pyrolysis begins with the release of volatile combustibles and organically bound sodium and sulfur. As the liquor mass builds on the furnace walls, its weight eventually causes it to break off and fall to the hearth. There, pyrolysis is completed and the char is burned, providing the heat and carbon required in the reduction reaction.

By the end of World War II, the recovery boiler design (Fig. 11) had evolved to the general two-drum arrangement that represented B&W's standard product until the mid-1980s. Retractable sootblowers using steam as a medium eliminated hand lancing in the 1940s; this significant development made large recovery boiler designs practical.

Fig. 11 General two-drum arrangement of the 1940s.

Wall and floor construction

By 1946, furnace wall construction had evolved from tube and refractory designs to a completely water-cooled furnace enclosure, using flat plate studs to close the space between tubes and to minimize smelt corrosion and the resultant smelt leaks. The flat stud design was superseded in 1963, with membrane tube construction where the gas-tight seal is along the plane of the wall rather than formed by casing behind the wall.

The 1963 furnace wall construction had 3 in. (76 mm) outside diameter (OD) tubes on 4 in. (102 mm) centers. The advantages of this construction included less air infiltration, reduced refractory maintenance, and a completely gas-tight unit. The design used cylindrical pin studs for corrosion protection of the tubes in the reducing zone of the lower furnace. The pin studs held solidified smelt, forming a barrier to the corrosive furnace environment. The current construction calls for 64 half-inch (13 mm) diameter studs per linear foot (0.3 m) of tubing.

The lower furnace design continued to evolve in the 1980s from the traditional pin stud arrangement to the use of composite or bimetallic tubes. The composite tubes are comprised of an outer protective layer of AISI 304L stainless steel and an inner core layer of standard American Society of Testing and Materials (ASTM) A 210 Grade A1 carbon steel. The composite tube inner and outer components are metallurgically bonded. The outer layer of austenitic stainless steel, which is also used to cover the furnace side of the carbon steel membrane bar, protects the core carbon steel material from furnace corrosion.

Not long after the introduction of 304L composite tubes, issues with sodium hydroxide attack of the stainless layer near air ports, and cracking of the 304L layer and tube-to-membrane weld, were discovered. The cracking and corrosion have typically been specific to the floor and primary air ports. Considerable investigation has occurred with other materials identified as probable substitutes for 304L. Differential expansion of the two layers has been identified as an issue. Table 3 shows the coefficients of expansion and tensile strength for different materials commonly used to protect recovery boiler lower furnace tube surfaces.

Several methods are used for lower furnace corro-

sion protection. Lower furnace protection should be determined from criteria such as steam pressure, the history of furnace corrosion, capital budget, and maintenance expectations. The list of common means of protection includes chromized carbon steel tubes, chromized pin studs, carbon steel pin studs, metallic spray coatings, high density pin studs, 304L, Alloy 825 and Alloy 625 composite tubes, and weld overlay of carbon steel tubes. Normally, carbon steel tubes are used below 900 psig (6.2 MPa) and tubes with an alloy outer surface are used above this pressure.

A new or rebuilt high pressure recovery boiler may have several different tubes in the lower furnace (see Fig. 12). The floor may be carbon steel with pin studs. To provide additional circulation margin in the floor, and protect against extreme heat absorption upset conditions, the use of multi-lead ribbed (MLR) tubing has become common, and has become the norm in carbon steel floors regardless of whether the floor is sloped or flat. It is also common for carbon steel floors to use tubes with an alloy outer surface for the first 3 ft (0.9 m) from each side wall, as these tubes can have accelerated corrosion rates over the remainder of the floor due to the continued exposure to molten smelt. The vertical walls from the floor to an elevation above the primary air port elevation would normally be 825 composite or 625 weld overlay. Above this elevation, up to approximately 3 to 15 ft (0.9 to 5 m) above the tertiary air ports (or quaternary zone), 304L can be used to reduce costs.

Materials continue to be studied and evaluated in the laboratory and in operating recovery boilers for corrosion protection.

Property	Carbon Steel	Type 304L	Incoloy 825	Inconel 625
Expansion coefficient Mean to 700F (371C) x 10 ⁻⁶ (in./in. F)	7.59	9.69	8.3	7.5
Thermal Conductivity at 700F (371C) (Btu/h ft ² F)	320	142	115	117
Ultimate Tensile Strength ksi at 1000F (538C)		56	86	132

Fig. 12 Material zones in lower furnace.

Increased industry emphasis on high pressure and temperature operation, along with the higher availability demanded of large boilers and the trend of many mills being dependent upon a single recovery boiler, have required the decreased maintenance afforded by modern composite tubes. The single-drum boiler designed in 1987 featured readily available 2.5 in. (64 mm) OD composite tubes with 0.5 in. (13 mm) wide membrane bars. Fig. 13 chronicles the evolution of furnace wall construction with the decreasing width between tube seal bars.

Two-drum generating bank

The two-drum generating bank has evolved from a multi-pass design to a single pass design, common since the early 1960s. The multi-pass design generally had two flue gas passes, with the gases entering the bank near the top, being directed downward with a tile baffle wall integral to the bank, then turning and flowing upward, exiting the bank near the top and flowing out to the economizer.

In the 1960s, the generating bank became a single gas pass bank. The flue gas enters and traverses the entire generating bank height in one horizontal crossflow pass to the outlet flue. The tube spacing is 5 in. (127 mm) side spacing using 2.5 in. (64 mm) tubes. The generating bank screen, tubes between the superheater and generating bank, was also originally on 5 in. (127 mm) side spacing and became an area for pluggage, especially when the original capacity of the recovery boiler was exceeded. Today, an existing generating bank screen can be rearranged to provide

a wider 10 in. (254 mm) side spacing to alleviate this pluggage potential.

In the 1980s, a corrosion phenomenon was discovered in the lower portion of the generating bank just outside the lower drum. Near-drum corrosion could result in rapid corrosion of the generating bank tubes immediately above the lower drum surface. The corroded area is typically 0.25 to 0.50 in. (6 to 12 mm) in diameter and can be located 180 degrees apart on the sides of the tubes. The corrosion is normally within 1 in. (25 mm) of the lower drum top surface. The corrosion rate can be very high and is identified through ultrasonic testing of the tubes from inside the lower drum. In 2001-2002, B&W developed and patented a new product called GenClad® to protect the carbon steel tube surface immediately above the lower drum (see Fig. 14). The generating bank tube is coated with 309H stainless steel, approximately 0.050 in. (1.27 mm) thick, using a laser fusion method. The tube is then swaged to reduce the tube outside diameter to match the drum hole and the cladding is smoothed in the process, ready for rolling into the lower drum. The cladding is put on the tube in an area that is swaged and is extended into the gas stream several inches to provide protection from near-drum corrosion.

Evolution of the modern, single-drum design

The 1980s saw an increase in the pulp and paper industry's need for high pressure and temperature steam generation from the recovery boiler. This trend was paralleled by the demand for large, conservatively sized furnaces and general acceptance of the single-drum, all welded boiler design. B&W commissioned its first modern single-drum boiler in 1989, at Gaylord Container Corporation in Bogalusa, Louisiana.

In the two-drum design arrangement, the drums are exposed to combustion gases which limit the drum length that can be effectively supported. This maximum length established the design capacity of the two-drum arrangement at about 5×10^6 lb (2.3×10^6 kg) of dry solids per day. In the single-drum arrangement, the steam drum is moved out of the gas flow path, thereby removing this limitation and allowing recovery boilers designed to process daily solids rates of up to 9 to 10×10^6 lb (4.1 to 4.5×10^6 kg) of dry solids per day.

Black liquor solids concentration

The air pollution legislation of the mid-1960s forced major changes in recovery boiler design. To reduce malodorous emissions, the direct contact evaporator was replaced by additional multiple effect evaporator capacity to obtain the optimum liquor concentration. Economizer surface was added for flue gas cooling that was previously accomplished in the direct contact evaporator.

Floor design

There are two generally accepted floor arrangements for recovery boilers: a full sloped floor design and a flat or decanting style. The full sloped design slopes the entire floor at 4 to 6 degrees, and is intended to produce an arrangement that results in a complete drainage of the smelt. The flat or decanting style has

Fig. 13 Evolution of wall construction.

Fig. 14 Carbon steel tube surface protected with GenClad®.

little or no slope, and is intended to maintain a pool of smelt in the lower furnace. B&W traditionally provided only the sloped floor for all two-drum units and all single-drum units. Sloped tubes provide positive circulation and greater margin for waterside operational upsets in this high heat input area of the furnace. Floor arrangements are shown in Fig. 15.

Flat or decanting floors may be modified to incorporate some sloping capabilities, primarily at the front and rear of the furnace and along the side walls. B&W has a dual-sloped dihedral design, sloped at the sides, which can increase flow and circulation margin when conditions require. From an operational standpoint, the sloped or decanting styles allow some inventory of smelt in the lower furnace. Some operators feel this improves operation and reduces smelt spout and opening issues. Existing fully-sloped floors may be modified to achieve a partial decanting effect by dual sloping the floor from the front and rear. This provides the desired smelt inventory while maintaining sloped tubes for circulation. Smelt spouts may also be raised slightly above the floor level to provide a pool of molten smelt immediately in front of the smelt openings.

Lower furnace floor support design has evolved over the years. Floor beams under the floor tubes have increased in number to help strengthen the floor and reduce the potential for damage that can result from heavy salt cake falls from the upper furnace elevations. Floor beam end connections at the side walls have been redesigned for additional strength, to hold side walls against the floor in the event of a major furnace upset or explosion. These improvements have led to a more rigid design able to withstand a variety of operational conditions.

Superheater design

B&W's first recovery boiler designed for elevated pressure and temperature was placed in operation in 1957, at Continental Can Company (now Smurfit-Stone Con-

tainer Corporation) in Hodge, Louisiana; it generated steam at 1250 psig (8.6 MPa) and 900F (482C).

B&W's high steam temperature design philosophy is reflected in the arrangement of superheater surface. The inlet primary superheater bank is placed following the furnace cavity, with steam flowing through the bank parallel to the gas flow. This results in the coolest available steam flowing through the superheater tubes exposed to the hottest gas temperatures and the radiant heat from the furnace. This arrangement minimizes the metal temperature of the superheater tubes.

Early recovery boilers had front superheater sections spaced on 10 in. (254 mm) side spacing and rear sections spaced on 5 in. (127 mm) side spacing. This arrangement was used when the furnace construction

Fig. 15 Recovery boiler floor arrangements.

was 3 in. (76 mm) tubes on 5 in. (127 mm) centers. The closer spaced 5 in. (127 mm) side spaced sections may be modified to 10 in. (254 mm) side spacing to alleviate a potential pluggage area, particularly at higher loads. When these superheater components are replaced for any reason, consideration should be given to make the banks consistent with all 10 in. (254 mm) side spacing. This may require a change in superheater surface area, but will result in a superheater that offers improved cleanliness.

Ash buildup and superheater surface plugging have frequently limited availability of the recovery boiler. To avoid these conditions, in 1968 B&W established a 12 in. (305 mm) side spacing for the entire superheater bank, abandoning the conventional 5 and 6 in. (127 and 152 mm) spacing in the secondary superheater construction. This increased the clear side spacing in the superheater from 3.5 to 9.5 in. (89 to 241 mm).

Superheater tie arrangements have evolved as tube backspacing has changed and improved surface configurations have been adopted. Pendant superheaters (see Fig. 18) have utilized D-links or tongue and groove ties in the fore and aft direction. The tongue and groove tie allows for greater tube differential expansion and improved welding capabilities. Platen superheaters (see Fig. 18) have used pin and pipe ties, or a slip spacer type of tie, to restrain the tubes.

Economizer design

The recovery boiler economizer has evolved several times over the years in response to the change to low odor operation, cleanliness, increased heat utilization (efficiency), and reliability. There are several current designs which meet the needs of the industry (see Fig. 16).

The close side-spaced, horizontal, continuous-tube economizer was an early design used to reduce the temperature going to the direct contact evaporator or air heater. To keep gas temperatures high for the direct contact evaporator or air heater (600F/316C or greater), the economizer was small. This economizer was always a crossflow arrangement with the gases flowing perpendicular to the tube surface. This was an efficient method of heat absorption, but presented a cleaning problem. Instead of sootblowers, B&W developed and used shot systems for cleaning gas side deposits. This system took small pieces of metal, such as blanks from the manufacture of nuts and bolts, and dropped them across the economizer surface. The shot was collected in a hopper and returned to drop on the economizer surface. This was done repeatedly to clean any salt cake deposits from the outer surface of the tube. This method of cleaning was not as effective as sootblowing and presented problems with both the return system and tube damage over time.

When direct contact evaporators were discontinued, the economizer size needed to increase. The gas temperature exiting the direct contact evaporator is normally around 400F (204C) and a new, larger economizer was designed to provide the same exit temperature. Gas flow across the tubes (perpendicular) was maintained due to its efficient heat transfer, but to accommodate the increased economizer size necessary, the economizer arrangement was changed to vertical tubes with multiple (three or five) crossflow gas paths.

When direct contact evaporators were discontinued, the economizer size needed to increase. The gas temperature exiting the direct contact evaporator is normally around 400F (204C) and a new, larger economizer was designed to provide the same exit temperature. Gas flow across the tubes (perpendicular) was maintained due to its efficient heat transfer, but to accommodate the increased economizer size necessary, the economizer arrangement was changed to vertical tubes with multiple (three or five) crossflow gas paths.

Fig. 16 Recovery boiler economizer arrangements.

The five-pass bare tube economizer design contained much greater heating surfaces than would have been available with the close side-spaced horizontal surface, and was designed to improve gas-side cleanliness.

As new recovery boilers became larger in capacity or existing boilers underwent capacity increases, the higher flue gas quantities, velocities and carryover made cleanliness an issue. This promoted the development of the longflow economizer (Figs. 4 and 20). The longflow economizer is a two gas/two water pass arrangement that has some limited amount of crossflow surface at entrances and exits of the banks, but primarily relies on the parallel flow of gases across the tubes for heat transfer. Because the flow of gases parallel to tube surfaces is less efficient than gas flow across tubes, longitudinal fins were added to the tube to enhance the effective tube surface area and improve heat transfer. Minor revisions have occurred to the longflow economizer over the years to make all tubes straight along with improving the tie design and arrangement. Water flow is always from bottom to top. The economizer bank closest to the gas outlet is the first water pass. The feedwater enters the bottom of this bank, exits the top, and is piped to the bottom of the bank closest to the generating bank. The water exits the top of this second water pass and is directed to the steam drum.

Space may sometimes be limited for a longflow economizer retrofit without major building modifications. An alternative finned tube design was developed by B&W for this condition, the three-pass cascading longflow arrangement. This design incorporates considerable crossflow effectiveness while opening up the bank to reduce gas-side velocity and improving the overall cleanliness.

The horizontal continuous tube economizer was re-introduced in a version that has increased the tube spacing and provided for effective sootblowing. This economizer can be supplied when space limitations dictate a more compact design to reduce building modifications. It is used primarily when large regenerative air heaters are replaced with an economizer.

The choice of economizers for retrofitting existing recovery boilers should be made by the boiler designer, working with the mill and the existing arrangement. New recovery boilers will be arranged with straight tube longflow designs, while retrofits may use any of the designs identified in the evolution discussion. Regardless of arrangement, the economizer must have good sootblower coverage and personnel access for inspection.

Combustion air system

The first recovery boiler to introduce air at three furnace levels – primary, secondary and tertiary – was built by B&W in the late 1940s. In 1956, a concentrated development effort was successful in providing fuller utilization of tertiary air, which had been largely ineffective in earlier designs. Today's advanced air management system is a result of extensive laboratory scale and computer flow modeling, theoretical consideration for the air penetration across the furnace at the secondary and tertiary air levels, and testing of different air system configurations on operat-

ing boilers. Several features resulting from this development program include the use of variable velocity control dampers on the secondary and tertiary air ports to better regulate air penetration across the furnace area, an interlaced port arrangement to provide better gas mixing within the furnace, and optimization of port location.

Design considerations for B&W recovery boiler

Furnace design

The design of the modern recovery boiler and its associated equipment systems must first consider efficient black liquor combustion.

The overall black liquor composition (chemistry, percent solids, and heating value) determines how the liquor dries in the furnace. Some compositions of liquor characteristics (higher solids and heating values) are more conducive to in-flight, suspension drying of the droplets, while other characteristics (lower heating values or solids) may require additional droplet drying time. In these instances, spraying liquor on the walls between the secondary and tertiary air port levels can provide greater dehydration prior to falling onto the hearth char bed. Flexibility in operating parameters (combustion air quantities, distribution and temperatures, liquor spray methods and characteristics) is required to accommodate potentially varying conditions.

Primary air enters the furnace around the perimeter of the hearth bed. The controlled reducing atmosphere at the hearth burns the char at the bed surface to maximize reduction of Na_2SO_4 to Na_2S in the smelt. The remaining air is admitted at the secondary and tertiary air zones. The total air admitted through the primary and secondary air ports is approximately the stoichiometric requirement for black liquor combustion. High pressure air entering through large secondary ports penetrates across the furnace to assure mixing with the volatile gases rising from the char bed. Combustion at the secondary air level achieves a maximum furnace temperature zone below the liquor spray for drying the liquor. Secondary air also limits the height of the char bed by providing air for combustion across the bed surface.

Further turbulence and mixing are created by admission of tertiary air, which assures complete combustion of unburned gases rising from the secondary zone and of volatiles escaping from the sprayed liquor. Tertiary air mass penetration also provides a uniform temperature and velocity profile of combustion gases entering the convection surface. Quaternary air is a fourth level of air which is sometimes applied above the tertiary zone. Quaternary air has been shown to lower NO_x and particulate emissions, and is being applied to recovery boilers in original design or as retrofits and upgrades.

The recovery boiler furnace must also be designed for efficient removal of the molten inorganic chemicals as smelt. Finally, the combustion gases and particulate carryover must be adequately cooled in the

furnace to minimize deposition on convection surfaces.

The first step in the design of a new recovery boiler is the selection of furnace plan area, defined as the furnace width times depth. The plan area is generally set to achieve a black liquor solids heat input of 900,000 to 950,000 Btu/h ft² (2.83 to 2.99 MW/m²). As the solids heating value decreases, a larger furnace plan area is desirable. However, an oversized plan area can lead to local cold spots on the smelt bed, which in turn limit reduction efficiency. Cold spots can also lead to unstable furnace blackouts. A large plan area further constrains load turndown with stable combustion. An undersized plan area generally leads to increased fume and particle carryover.

Once the plan area is established, the width and depth dimensions are selected. Maintaining a depth to width ratio between 1.0 and 1.15 allows an effective arrangement of the combustion air ports and generally permits an economical arrangement of convection pass heat transfer surfaces. In smaller recovery furnaces designed for high steam temperature, a higher aspect ratio permits increasing the depth to accommodate the large superheater surface. Furnace height is then determined by the radiant furnace heat transfer surface required to cool the combustion gases below 1700F (927C).

The surface of the floor and wall tubes in the lower furnace must be protected against the corrosiveness of the smelt and partially combusted gases. The most widely accepted approach today is to build the furnace and floor of composite tubes (alloy tube material over a base carbon steel tube). This tube construction should extend to 3 ft (0.9 m) above the tertiary air ports. Above this elevation, carbon steel tube and membrane construction is adequate.

Wide closure plates attached to tubes bent to form air ports and other openings can result in potentially high localized stress areas. Wide closure plates suffer from corrosion, burn back and cracking. This adversely affects the air flow area of the port opening and has the potential for closure plate cracking that propagates into the furnace wall tubes. The modern furnace openings are designed without closure plates to minimize this potential (Fig. 17).

Structural attachments must also minimize tube stresses. In high stress areas, a plate stamping is welded to the tubes, and the structural member is attached to this plate. This plate stamping is contoured to provide additional weld carrying load into the tube wall, permit flexibility for the absorption of thermally induced loads, and lower the potential for fatigue and stress corrosion related failures. The windbox attachment to the tube wall, shown in Fig. 17, uses plate stampings that are shop-attached, which permits field erection without having to make any field attachment welds directly to the pressure part. This design and construction philosophy is applied throughout the pressure part enclosure for all attachment welds.

Upper furnace and arch arrangement

Combustion is completed in the tertiary zone. The water-cooled furnace walls and volume above this zone provide the necessary surface and retention time to cool

Fig. 17 Burner and secondary air port windbox attachments.

the gas to temperatures where sootblowers can effectively remove the chemical ash from convection surfaces.

The furnace arch, or *nose*, serves several important functions. The arch shields the superheater from the radiant heat of the furnace. The high temperature steam loops of the superheater are completely protected. Penetration of the arch into the furnace uniformly distributes the gas entering the superheater. An eddy above and behind the arch tip causes the gas to recirculate in the superheater tube bank, with a reverse gas flow between the superheater and the upper arch face preventing hot gas from bypassing the superheater surfaces. The angle of the arch is set to minimize the repose of deposited ash on its surface.

Furnace screen

In some recovery boilers, the superheater surface is insufficient to adequately cool the combustion gases before they enter the boiler bank. This is common in boilers designed for low steam temperature or when a recovery boiler's liquor burning capacity is significantly increased resulting in an increase in furnace exit gas temperature. A furnace screen can be used to absorb the additional heat, thereby maintaining an acceptable temperature of the gas entering the boiler bank section. When designing a new recovery boiler, the required heat absorption can often be accomplished through added furnace surface (height) and/or an oversized superheater. Larger furnaces can impact the overall building size and therefore increase the cost of the project. The furnace screen represents an economical alternative to a larger furnace or superheater component.

When a furnace screen is required, the screen tubes are in line with the superheater sections to reduce pluggage potential. The sloped section of the screen originates inside the furnace arch to protect the tubes from falling salt cake deposits and to add strength to the sloped tubes. Tubes in the sloped section of the screen were originally attached to each other using round bars on either side of the tubes, welded parallel to the tubes to provide structural integrity. Current retrofit designs use membrane bar similar to furnace wall construction (see Chapter 23). The top most tube currently has a half-wide membrane bar on the top

surface to improve structural integrity and further reduce potential tube damage caused by salt cake falls.

Convection surface

After leaving the furnace, the flue gases pass across the steam-cooled superheater banks to the longflow boiler bank and finally to the economizer sections. (See Fig. 4.) As the gas is cooled, entrained ash becomes less sticky and adheres less to the tube surfaces. As a result, it is possible to space the tubes in the convection banks progressively closer together. The closer spacing results in higher gas velocities and improved convection heat transfer rates, which in turn permit a more economical design as less heat transfer surface area is required.

Superheater

The superheater surfaces are exposed to the highest gas temperatures and, consequently, are arranged on a 12 in. (305 mm) side spacing. This results in very low gas velocities and prevents the bridging of deposits.

In arranging superheater surface, it is desirable to maintain low tube temperatures. Lower temperatures reduce the potential for high temperature corrosion and allow the use of less expensive low alloy steel. Temperatures are reduced by establishing a high steam flow through each tube, by arranging the coolest steam to flow through the superheater tubes exposed to the hottest gas temperatures, and by locating the majority of the superheater tube banks behind the furnace arch tip, shielded from furnace radiation. Superheater surface behind the furnace arch tip is considered convective surface and does not experience furnace radiation. Superheater surface types and arrangements are shown in Fig. 18.

From the drum, saturated steam enters the front tube row in the first or primary inlet superheater bank and flows through successive tube loops in parallel with the flue gas flow. (See Fig. 18.) The secondary superheater is located in the cooler gas region between the primary banks or behind the primary banks, depending upon final steam temperature. Steam flow in this secondary superheater is generally opposite to the gas flow to achieve a higher steam temperature. The superheater surface, steam direction and bank placement are determined by engineering and balancing steam temperature and flue gas temperature. Using these design guidelines for superheater design, arrangement, and materials selection permits final steam temperatures up to 950F (510C).

The superheater banks are top supported with the tube elements expanding downward. The tubes are interconnected with flexible support ties which allow independent tube expansion. Tube movement is critical to effective sootblowing. However, lack of tube restraints within a bank can lead to failure at the bank's top supports.

The superheater can be arranged as pendant surface (clear backspace between tubes) or platen surface (near-tangent backspace between tubes). Different heat transfer methods are used when calculating pendant and platen arrangements. The pendant arrangement has greater effective surface area due to a greater

amount of the tube circumference available to absorb heat from the flue gases. This results in fewer superheater rows in depth for the same steam temperature rise. Superheater banks can be radiant, convective, or a combination (see Chapter 19). Radiant surface is in front of the furnace arch tip. This surface is the first steam pass after leaving the steam drum in order to utilize non-stainless steel tubing.

Boiler bank

Today's kraft recovery boiler generally incorporates a single steam drum, with a longflow boiler bank arranged downstream of the superheater. In passing across the superheater and rear wall screen tubes, the flue gas should be cooled below the ash sticky temperature prior to entering the boiler bank. For ashes with extremely low sticky temperatures, particular attention must be given to sootblower locations.

The boiler bank is constructed of shop-assembled tube sections arranged as modules inside a water-cooled enclosure (Fig. 19). Tubes in each section are connected to headers, with water entering the lower header and the steam-water mixture exiting the upper headers. As the flue gas enters the bank, it turns downward and flows parallel to the tube length, providing easy cleanability. Within the bank, a central cavity accommodates fully retractable sootblowers. The cavity permits personnel access for visual tube inspection adjacent to sootblower lance entry. Ash deposits dislodged during sootblowing are collected in

Fig. 18 Superheater arrangements.

Fig. 19 Boiler bank isometric.

a trough hopper connected to the bank enclosure. Tube section inlet headers are widely spaced and vertically staggered to facilitate ash dropping into the hopper.

Impact-type particle deposition on the boiler bank tubes is less likely to occur with the gas longflow orientation. As a result, the allowable gas velocity in the downflow portion of the bank can be increased.

To improve heat transfer, longitudinal fins are welded to the front and back of each tube. Fins are tapered at the ends and welded to the tube on both sides. The welds are terminated by wrapping around the end of the fin. This combination of welding technique and tapered ends assures minimal stress concentration at fin termination for fins as large as 1.5 in. (38 mm).

Economizer

The boiler bank surface area is typically set to achieve a nominal exit gas temperature of about 800F (427C). This temperature maintains a reasonable differential with the saturated steam temperature [610F (321C) for a 1650 psig (11.4 MPa) drum pressure] and allows the use of carbon steel casing to enclose the downstream economizer banks. The modular economizer has vertical finned tubes arranged in multiple sections with upward water flow and downward longflow of gas (Fig. 20). The common arrangement features two banks. The flue gas enters at the upper end and discharges at the lower end of each bank. Gas flows down the length of the bank to provide good cleanability. As in the boiler bank, a central cavity dimensioned for personnel access accommodates fully

retractable sootblowers. Trough hoppers are attached to the economizer casing to collect dislodged ash deposits.

The economizer surface area is set to achieve a final gas outlet temperature approximately 100F (56C) higher than the feedwater temperature. Although it is possible to achieve an exit gas temperature closer to that of the feedwater, the decreased temperature differential results in substantially increased surface requirements for small improvements in end temperature. In addition to this thermodynamic limitation, concern for cold end corrosion generally establishes a minimum gas exit temperature around 350F (177C). The minimum recommended temperature of the feedwater entering the economizer is 275F (135C) for corrosion protection of the tube surface. With special considerations, the feedwater entering the economizer can be designed for as low as 250F (121C).

Emergency shutdown system

An emergency shutdown procedure for black liquor recovery boilers has been adopted by the Black Liquor Recovery Boiler Advisory Committee (BLRBAC) in the U.S. An immediate emergency shutdown must be performed whenever water enters the furnace and can not be stopped immediately, or when there is evidence of a leak in the furnace setting pressure parts. The boiler must be drained as rapidly as possible to a level 8 ft (2.4 m) above the mid point of the furnace floor.

An auxiliary fuel explosion can occur when an accumulated combustible mixture is ignited within the confined spaces of the furnace and/or the associated boiler passes, duct work and fans which convey the combustion gases to the stack. A furnace explosion will result from ignition of this accumulation if the quantity of the combustion mixture and the proportion of air to fuel are within the explosive limit of the fuel involved. The magnitude and intensity of the explosion will depend upon both the quantity of accumulated combustibles and the proportion of air in the mixture at the moment of ignition.

Contacting molten smelt with water can also result in a very powerful explosion. The mechanism for a smelt-water explosion is keyed to the contact of water with hot liquid smelt. Rapid water vaporization causes the propagation of a physical detonation or shock wave.

In the design and operation of black liquor recovery boilers, every effort is made to exclude water from any source from getting to the furnace, or introducing liquor at less than 58% solids. For example, furnace attachment details are designed to prevent external tube loads, which can lead to stress assisted corrosion.

Recovery boiler auxiliary systems

Black liquor evaporation

The high black liquor solids concentration required for efficient burning is achieved by evaporating water from the weak black liquor. Large amounts of water can be economically evaporated by multiple effect evaporation. A multiple effect evaporator consists of a series of evaporator bodies, or effects, operating at different pressures.⁵ Typically, low or medium pres-

Fig. 20 Economizer isometric.

sure steam is utilized in the first evaporator effect and then the vapor from one body becomes the steam supply to the next, operating at a lower pressure. Modern evaporator systems integrate a concentrator into the flow sequence to achieve the final liquor concentration. As a general rule, each pound of water evaporated from the weak liquor results in one additional pound of high pressure steam generation in the recovery boiler.

For many years, direct contact evaporation was the technology used to achieve firing solids to the recovery boiler, and may still be necessary to evaporate liquor from some special fiber sources. In the direct contact evaporator, liquor and flue gas are brought together, heat is transferred from flue gases to the liquor, and mass transfer of liquor water vapor to the gas occurs across the liquor-gas interface. Adequate liquor surface must be provided for the heat and mass transfer. The gas contact acidifies the liquor by absorbing CO_2 and SO_2 , which decreases the solubility of the dissolved solids and requires continuous agitation. The acidification also results in the release of malodorous compounds into the flue gas, a negative aspect of direct contact evaporation.

There are two types of direct contact evaporators used in the recovery unit, cyclone and cascade. The cyclone evaporator (Fig. 21) is a vertical, cylindrical

vessel with the flue gas admitted through a tangential inlet near the conical bottom. The gas flows in a whirling helical path to the cylinder's top and leaves through a concentric re-entrant outlet. Black liquor is sprayed across the gas inlet to obtain contact with the gas. The liquor droplets mix intimately with the high velocity gas and are centrifugally forced to the cylinder wall. Re-circulated liquor flowing down the cylinder wall carries the droplets and any dust or fumes from the gas to the conical bottom, out through the drain, and into an integral sump tank. Sufficient liquor from the sump tank is recirculated to the nozzles at the top of the evaporator to keep the interior wall wet, preventing ash accumulation or localized drying.

In the cascade evaporator, horizontally spaced tubular elements are supported between two circular side plates to form a wheel that is partially submerged in a liquor pool contained in the lower evaporator housing. The wetted tubes are slowly rotated into the gas stream. As the tubes rise above the liquor bath, the surface coated with black liquor contacts the gas stream flowing through the wheel.

Black liquor oxidation

When a direct contact evaporator is used, odor can be reduced by oxidation of sulfur compounds in the liquor before introduction to the evaporator. The oxidation stabilizes the sulfide compounds to preclude their reaction with flue gas in the evaporator and the consequent release of reduced sulfur gases. Oxidation can effectively reduce, but does not eliminate, discharge of these reduced sulfur gases. The direct contact evaporator is the prime source of odor.

Odor is generated in direct contact evaporators when the hot combustion gases strip hydrogen sulfide gas from the black liquor:

Fig. 21 Cyclone evaporator.

Oxidation stabilizes the black liquor sulfur by converting it to thiosulfate:

Black liquor oxidation involves high capital and operating costs; the oxidation step also robs the liquor of heating value. Modern recovery facilities incorporate multiple effect evaporators, and the low odor design, which eliminates the need for a direct contact evaporator.

Black liquor system

Recovery boilers are operated primarily to recover pulping chemicals. This objective is best realized by maintaining steady-state operation. Recovery boilers are base loaded at a selected black liquor feed flow or heat input, in contrast to power boiler applications where fuel flow is varied in response to demand for steam generation.

The black liquor solids concentration can vary with the rate that recirculated ash sheds from heat transfer surfaces, the rate it is collected in the precipitator, and the rate it is returned to the black liquor stream system. Considerable fluctuations can occur, depending on which surface is being cleaned by sootblowers, the frequency of sootblower operation, and the rapping sequence of precipitator collection surfaces. The black liquor system design should provide uniform dispersion of the ash into the liquor to minimize the fluctuation of solids at the burner. This is increasingly important as the liquor solids concentration is increased into the regime where burners are maintained in a fixed position and liquor drying is in-flight (not on the walls). A fluctuation in ash flow would change the solids concentration by several percent, significantly impacting the characteristics of the liquor.

A heater is used to adjust the black liquor temperature to that required for optimum combustion and minimum liquor droplet entrainment in the gas stream. The black liquor is typically heated in a tube-and-shell heat exchanger, using low pressure steam on the shell side and black liquor on the tube side. There are two general categories of heater designs that can be operated with minimum scaling of the heat transfer surface. The first uses a conventional heat exchanger with once-through flow of liquor at high velocity in the tubes. The tubes have polished surfaces to inhibit scale formation. This heat exchanger is satisfactory for long periods of operation without cleaning.

The second approach is to recirculate liquor through a standard heat exchanger with stainless steel tube surface to maintain high velocities that inhibit scale formation. This approach also permits long periods of operation without cleaning.

As the liquor solids concentration increases above 70%, storage can become a problem. Moreover, it becomes increasingly difficult to blend recycled ash into the highly concentrated liquor. Recycled ash can be returned to an intermediate concentration liquor stream (of about 65% concentration) prior to final evaporation in a concentrator. In this type of arrangement, liquor is routed to the recovery furnace from an evaporator system product flash tank. The as-fired

liquor temperature is established by controlling the flash tank operating pressure.

There are two designs of liquor burners, the oscillator and the limited vertical sweep (LVS). Oscillators are generally applied to liquors of lower heating values or percent solids where longer droplet drying time is necessary. LVS burners are best used for higher percent solids and heating value liquors where in-flight, suspension drying of the droplets works well. Both types of burners utilize a nozzle splash plate to produce a sheet spray of coarse droplets.

The oscillator sprays the black liquor on the furnace walls, where it is dehydrated and falls to the char bed. The oscillator burners, located in the center of the furnace wall between the secondary and tertiary air ports, are continuously rotated and oscillated, spraying liquor in a figure eight pattern to cover a wide band of the walls above the hearth. Oscillators work well on smaller units, or with a wide range of liquor characteristics.

With LVS burners (Fig. 22), black liquor is sprayed into the furnace for in-flight drying and devolatilization of the combustible gas stream rising from the char bed. The objective of the LVS burner is to minimize the liquor on the wall. The LVS gun is normally used in a fixed position, but can also sweep vertically to burn low solids liquor or those with poor burning characteristics. LVS burners are normally applied to larger sized, heavier loaded units.

The temperature and pressure of atomized liquor directly impact recovery furnace operations. Lower temperature and pressure generally create a larger

Fig. 22 Limited vertical sweep burner.

particle or droplet of atomized liquor. This minimizes the entrainment of liquor in the combustion gases passing to the heat absorbing surfaces. Where wall drying is carried out, large liquor droplets maximize the liquor sprayed on the wall and minimize in-flight drying. For oscillator firing, liquor at approximately 230F (110C) and 30 psig (207 kPa) generally provides the most satisfactory operation. For LVS burners, liquor with a slightly lower pressure of 25 psig (172 kPa) and higher temperature of 250F (121C) provides acceptable results.

As the liquor sprayed on the walls builds, it eventually falls to the char hearth. The majority of the char falling from the wall is deposited in front of the primary air ports, requiring 30 to 50% of the total air to be introduced through the primary ports.

In-flight drying deposits a minimum of char in the primary air zone around the periphery of the unit, as all the drying and a majority of the devolatilization are in-flight over the furnace area. Consequently, less primary air flow is required to keep the char from in front of the primary air ports. Because the higher liquor solids concentration dictated by in-flight drying translates into less water evaporated in the furnace, a greater fraction of the combustion heat released is available to maintain bed temperatures. Less primary air is therefore required when burning liquor in-flight in contrast to the lower concentration liquors encountered in oscillator burner applications.

Ash system

The sodium compounds entrained in the flue gas originate from fume generation and liquor droplet carryover from the lower furnace. The resultant ash drops out of the flue gas stream and is collected in trough hoppers located below the boiler and economizer modules. The electrostatic precipitator removes nearly all the remaining ash.

The majority of the entrained ash is Na_2SO_4 , and is commonly referred to as salt cake ash, or simply, salt cake. The ash collected in the trough hoppers and precipitator must be returned to the black liquor to recover its significant sodium and sulfur contents. This is accomplished by mixing the ash into the liquor in a specially designed tank. The salt cake ash is transferred to the mix tank through a wet ash sluice system or a drag chain ash conveyor system.

With a dry ash system (Fig. 23), mechanical drag chain conveyors are bolted to the bottom of the boiler and economizer trough hoppers, which extend across the full unit width. The drag chain conveyors are equipped with heat treated, high alloy forged link chains to support and convey the flights. The conveyors discharge through rotary seal valves into a collection conveyor. The collection conveyor discharges to the mix tank where the ash is uniformly mixed with the liquor.

Drag chain conveyors are also provided across the floor of the electrostatic precipitator, beneath the collecting surfaces. The conveyors discharge to mechanical combining conveyors, which in turn discharge the salt cake ash through rotary valves into the mix tank. Frequently, the dry ash system is arranged with two

Fig. 23 Dry ash system.

mix tanks, one serving the boiler and economizer hopper ash system and one dedicated to the precipitator.

As discussed previously, successful reductions of chloride and potassium levels in the ash and black liquor have been achieved through precipitator ash purging. Ash can be removed periodically to maintain chloride or potassium concentrations at a specified level. An ash chute with a rotary valve is added to the back end of an existing precipitator ash transfer conveyor. When ash purging is desired, the ash conveyor is reversed and the ash falls through the chute into a sluice tank.

In a wet ash removal system, black liquor is circulated through the hoppers to sluice the collected ash. The sluice discharges directly from the hoppers through large pipes to the mix tank. However, these pipes can become plugged with ash and overflow liquor which create safety and cleanliness problems. This has led to wider acceptance of the dry ash mechanical conveyor system. However, the mechanical conveyors generally require more maintenance than the wet ash sluice designs.

The mix tank (Fig. 24) includes a mechanically scraped screen to assure that all material which passes to the fuel pumps is small enough to readily pass through the burner nozzles. Scraping is provided by flights on a low horsepower, slow moving agitator. The tank is designed to receive salt cake from the generating bank, economizer or precipitator hoppers, mixing it with the incoming black liquor.

Combustion air system

B&W's advanced air management system provides combustion air at three, and sometimes four, elevations of the furnace: primary, secondary, tertiary, and potentially quaternary (Fig. 25). The use of at least three levels allows performance optimization of the respective furnace zones – the lower furnace reducing zone, the intermediate liquor drying zone, and the upper furnace burnout or combustion completion zone. A quaternary air level may also be applied above the tertiary zone for additional NO_x or particulate control.

Fig. 24 Salt cake mix tank.

The primary air flow quantity must be sufficient to produce stable combustion and to provide the hot reducing zone for the molten smelt. Increasing primary air flow beyond the level required to achieve these objectives increases the amount of Na_2S re-oxidized to Na_2SO_4 . The balance of the air at or less than the stoichiometric requirement is introduced above the char bed at the secondary level to control the rate at which the liquor dries and the volatiles combust, and to minimize the formation of NO_x . The additional air required to complete combustion is introduced at the tertiary level (and quaternary if supplied).

The air system may be arranged as a single-fan, two-fan (one primary and one secondary/tertiary/quaternary) or three-fan system. On larger systems, additional provisions are made to bias the air flow between respective air levels, from side to side on the primary and secondary air, or from front to rear on the tertiary air. This gives additional flexibility to the operator.

The primary air ports are arranged on all four furnace walls about 3 ft (0.9 m) above the floor. Air is introduced at a low velocity and 3 to 4 in. wg (0.75 to 1.0 kPa) static pressure which prevents it from penetrating the bed. The air lifts the carbon char in front of the port back onto the bed and maintains ignition.

Approximately 40% of the total air is admitted at the secondary zone. The air is introduced at the pressure and velocity needed to penetrate the furnace 4 to 6 ft (1.2 to 1.8 m) above the primary air ports. A velocity damper is used on each port.

Proper secondary air mixing with the gases rising from the char bed results in volatile combustion generating the heat required for in-flight liquor drying. This secondary zone typically exhibits the highest temperatures in the recovery furnace. The quantity of secondary air is dictated by the amount of burning required

to dry liquor and control bed height, and decreases as the black liquor solids concentration increases.

The balance of the air is admitted at ambient temperature through the tertiary air ports located above the liquor guns, and through quaternary ports, if supplied. A velocity damper is again used on each port. The tertiary (and quaternary) flow increases proportionately as the solids increase.

The secondary air ports are normally arranged on the longest furnace wall, generally the side walls, as the furnace is deeper than it is wide. In contrast, the tertiary air ports are arranged on the front and rear walls.

Buildup of smelt and char that restricts the air port openings can cause a performance deterioration. A reduction in port area affects air pressure at the port or air flow through the port, depending on which is being controlled. When air flow is controlled, the effect of plugged ports is to increase air pressure and push the bed farther from the wall. If pressure is controlled, the effect is a resultant decrease in air flow. This results in less effective burning of the primary zone with a decrease in furnace temperature and increased emissions.

Primary air port openings are generally cleaned (rodded) every two hours to maintain proper air distribution and bed height. Automatic port rodders provide continuous cleaning to maintain a constant flow area. The automatic port rodding system stabilizes lower furnace combustion for maximum thermal efficiency and is vital in achieving low emissions.

Secondary and tertiary air ports also require periodic rodding, although the plugging that occurs at these ports is generally less severe than at the primary air ports. In the secondary and tertiary ports, the rodding equipment can be integrated with the velocity control damper. This is necessary to provide synchronization of the damper and rodder drives.

Fig. 25 Advanced air management system.

To further enhance stability in the lower furnace, the primary and secondary air is preheated in a steam coil air heater. Low pressure steam, normally 50 to 60 psig (345 to 414 kPa) is used for preheating. Additional preheating is provided by steam at 150 to 165 psig (1034 to 1138 kPa), typically achieving a 300F (149C) combustion air temperature. When burning liquors with a low heating value or from a nonwood fiber, air should be preheated to about 400F (204C). Water coil air heaters, sometimes used within the feedwater circuit around the economizer, may also be used to provide these air temperatures.

Flue gas system

Combustion gas exiting the economizer is routed through flues to the electrostatic precipitator and induced draft fan before discharge through a stack to the atmosphere.

The induced draft fan speed controls the pressure inside the furnace. The fan is normally located after the precipitator, allowing the fan to operate in the cleaner gas.

A two-chamber precipitator is normally used. Each chamber is equipped with isolation gates or dampers and a dedicated induced draft fan discharging to a common stack. Flue gas exiting the economizer is divided into two flues, which route the gases to the precipitator's two chambers. Each chamber typically has sufficient capacity to operate the recovery boiler at 70% load, corresponding to a stable black liquor firing mode. When designing the precipitator chamber, the expected gas flow rate should include that of the sootblower steam and the increased excess air under which the boiler would operate at a reduced rating. The maximum permissible particulate discharge rate then establishes the electrostatic precipitator size.

Cleaning system

Ash entrainment in furnace gases is affected by gas velocity, air distribution and liquor properties. The design of all recovery unit heating surfaces should include sootblowers using steam as the cleaning medium. Gas temperatures must be calculated to make certain that velocities and tube spacings are compatible with the sootblowers.

High levels of chloride and potassium in the black liquor may require greater cleaning frequency. As unit overload is increased, additional entrainment of ash and sublimated sodium compounds also leads to more frequent water washing. This term describes an off-line cleaning procedure which uses high pressure water to eliminate excessive deposits or buildups on the boiler's convection surfaces. In addition to excess quantities of flue gas ash, velocities and temperatures throughout the unit are increased, making ash deposits more difficult to remove.

Auxiliary fuel system

The primary objective of the recovery boiler is to process black liquor. However, the unit can fire auxiliary fuel, usually natural gas and/or fuel oil. This fuel is fired through specially designed burners, arranged at the secondary air level. These burners raise steam

pressure during startup, sustain ignition while building a char bed, stabilize the furnace during upset conditions, carry load while operating as a power boiler, and burn out the char bed when shutting down.

In some installations, the recovery boiler must be able to generate full load steam flow and temperature on auxiliary fuel. These applications typically arise in mills that cogenerate electricity and/or have limited power boiler steam generating capability. Increased auxiliary fuel capacity can be accommodated by adding auxiliary burners above the secondary air level (typically at or above the tertiary air level).

Upper level burners allow combination black liquor and auxiliary fuel firing with minimal interference with lower furnace operations. This is not possible when operating the secondary level auxiliary burners. Also, the upper level burners can provide higher steam temperatures at lower loads during startup, which can be important in mills operating high steam temperature turbine-generators.

The auxiliary fuel burners are in a very hostile environment that compromises burner reliability and increases burner maintenance. B&W has always utilized rectangular shaped bent tube openings for burners to reduce accumulations of salt cake in the burner windbox and to keep the damaging furnace radiant heat away from vulnerable burner and lighter components. The oil atomizer or gas pipe elements are manually retracted when not in use. They would then be manually inserted when needed to start the burners.

The LM2100® auxiliary burner (Fig. 26) is designed to retract the burner and lighter elements into the windbox and insert them again to the same location using locally activated air cylinders. In addition to protection from radiant heat, the use of air cylinders also keeps the fuel elements at the correct position when inserted. The LM2100 improves burner reliability and maintenance. The LM2100 is standard design for new recovery boilers and can be retrofit to existing recovery boilers of any manufacturer.

Non-condensable gases/waste streams

Within the typical pulp and paper mill, there are numerous liquid and gaseous waste streams that are subject to stringent environmental disposal regulations. These waste streams are commonly incinerated on site. One simple and effective incineration method is to introduce these streams into an operating boiler.

Gaseous streams are typically characterized as non-condensable gas (NCG) or stripper off gas (SOG). NCG is a mixture of sulfur compounds and hydrocarbons mixed with air and is either dilute (DNCG) or concentrated (CNCG). These terms refer to the concentration of *active* compounds within the NCG. If the percentage of sulfur compounds and hydrocarbons is below the lower explosion limit (LEL) in air, the NCG is considered dilute, is essentially foul air, and is relatively easy to handle. It does, however, present minor challenges. It can be corrosive and is unpleasant to smell. If the percentage of active compounds is above the upper explosion limit (UEL) in air, the NCG is considered concentrated. CNCG should be treated as a corrosive fuel stream. These streams require added precautions.

Fig. 26 B&W's LM2100® burner.

The explosion limits for some representative gases found in NCG are shown in Table 4. The generally accepted LEL for mixtures of gases in air is 2% by volume, and the generally accepted UEL is 50%. SOG is usually a mixture of methanol in air, and is typically handled like CNCG.

These gases require special safety precautions for collection and handling. Their escape must be prevented in and around the boiler building for personnel and equipment protection, and condensate must not be allowed to enter the furnace. For CNCG gases, additional precautions are required to avoid fire and explosion in equipment and transport systems. Positive ignition systems are required for gases entering the furnace.

It is generally preferred that these non-condensable gases be burned in mill power boilers, as these units can more easily include the appropriate safety equipment. One disadvantage to using power boilers is the requirement to capture the SO_2 generated by combustion of the sulfur compounds, unless the boiler is equipped with a scrubber. For recovery boilers, the explosion potential due to tube failures does not make this type of boiler a good application to introduce foreign streams. BLRBAC does not encourage the introduction of waste streams into recovery boilers. It has, however, become more commonplace in recent years to utilize recovery boilers for this disposal, as mills are

required to meet more stringent regulations. Recovery boilers can have the ability to capture the SO_2 from NCG combustion. Significant caution and special system design are necessary to safely burn NCG in a recovery boiler.

DNCGs can often be mixed with the combustion air for the tertiary air port level on a recovery boiler, or for the stoker on a power boiler. The primary concern is to assure adequate main fuel, usually equal to or above 50% of load, to assure burnout of the gases. To avoid odor problems, the ducts, windboxes and other air transport components must be air tight. Corrosion in the feed ducts can be reduced by mixing the gases with hot air or heating the mixture. For power boilers, if the sulfur input is high, boiler exit corrosion and emissions can increase. The corrosion rate can be reduced by upgrading alloys and/or coatings or by increasing the gas temperature to stay above the dew point.

For CNCG gases, transport must avoid air leakage that could move the mixture into the explosive range. Typically, these gases are fired with a support combustion source, such as an igniter in close proximity, to assure burnout. Stainless steel piping is used to avoid corrosion. One stream explicitly excluded from any boiler incineration consideration is terpenes (turpentine vapor). The UEL of these streams is not defined, and terpenes have been the most prevalent causes of explosions in non-condensable gas collection, transport and combustion systems.

For either gas, provision must be made to avoid slugs of liquid entering the furnace. System design uses flame propagation arresters to avoid explosions, and safety interlocks must be integrated into the existing controls.

For any type of waste gas, it is important that a complete analysis of the fuel parameters (constituents, amounts, moisture, etc.) be understood so that the appropriate systems and safeguards can be designed. It is then possible to determine the proper furnace temperatures and residence times required to assure complete combustion.

There are also several liquid waste streams with disposal requirements. These include soap, tall oil, methanol, spent acid and secondary sludge. These are normally blended and combusted with the black liquor fuel. Under specific circumstances, they may be fired in a separate, dedicated burner. Turpentine, another liquid stream, is extremely unpredictable and generally restricted from either of the above methods. Handling and combusting recommendations and cautions can be found in BLRBAC guidelines.

Smelt spout system

Smelt exits the furnace through specially designed openings at the low point of the floor and is conveyed to the dissolving tank in a sloped water-cooled trough, or smelt spout (Fig. 27). The spout is bolted to the furnace wall mounting box. Most original spout designs had the machined face of the spout positioned against the outside of the furnace wall tubes surrounding the opening. While many of this arrangement are still in operation, the fully insertable spout has become common. This type of spout inserts directly into the spout opening, where the spout taps the smelt directly from

Table 4
NCG Gases Explosion Limits

Constituent Gas	Lower Explosion Limit (LEL) % Volume in Air	Upper Explosion Limit (UEL) % Volume in Air
Turpentine	0.8	Not established
Methanol	7.3	36.0
Hydrogen Sulfide	4.3	45.0
Methyl Mercaptain	3.9	21.8
Dimethyl Sulfide	2.2	19.7
Dimethyl Disulfide	1.1	16.1

Fig. 27 Integral smelt spout hood with shatter jet assembly.

the furnace and no smelt contacts the spout opening tube surface. This has helped alleviate significant spout opening wear and deterioration.

Insertable spouts use a round-shaped trough. For noninserted spouts, the trough is V-shaped to correspond to the V-shaped bottom of the wall opening. Either spout design is constructed of a double wall carbon steel trough, with a continuous flow of cooling water passing between the inner and outer walls. Given the explosive nature of smelt-water reactions and the extreme temperature of the molten smelt, the spout must receive adequate cooling water. A dedicated cooling system with built in redundancy and multiple sources of backup water assures system reliability (Fig. 28). This system may either be a pressurized cooling system, or more commonly a gravity flow, induced vacuum system where the water in the smelt spout is at less than atmospheric pressure. The cooling water is treated in a dedicated, closed cycle to minimize scale-forming contaminants.

Green liquor system

The smelt is dissolved in green liquor in an agitated tank. Green liquor is withdrawn from the tank at a controlled density and the volume replaced with weak wash. The entering smelt stream must be finely dispersed, or shattered, to control the smelt-water reaction by rapid dissolution of the smelt into the green liquor. Excessively large smelt particles entering the tank can lead to explosions. The outer surface of a large smelt particle cools quickly as it contacts the green liquor, forming an outer shell around its hot core. As the shrinking forces build, the particle shell explodes, exposing the hot core to water and resulting in the sudden release of steam. To eliminate large smelt particles from reaching the dissolving tank contents,

steam shatter jets are located above the smelt stream to disperse the flow into the tank.

The smelt spout discharge is enclosed by a hood (Fig. 27). The steam shatter jets are mounted on the top of the hood, with the nozzle angle adjusted to direct the jet at the smelt stream cascading off the spout end. The periphery of the hood is equipped with wash headers to flush the hood walls and prevent smelt buildup. A door is provided in the hood for operator access to inspect and to rod the spout and opening.

The dissolving tank is of heavy construction and is equipped for agitation. One or more agitators, either side or top entering, are generally used, including an emergency backup system, such as steam nozzles. A stainless steel band is commonly used in the carbon steel tank at the liquor level for corrosion protection, while the floor is protected with steel grating or poured refractory.

As the smelt is cooled and dissolved into the green liquor, large quantities of steam are released. The steam vapors are pulled through an oversized atmospheric vent on the tank to quickly relieve pressure in the event of a surge or explosion. Smelt particles and green liquor droplets are entrained in the steam-air mixture vented from the tank. These vented gases also contain H_2S that must be removed prior to discharge to the atmosphere. Typically, a vent stack scrubber (Fig. 29) is used to reduce H_2S emissions and to trap entrained particulates. Weak wash is used as the scrubbing medium to take advantage of its residual NaOH, which absorbs the malodorous gases.

Alternate processes and liquors

Soda process

With few exceptions, the requirements and features of the kraft recovery boiler apply to the soda recovery boiler. Because sulfur is not present in the soda pro-

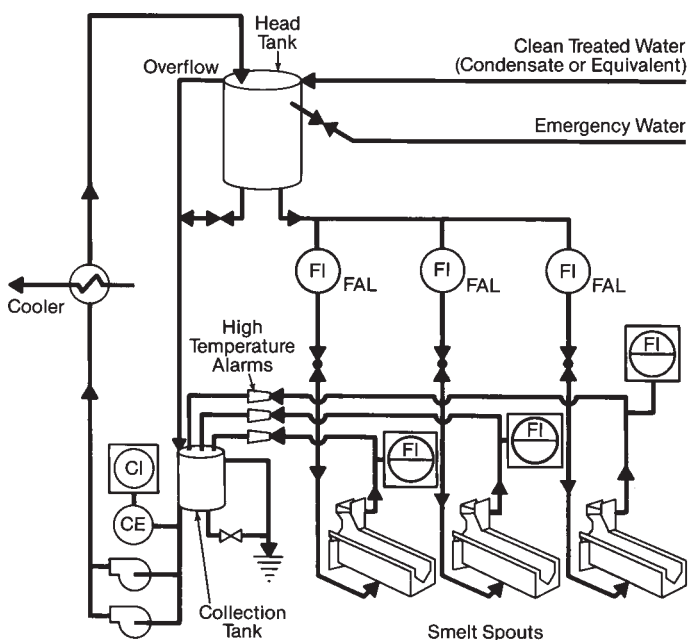

Fig. 28 Smelt spout cooling system.

Fig. 29 Vent stack scrubber.

cess, there is no sulfur reduction in the recovery furnace. Soda ash (Na_2CO_3) is added to the recovered green liquor. The ash collected from the boiler hoppers and the electrostatic precipitator is in the form of Na_2CO_3 and can be added directly to the green liquor in the dissolving tank. A salt cake mix tank is not required.

In the furnace, the soda liquor does not form a suitably reactive char for burning in a bed. It is finely atomized and sprayed into the furnace by multiple soda liquor burners. The fine spray dehydrates in flight and combustion takes place largely in suspension in an oxidizing atmosphere. Combustion air is admitted through primary and secondary air ports around the furnace periphery, with the hottest part of the furnace just above the hearth. The Na_2CO_3 collects in molten form on the hearth and discharges through the smelt spouts.

The Na_2CO_3 smelt has a higher melting point than the kraft process smelt. This makes the soda smelt more difficult to tap from the furnace and shatter. Auxiliary fuel burners can be located low in the side walls, close to the spout wall, to keep the smelt hot for easier tapping.

Nonwood fiber liquor

Many countries do not have adequate forest resources for pulp production. As a result, alternative fiber sources are used, such as bamboo, sugar cane bagasse, reeds and straw. Black liquor from these fibrous materials requires special consideration in recovery system design.

The liquor is generally characterized by high viscosity and high silica content. The high viscosity limits the level at which liquor can be concentrated in multiple effect evaporators, and direct contact evaporators are generally required. Higher combustion air temperatures are used to compensate for the low liquor concentrations while allowing flexibility in adjusting the firing conditions.

Sulfite process

Pulp produced by the sulfite process is divided into two broad categories, semi-chemical and chemical. Semi-chemical pulp requires mechanical fiberizing of the wood chips after cooking. Chemical pulp is largely manufactured by the acid sulfite and bisulfite processes, which differ from the alkaline processes in that an acid liquor is used to cook the wood chips. The acid sulfite process is characterized by an initial cooking liquor pH of 1 to 2. The bisulfite process operates with a pH of 2 to 6. Cooking liquor used in a neutral sulfite process for manufacture of semi-chemical pulps has an initial pH of 6 to 10. Spent sulfite liquor, separated from chemical and semi-chemical pulp and containing the residual cooking chemicals and dissolved constituents of the wood, is evaporated and burned, and the chemicals are recovered in a system particular to each base.

Sulfite process pulp mills normally use one of four basic chemicals for digestion of wood chips to derive a large spectrum of pulp products: sodium, calcium, magnesium or ammonium. The principal differences in the sulfite waste liquor of the four bases are the physical properties of the base and the products of combustion.

Sodium This system reconstitutes the base in a form suitable for reuse in the pulping cycle. The sodium-base liquor may be burned alone or in combination with black liquor in a kraft recovery unit. The base chemical is recovered as a smelt of Na_2S with some Na_2CO_3 which would be a suitable makeup chemical for a nearby kraft mill. The combination of sulfite liquor and kraft liquor, referred to as *cross recovery*, is common to pulp mill operations. The proportion of sulfite liquor in cross recovery is generally the equivalent of the sodium makeup requirement of the kraft mill cycle.

Calcium Calcium-base liquor is concentrated and burned in specially designed furnaces. The furnace and boiler design applicable to magnesium-base liquor combustion can also be applied to calcium. This process is largely historic today due to its unacceptable effluents.

Magnesium With the magnesium base, a simple system is available for recovery of heat and total chemicals. This is due to the chemical and physical properties of the base. The spent liquor is burned at elevated temperatures in a controlled oxidizing atmosphere, and the base is recovered in the form of an active magnesium oxide (MgO) ash. The oxide can be readily recombined in a simple secondary system with the SO_2 produced in combustion, thereby reconstituting the cooking acid for pulping.

Industrial interest in the improved pulp from a variety of wood species stimulated the development of pulping techniques using a magnesium base. The two major pulping procedures, whereby a variety of pulps can be produced, are magnesium acid sulfite and

bisulfite, or magnesite. The basic magnesium recovery system is appropriate for each of the pulping processes.

The heavy liquor is fired with steam-atomizing burners located in opposite furnace walls (see Fig. 30). The combustion products of the liquor's sulfur and magnesium are discharged from the furnace in the gas stream as sulfur dioxide and solid particles of MgO ash. Most of the MgO is removed from the gas stream in a mechanical collector or electrostatic precipitator and is then slaked to magnesium hydroxide, or $Mg(OH)_2$. In the complex secondary recovery system, the SO_2 is recovered by reaction with the $Mg(OH)_2$ to produce a magnesium bisulfite acid in an absorption system. This acid is passed through a fortification or bisulfiting system and is fortified with makeup SO_2 . The finished cooking acid is filtered and placed in storage for reuse in the digester.

Ammonium Ammonium-base liquor is the ideal fuel for producing a low ash combustion product. Burning can be accomplished in a simple recovery boiler. The ammonia decomposes on burning to nitrogen and hydrogen, the latter oxidizing to water vapor and thus destroying the base. Concentrated ammonium sulfite liquor is burned in a furnace and recovery system similar to magnesium-base liquor. SO_2 produced in combustion can be absorbed in a secondary system to yield cooking acid for pulping. The SO_2 reacts in an absorption system with an anhydrous or aqueous ammonium makeup chemical to produce ammonium bisulfite acid. In a neutral sulfite semi-chemical plant, the absorption system produces cooking liquor consisting essentially of ammonium sulfite.

Black liquor gasification

Advanced technologies – gasifier development

A new technology being investigated for the combustion/reduction of black liquor (and thus replacing the process recovery boiler) is black liquor gasification (BLG). This technology involves the partial oxidation of the black liquor to produce a fuel gas that can be burned in a gas turbine/electric generator or fired in a power boiler. In the process, sulfur and sodium compounds are recovered from the fuel gas, before it is sent to the turbine or boiler, for regeneration of the pulping chemicals.

Potential BLG advantages

The pulp and paper process requires high capital investment in plant equipment, high internally generated energy consumption, and high purchased power consumption. BLG may have the potential to favorably impact mill energy efficiency, environmental performance, operating costs and pulp yields.

Energy efficiency The amount of electricity pulp mills need to import varies considerably from mill to mill and is dependant on the power/steam cycle used and on the type of pulp produced. Electrical loads have increased relative to steam loads as more electricity is needed to operate recycling, mechanical pulping, and pollution control equipment. Most mills import a significant portion of the mill's electricity demand, and

BLG, integrated with combined cycle power production, may offer increased cycle efficiencies and electricity production.

Process flexibility Gasification technology can return sulfur to the pulping process in a variety of forms (sulfide, elemental sulfur, polysulfide, and/or sulfite). This provides opportunities to produce pulp with substantially improved yields and properties.

Availability The fouling of convection pass surfaces can reduce recovery boiler availability. BLG may provide a greater availability in that heat transfer surface fouling in either a power boiler or gas turbine heat recovery steam generator might be lower. Intermediate cleanup equipment removes sulfur compounds and alkali fume from the product gas.

Safety Smelt-water reactions are largely unpredictable and continue to pose a risk when operating kraft recovery boilers. Low-temperature BLG produces no molten smelt, eliminating the potential of smelt-water reactions, and high-temperature BLG at elevated pressure is expected to significantly reduce the likelihood and resultant force of an explosion.

Fig. 30 MgO recovery boiler.

Emissions BLG processes require that sulfur and particulate emissions be removed from the fuel gas. As a result, overall emissions from a BLG-based process are expected to be low.

BLG processes

Black liquor gasification technologies can be classified by operating temperature. Low-temperature BLG is operated below the first melting temperature of the inorganic salts, typically 1112 to 1292F (600 to 700C), to produce a solid inorganic ash. High-temperature BLG is operated above the final melting temperature of the inorganic salts, typically 1652 to 1832F (900 to 1000C), to produce a molten smelt. Black liquor gasifiers have utilized either the fluidized-bed (for low-temperature BLG) or entrained-flow designs (for high-temperature, molten-phase designs), as described in Chapter 18. Typical BLG processes are shown in Fig. 31.

Low temperature gasifiers operate at 1292F (700C) or lower so that the organics leave as dry solids. This type of gasification process is normally conducted at atmospheric pressure and produces a product gas of approximately 200 to 300 Btu/DSCF (11.8 MJ/Nm³). Minimal gas cleanup is required, and the product gas is generally fired to offset auxiliary fuel in a power boiler. This allows additional black liquor processing capacity, provides a useful product gas for auxiliary fuel use, and is well suited for incremental capacity additions at existing mills.

High temperature gasifiers generally operate at 1742F (950C) or higher and produce a product gas of approximately 85 to 100 Btu/DSCF (3.9 MJ/Nm³) and a molten smelt of inorganic chemicals. High-temperature BLG can be pressurized and integrated with a combined cycle system for power generation. Product gas cleanup systems are required for the removal/reduction of sulfur and particulate emissions before the gas turbine. These systems can also separate the sul-

fur compounds from the product gas and return them to the pulping process.

Status and development needs

Atmospheric pressure BLG has had the most development to date. Various concepts, both high and low temperature, have been in design and pilot stages since the early 1990s. The first fully commercial process is an air-blown, high-temperature entrained flow gasifier with a processing capacity of 15 t/h of dry solids. This process provides incremental recovery capacity with product gas burned in a boiler.

High-temperature BLG with combined-cycle power generation is in development. Various pilot work is being done for pressurized, oxygen-blown entrained-flow reactors and large-scale commercial units are contemplated for the near future.

Black liquor gasification is a promising technology, but key issues must be resolved before full commercialization. While current Tomlinson technology is capital intensive, early BLG installations are expected to be quite expensive. Capital costs must be reduced, positive economics must result and the overall economic case must be strengthened for BLG to provide superior returns.

Specific gasifier design and process integration issues exist, including gasifier materials selection, refractory corrosion, product gas cleanup equipment, tar formation, sulfur removal, and an increased causticizing load. Many activities are underway within the industry to investigate and resolve these and other issues.

An important aspect of the overall process and economics is the effect of integrating higher yield pulping technologies into the BLG cycle (split sulfidity, polysulfide, etc.), as these can have significant positive impact on overall economics. They, too, are capital intensive and will take some development, but integrating them into the process is the key to providing acceptable, positive economic returns.

Chapter 29

Waste-to-Energy Installations

The disposal of garbage is a problem that has existed since civilization began. At various times throughout history, composting, animal feed, landfill and incineration have all been popular disposal methods. Today, refuse disposal methods are determined by cost and the effect on our environment.

The most common means of refuse disposal is still landfilling. Even in the late 1970s, nearly all of the refuse generated in North America was landfilled. Incineration with no heat recovery was a popular option that became economically unacceptable with the advent of environmentally responsible air pollution regulations and inexpensive landfill alternatives.

In Europe and Japan, where new landfill sites were less available, incineration continued as a viable option and those plants became the predecessors of today's refuse-to-energy plants. Heat recovery was added in the form of waste heat boilers which were originally hot water boilers and later low pressure and temperature steam boilers. These incinerators with waste heat boilers then evolved into waterwall boilers with integral stokers.

Refuse-fired boiler design parameters and operating characteristics are strongly affected by the components of the refuse, which change with time. The components also vary greatly by location. In North America, typical municipal solid waste (MSW) is high in paper and plastics content (Fig. 1) and typically has a lesser moisture content and greater heating value than that found worldwide. In a less industrialized country the refuse tends to have a greater moisture and ash content and lesser heating value. Table 1 shows representative refuse analyses ranging from 3000 to 6000 Btu/lb (6978 to 13,956 kJ/kg) higher heating value (HHV) basis.*

In the United States (U.S.) and North America, the refuse characteristics have changed dramatically in a short period of time. With more and more convenience foods, plastics, packaging, containers, and less

food scraps due to home garbage disposals, the average refuse heating value has increased and the moisture content has decreased (Table 2). As more recycling programs are implemented, the analysis will continue to change. As glass, aluminum and other metals are recycled, the refuse heating value will increase; as paper and plastics are recycled the heating value will decrease.

In 2000, approximately 232 million tons (210 million t_m) of MSW were generated in the U.S. About 30% of that total was recycled (including composting), 15% sent to refuse-to-energy facilities, and the balance landfilled. The growth of refuse-to-energy facilities in the U.S. accelerated in the 1980s and early 1990s (Fig. 2) due to the growing disposal costs for landfills and a government-created market for the sale of electric power.

As old landfills closed, new landfills became more difficult and costly to open and tended to be located farther from the source of the refuse, increasing transportation costs. Concerns about ground water contamination resulted in more expensive landfill designs with several containment layers and leachate monitoring and control systems. The passage of the Public Utility

Fig. 1 U.S. municipal solid waste generation – 2001.

* Throughout this chapter, fuel energy content, or heating value, is stated as the higher (or gross) heating value which includes the total energy in the fuel without correcting for losses due to water evaporation.

Regulatory Policies Act of 1978 (PURPA) required public utilities to purchase the electric power generated by refuse-to-energy plants. This created a revenue flow that helped offset the inherent high capital cost of these plants. These market forces resulted in a proliferation of refuse-to-energy facilities in the northeast U.S. where the costs of landfill and other disposal options were the highest, and selectively throughout North America in response to local environmental or economic factors.

Refuse disposal is a major problem worldwide and there is no single solution. An environmentally sound refuse disposal program includes generating less refuse, recycling components that can be economically reused, combustion of the balance of the refuse (including the efficient generation of electric power), and the landfill of the resulting ash.

Refuse combustion alternatives

Two main techniques are used for burning municipal refuse, distinguished by the degree of fuel preparation. The first technique, known as mass burning, uses the refuse in its as-received, unprepared state (Fig. 3). Only large or non-combustible items such as tree stumps, discarded appliances, and other bulky items are removed. Refuse collection vehicles dump the refuse directly into storage pits. Overhead cranes equipped with grapples move the refuse from the pit

to the stoker charging hopper. Hydraulic rams located in the charging hopper move the refuse onto the stoker grates. The combustible portion of the refuse is burned off and the non-combustible portion passes through and drops into the ash pit for reclamation or disposal.

The second burning technique uses prepared refuse, or refuse-derived fuel (RDF), where the as-received refuse is first separated, classified, and reclaimed in various ways to yield salable or otherwise recyclable products (Fig. 4). The remaining material is then shredded and fed into the furnace through multiple feeders onto a traveling grate stoker. The RDF is burned, part in suspension and part on a stoker. The RDF can also be used as a fuel in circulating fluidized-bed (CFB) boilers and in bubbling fluidized-bed (BFB) boilers. More finely shredded RDF can be fired in suspension to supplement conventional fuels in large boilers used for power generation.

Corrosion

Combustion products from municipal refuse are very corrosive. The components that are present in coal, oil and other fuels that contribute to corrosion, as well as to high slagging and high fouling, are all present in refuse (Table 3). Corrosion in refuse-fired boilers is usually caused by the chloride compounds which deposit on the furnace, superheater and boiler tubes. Several modes of chloride corrosion may occur:

Fig. 2 U.S. refuse-to-energy market.

1. corrosion by hydrochlorides (HCl) in the combustion gas,
2. corrosion by NaCl and KCl deposits on tube surfaces,
3. corrosion by low melting point metal chlorides (mainly $ZnCl_2$ and $PbCl_2$), and
4. out-of-service corrosion by wet salts on the tube surface.

The rate of tube metal loss due to corrosion is temperature dependent with high metal temperatures correlating with high rates of metal loss (Fig. 5). Refuse boilers operating at higher steam pressures have higher temperature saturated water in the furnace tubes and, therefore, these furnace tubes have higher metal temperatures. Superheater tube metal temperatures are directly related to the steam temperature inside the tubes. In both cases, it is the temperature of the water or steam inside the tube that largely controls the tube metal temperature, rather than the temperature of the flue gas outside of the tube.

Furnace-side corrosion can be aggravated by poor water chemistry control. If water-side deposits are permitted to form, tube wall metal temperatures will rise and furnace corrosion will be accelerated. Standards for feedwater and boiler water quality are based on boiler operating pressures. These standards are no more stringent for refuse-fired units than for other fuels. However, the maintenance of feedwater and boiler water quality, and adherence to those standards, is more critical on refuse-fired boilers due to the highly corrosive nature of the fuel.

Lower furnace corrosion

The lower furnace environment of both mass-fired and RDF-fired units is constantly changing between an oxidizing atmosphere (an excess of O_2 beyond that needed for combustion) and a reducing atmosphere (a deficiency of O_2 below that needed for combustion)

Fig. 3 Mass burning schematic.

which can rapidly accelerate corrosion. Therefore, some form of corrosion protection is needed. Typically, the area of protection will encompass all four walls up to 30 ft (9.1 m) above the grate where there is reasonable assurance that an oxidizing atmosphere is prevalent and that combustion has been substantially completed.

Mass-fired units

A variety of solutions have been developed and used to address the issue of corrosion in the lower furnace. The lower furnace walls of virtually all mass-fired units have been protected by one or more of the following three systems: 1) pin studs with silicon carbide (SiC) refractory, 2) ceramic tiles manufactured from SiC (see Fig. 6), or 3) Inconel® weld cladding of the membrane tube panels.

The quality and physical characteristics of the sili-

		Vanadium	

con carbide refractory placed over the pin studs must be maintained through proper application and curing. Lack of control during installation will result in refractory spalling, deterioration, and increased maintenance. The refractory material should have a high rate of thermal conductivity to maximize the effectiveness of the water-cooled surface it is protecting. The pin stud pattern, pin stud length and pin stud diameter must be carefully chosen for its ability to hold the refractory in place and to maximize the heat transfer through the stud to the furnace wall tubes. This, in turn, serves two purposes. One is to provide maximum cooling to keep as low a refractory temperature as possible. Maintaining a low refractory surface temperature has a dramatic effect on refractory life, furnace wall fouling and maintenance costs. Second, with more heat removed in this lower furnace area, less heating surface is required in the upper furnace to achieve the desired flue gas temperature leaving the furnace.

SiC tiles have a much harder and smoother surface than that produced with the pin studs and refractory; therefore, the tiles are more resistant to spalling and less prone to slag buildup. The attachment system used to anchor the ceramic tiles to the furnace walls must keep the tiles in contact with the furnace walls in order to cool the tiles. The anchors must also permit movement between the tiles to minimize expansion stresses that may damage the tiles.

Inconel weld overlay has gained general acceptance since the year 2000 for application in the lower furnace walls of large mass-fired boilers, as it had earlier for RDF-fired boilers. The good corrosion resistance, high thermal conductivity, metallurgical bond to the base tube and membrane bar metals, and wear resistance have made Inconel overlay the primary ap-

Fig. 5 Corrosion rate of carbon steel in chlorine and hydrogen chloride.

Fig. 6 Silicon carbide tiles for lower furnace wall corrosion protection.

proach for lower furnace corrosion protection in new European designs. In such units, high temperature gunned-on and cast refractory systems also continue to be used in selected areas of the furnace where heat absorption must be limited or heat must be radiated back into the combustion zone while still providing corrosion protection. Typically, refractory is used on: 1) furnace arch areas over the grate feed and burn-out zones, 2) on the intermediate elevation furnace walls where heat absorption must be minimized to maintain adequate furnace temperatures during continuous low-load firing, and 3) on the furnace walls in smaller boilers where the ratio of furnace wall area to furnace volume is so high that the gas temperature within the furnace is suppressed below the point required for optimal combustion (see Fig. 7).

The furnace side walls along the grate line generally experience the most erosion due to the scrubbing action of the refuse fuel and ash as it moves along the grate to the ash discharge. Increased erosion-resistant SiC materials are available for these zones. They do, however, have lower thermal conductivities.

An alternative near the grate line is the use of armour blocks or refractory blocks, rigidly attached to the furnace walls. These blocks extend up the full height of the charging hopper opening which is about 4 ft (1.2 m) high at the front of the furnace and tapers off to about 1 ft (0.3 m) high at the ash discharge end (Fig. 8).

Another method used for protection of the furnace walls immediately adjacent to the grate is the use of a separate water-cooled *wear zone panel* placed horizontally along the grate line and in front of the lower furnace walls as shown in Fig. 7. A flexible tight seal is created between the wear zone panel and the vertical furnace wall to accommodate expansion between the top-supported boiler and the bottom-supported grate structure. Depending upon the cooling water temperature and corrosion potential, the water-cooled wear zone panel may be protected from corrosion by Inconel weld overlay similar to the boiler walls. This low maintenance design provides a relatively cool surface which resists the buildup of significant slag while also providing corrosion protection and wear resistance with little demand for maintenance.

Fig. 7 Corrosion protection and design of a 26 t/h mass-fired unit.

RDF-fired units

Prior to the late 1980s, RDF boilers were installed with bare carbon steel tubes in the lower furnace and no corrosion protection. It was thought that with the more even combustion with a processed fuel, corrosion would not be a concern in the lower furnace. Early units, operating at low steam pressures and temperatures, did not experience corrosion problems. However, as higher pressure and temperature units went into operation, corrosion increased and lower furnace protection was needed.

The same pin stud and refractory design used on mass-fired units has also been tried on RDF units. This solved the corrosion problem but created another. Inherent in the RDF combustion process is a high degree of suspension firing and high flame temperatures in the lower furnace. When pin studs and refractory are applied, the lower furnace tubes are insulated, resulting in less heat transfer and hotter flue gas temperatures in the lower furnace. This, in turn, can result in significant slagging on the refractory wall surface. Pin studs and refractory were tried at two RDF facilities. However, increased furnace slagging resulted, and eventually the pin studs and refractory were removed.

The industry needed a material that was resistant to the chloride corrosion found in refuse boilers while not insulating the lower furnace tubes. The Babcock & Wilcox Company (B&W) pioneered the use of

Inconel material as a solution to this lower furnace corrosion problem. In 1986, following rapid corrosion of the bare carbon steel tubes, the lower furnace of the Lawrence, Massachusetts unit was covered with a weld overlay of Inconel material. This overlay proved to be effective in minimizing corrosion in the lower furnace. Based on this early experience, the industry followed B&W's lead and Inconel weld overlay was subsequently field applied to the lower furnace of a number of operating boilers.

For the RDF boilers supplied as part of the refuse-to-energy plant in Palm Beach County, Florida, the decision was made to add the Inconel protection prior to manufacture. A bimetallic tube construction was used consisting of a carbon steel inner tube co-extruded with an Inconel outer tube (Fig. 9). These boilers went into operation in 1989 and the Inconel bimetallic tubes have proven to be an effective means of reducing lower furnace corrosion. Today, Inconel bimetallic tubing and carbon steel tubing with an Inconel weld overlay are the industry standard for lower furnace corrosion protection in RDF-fired boilers.

Mass burning

Mass burning is the most common refuse combustion technology worldwide. When the market for refuse-to-energy facilities expanded rapidly in the

Fig. 8 Refractory type and location, mass-fired unit.

U.S. in the early 1980s, many of the U.S. refuse plants (Fig. 10) adopted the well-proven mass burning technology that had been developed in Europe. A modern B&W European mass burn power plant is shown in Fig. 11. The boiler is a multi-pass, top-supported design.

Some major differences in the application of the European technology in the U.S. resulted in several operational problems. U.S. applications tend to require large units to accommodate larger regional facilities than European and Japanese applications. U.S. plants were designed to operate at significantly higher operating pressures and temperatures to take advantage of the economics of production and sale of electric power while typical non-U.S. applications produced hot water and low pressure steam for heating applications. U.S. refuse fuel typically had a higher heating value and lower moisture content. Finally, these units were first installed at a time when environmental concerns were increasing.

The net result of these characteristics of the market resulted in many early refuse units experiencing operating problems related to:

1. high rates of slagging in the furnace,
2. higher gas temperature leaving the furnace resulting in overheating of superheaters and excessive fouling in the convection section,
3. tube failures from accelerated corrosion that were metal temperature related, and
4. concerns about the creation of dioxins (polychlorinated dibenzoparadioxin, PCDD) and furans (polychlorinated dibenzofurans, PCDF) during the combustion process that were related to less than optimum combustion systems, particularly less than optimum turbulence and mixing of fuel and air in the lower furnace.

Each of these problems has been taken into consideration as the design of mass-fired boilers has evolved.

Overall boiler design and gas flow path

B&W offers two basic designs for large mass-fired boilers. Fig. 12 shows a typical mass burn unit supplied in the U. S. while Fig. 13 illustrates a horizontal convection pass unit supplied in Europe. Both are single drum, top-supported, natural circulation boilers capable of supplying superheated steam at a range of pressures and temperatures to meet individual site requirements. The steam drums are supplied with the appropriate steam separation equipment to supply high purity dry steam to the superheater while spray attenuators closely control the steam temperature. The furnaces are fully water-cooled with membrane wall construction using the appropriate corrosion protection system (see earlier discussion). Cleaning of boiler surfaces is accomplished by a combination of mechanical rapping and sootblowers as discussed later in this chapter. Both designs utilize a reciprocating combustion grate and similar lower furnace configurations to provide efficient burnout of the fuel before the ash is discharged. The gas flow paths of the two units differ to meet market requirements and preferences.

As shown in Fig. 12 for the U.S. market design, the combustion products from the grate flow upward through the single furnace pass to provide sufficient residence time and temperature to burn the fuel con-

Fig. 12 Typical U.S. mass burning unit.

stituents and other hydrocarbons, and cool the flue gas to the required furnace exit gas temperature before entering the superheater. Where required, the design provides the necessary reaction time for a selective non-catalytic reduction (SNCR) process to control nitrogen oxides (NO_x). The flue gas then turns 90 degrees around a large furnace arch to pass through the crossflow superheater section before turning downward to flow parallel through the longflow boiler steam generating bank. The flue gas then flows upward through the crossflow economizer section and exits the boiler enclosure.

As shown in Fig. 13 for the European market design, a multiple pass furnace is used to cool the flue gas. The combustion products leave the grate and lower furnace to pass upward through the first open furnace pass and then downward through the second open pass. As noted earlier, a portion of the first pass may be covered with high SiC cast refractory to reduce heat absorption and permit the flue gas to maintain a suitable high temperature for a specified period of time for complete combustion of the fuel constituents and other hydrocarbons in smaller boilers and at lower load in larger units. At the bottom of the second open pass, the flue gas turns 180 degrees to pass upward through

the third pass to cool the flue gas to the required gas temperature before entering the horizontal convection pass. Additional parallel flow boiler circuits or baffles in the form of widely spaced tube panels are typically used in the third pass to increase the heat absorption. The flue gas flow path is designed to provide reasonably uniform cross-section flow and temperature distributions throughout by the use of physical and numerical computational fluid dynamics (CFD) modeling (see Chapter 6). Noses or arches (not shown) are used at the first pass exit, second pass inlet and third pass inlet, while inclined walls and roofs are used in each pass to achieve the desired flue gas distribution.

The bottom-supported convection pass contains a series of convection heat transfer surface sections in the direction of gas flow: steam generating surface, secondary superheater, tertiary superheater, primary superheater, more steam generating surface in some cases, and finally the economizer before the gas exits the boiler enclosure. The convection pass surfaces are arranged to minimize corrosion, and are widely spaced to prevent pluggage and allow adequate space for mechanical sootblowing equipment. The first steam generating surface protects the superheater from high temperature peaks. The secondary and tertiary superheaters are designed for parallel steam and flue gas flow to minimize metal temperatures and corrosion. The second optional steam generating surface may be used to cool the flue gas to avoid steaming in the economizer.

Boiler plant sizing

A refuse plant must be sized to handle the physical amount of refuse that is delivered to that plant, regardless of the refuse heating value. A refuse boiler, on the other hand, is a heat input device and must be sized for the maximum heat input expected. When designing a refuse boiler, consideration must be given to both the design tons per day of refuse to be combusted and the typical range of heating values that is expected for the refuse in that location.

The boiler is typically designed for the maximum ton per day input at the maximum refuse heating value. A 1000 t/d (907 t_m/d) refuse plant is actually not the same size plant in all locations. As an example, a plant in an industrialized country might be designed to handle refuse with a heating value of approximately 5500 Btu/lb (12,793 kJ/kg), or 458×10^6 Btu/h (134 MW_t) total heat input to the boilers. At the other extreme, a plant in a less industrialized country might be designed to handle refuse with a heating value in the range of 3500 Btu/lb (8141 kJ/kg), or 292×10^6 Btu/h (85.6 MW_t) total heat input. Both are 1000 t/d (907 t_m/d) plants, but one has refuse boilers that have a 50% larger capacity in terms of heat input.

For many of the early U.S. plants, good data were not available on the true range of heating values of the refuse. Refuse boilers were sized for typical heating values of 4500 Btu/lb (10,467 kJ/kg). When the actual heating values were found to be as high as 5200 to 5500 Btu/lb (12,095 to 12,793 kJ/kg), the boilers were actually undersized and could not process the available refuse on a ton per day basis.

Fig. 13 Typical European mass burning unit.

Stoker capacity

A refuse stoker has both a heat input limit and a ton per day refuse throughput limit. If a typical 1000 t/d (907 t_m /d) refuse plant has two 500 t/d (454 t_m /d) boilers, and the design refuse heating value is 5000 Btu/lb (11,630 kJ/kg), each boiler would have a maximum heat input limit of 208.3×10^6 Btu/h (61.1 MW_e). If the actual refuse heating value is above 5000 Btu/lb (11,630 kJ/kg), the unit's ton per day capacity would be reduced below 500 t/d (454 t_m /d) so not to exceed the maximum heat input limit. On the other hand, if the actual refuse heating value is below 5000 Btu/lb (11,630 kJ/kg), then the unit could actually process more than 500 t/d (454 t_m /d) of refuse, up to the maximum ton per day limit of that stoker.

The ton per day limit is usually set by a refuse capacity per unit of stoker width, a limit for optimum fuel feed and distribution, or a structural limit based on refuse weight per square foot (m^2). These limits are in the range of 30 t/d (27 t_m /d) per front foot (0.3 m) of

width and 65 lb/h ft^2 (2.74 kg/h m^2) of grate area. The grate surface area is set by a grate release rate generally in the range of 270,000 to 350,000 Btu/h ft^2 (852 to 1104 kW/ m^2), but may be lower for low heating value, high moisture fuels. The design limits stated above represent typical values for equipment installed in North America. Stokers supplied for European and Asian refuse installations have typically used lower design limits, especially with respect to the grate heat release rate.

The stoker width and depth are also related to the specific fuel. A high heating value, low moisture fuel would require a wider, less deep stoker because the fuel will tend to burn more rapidly. A low heating value, high moisture fuel would require a narrow, deeper stoker because more residence time on the stoker is usually needed. The combination of all these criteria will set the maximum ton per day rating of the stoker.

There is also a minimum load that can be effectively handled on a given stoker. This load is also set by both

a ton per day limit (minimum fuel inventory on the grate) and a heat input limit (minimum heat input for good combustion).

All of these limits can be incorporated into a capacity diagram, which provides the operator with the boundary limitations around a family of heating value curves. Fig. 14 is such a diagram for a typical 500 t/d (454 t_m/d) boiler burning 5000 Btu/lb (11,630 kJ/kg) refuse.

Stoker design

The combustion of MSW requires a rugged, reliable stoker to successfully convey and burn unsorted refuse. Most stokers use some variation of a reciprocating grate action, with either forward moving or reverse acting grate movement. Some arrangement of moving and stationary grates is used to move the refuse through the furnace and allow time for complete combustion.

A reciprocating grate stoker is typically designed with alternating moving and stationary rows of grate bars in a stairstep construction with a downward slope to help move the refuse along the length of the grate. Each row of grate bars overlaps the row beneath it and the alternate rows are supported from a moving frame driven by hydraulic cylinders. The moving rows of grate bars push the refuse over the stationary bars where it is picked up by the next row of moving bars. Fig. 15 shows a pivoting grate design where each row of grate bars is mounted on individual transverse shafts moving slowly 60 deg forward and backward so that the entire grate surface is in constant motion. The reciprocating grate shown in Fig. 16 has longitudinal grate girder assemblies filled with grate bars. Every other grate girder assembly is resting on a transverse shaft at the upper end, moving slowly 30 deg forward and backward so that the grate surface moves like a walking beam floor. The remaining assemblies are stationary. The typical grate drive units are equipped with hydraulic cylinders with a piston moving forward and backward and thereby creating the grate movement. The motion of these grates rolls and mixes the refuse, constantly exposing new material to the high temperatures in the fuel bed and allowing the combustion air to contact all of the burning refuse.

Fig. 14 Stoker capacity diagram.

Fig. 15 Pivoting refuse grate.

More recently, MSW heating values have increased to levels where water cooling of the grate has become more common for new mass-fired units. Typically, the upper half of the grate, nearest to the fuel feed point and most intense combustion zone, is water-cooled while the balance of the grate is air-cooled. The grates in Figs. 15 and 16 can be supplied with either water- or air-cooled versions. Water cooling also has the operational advantage that combustion air temperature can be preheated as required for combustion without consideration for grate cooling, which is controlled by the water flow.

For lower heating value, high moisture refuse, drop-off steps are often incorporated into the stoker design. The steps are located at the end of each grate module resulting in one to three steps depending on the overall stoker length. These steps promote a tumbling and rolling action as the burning refuse falls off the step. This type of design was used on a number of the early refuse units in the U.S. but was found to be unnecessary with the higher heating value and lower moisture refuse. In fact, it can be a detriment as the tumbling can also result in excursions of high carbon monoxide (CO) emissions.

The grates are usually constructed in a series of standard modules with independent drives and air plenums. This allows the individual grate modules to be factory-assembled to limit field construction time and provide complete duplication of parts for easy maintenance and repair. This modular construction allows any size stoker to be constructed from a small number of standard modules. A typical stoker is usually from two to four modules in length and one to four modules in width.

of 80 to 100% and complete combustion is generally indicated by a CO value in the range of 10 to 100 ppm.

The high percentage of excess air needed to ensure proper combustion can be reduced through flue gas recirculation. Flue gas recirculation involves the use of cooled flue gas, generally extracted from the system down stream of the baghouse, to offset a certain portion of the fresh air used in the overfire air system. The recirculated flue gas maintains the total flow volume in the combustion air system while reducing the percentage of excess O_2 , which improves boiler efficiency. Flue gas recirculation also reduces the production of NO_x by limiting the amount of O_2 present in the high temperature region of the furnace where NO_x is formed. The advantages of using flue gas recirculation can be offset by its disadvantages which include the capital cost of the system, power consumption of the recirculation fan, and overall system maintenance.

To aid in the combustion of wet fuels during extended periods of rainy weather, the air system includes steam coil air heaters designed to provide air temperatures in the range of 300 to 350F (149 to 177C) to help dry these fuels and maintain furnace temperature. These steam coil air heaters are commonly used only for the undergrate air because this is the air flow which directly aids in drying wet fuel. These air heaters must be conservatively designed with fin spacing not exceeding 4 to 5 fins/in. (1 fin/6.4 to 5.1 mm). Most plants take combustion air from the storage pit area to help minimize odors. This air is normally contaminated with dust and lint which could plug the steam coil. Some type of cleaning arrangement or filters must therefore be included to keep the steam coil clean.

When high moisture fuels are encountered, the first action by the operator is to use the steam coil air heater to provide hot air. However, for very high moisture fuels it may also be necessary to use the auxiliary fuel burners to stabilize combustion in the furnace. These cases are the exception, and in normal operation neither the auxiliary burners nor the steam coil air heater are needed for good combustion.

Ash handling systems

When refuse is burned, the ash takes the form of either light ash, called flyash, or coarse ash, which comes off the stoker. The flyash is entrained in the gas stream until it is removed in the particulate collection device or falls out into the boiler, economizer, or air heater hoppers. The stoker ash consists of ash from the fuel, slag deposits on the grate, ash from the furnace walls and, in some designs, ash from the superheater. The stoker ash is discharged through the stoker discharge chute and from the stoker siftings hoppers.

Ash extractor

The ash from the stoker discharge on mass-fired units may contain large pieces of non-combustible material, in addition to the normal ash from combustion. Ash consistency can vary from fine particles to large and heavy non-combustible objects in the fuel. The ash from the stoker discharge chute falls into a water bath in the ash extractor that quenches the ash

Fig. 18 Plunger ash extractor.

and controls dusting. In the plunger ash extractor (Fig. 18), the ash is quenched, a slow moving, hydraulically operated ram cycles forward and back to push and squeeze the accumulated ash up an inclined dewatering section to the discharge of the extractor. The ram cycles continuously at a slow speed to push the ash out of the extractor. The dewatered ash has a moisture content of 15 to 20% as a result of the squeezing process on the incline. The lower moisture content can have an economic advantage as the cost of landfilling ash is based on total weight, which includes the weight of water in the ash. Another option is a wet conveyor ash extractor. This is a water-filled conveyor trough where noncombustible items, ash and grate siftings are transported on a steel apron belt submerged in water. As with the chain conveyor discussed later in the chapter, the belt carries the noncombustibles, ash and siftings up an incline, effectively dewatering the material before it is discharged from the belt to a bin or hopper, and the belt cycles around to the water-filled trough to collect more material.

To keep the ash system simple and to minimize costs, ash from the extractor can discharge directly into a truck or bin for final disposal. To move the ash away from the vicinity of the stoker discharge, vibrating and belt-type conveyors are used. A short vibrating conveyor is placed at the discharge of the ash extractor; its metal trough can withstand the impact of the oversized, non-combustible material falling from the extractor. The vibrating conveyor then transfers the ash to a belt conveyor, minimizing the wear on the belt conveyor that would occur if the extractor discharged directly onto it.

Scrubber, precipitator, and baghouse flyash

The flyash collected in the scrubber, precipitator, or baghouse hoppers can be handled by dry mechanical screw or chain-type conveyors. These conveyors op-

erate continuously to minimize hopper pluggage problems and they discharge onto a collecting conveyor, which is usually a dry chain type. Because the mechanical conveyors are dust-tight, but not designed to be gas-tight, separate sealing devices such as rotary seals or double flop valves are used. The collecting conveyor will collect the flyash discharged by all the conveyors under the rows of hoppers, and move it to a single collection point for ultimate disposal.

RDF firing

RDF technology was developed in North America as an alternative to the mass burning method. Initially, RDF was used as a supplementary fuel for large, usually coal-fired, utility boilers. For this application, the RDF is finely processed and sized to 1.5 in. (38.1 mm) maximum size. The resulting RDF is nearly all light plastics and paper.

For supplemental firing, B&W recommends a maximum RDF input of 20% on a heat input basis, and no RDF input until the boiler is operating above 50% load. In most cases the RDF is blown into the furnace at

the pulverized coal burner elevation through an RDF burner with a fuel distribution impeller. Most of the RDF burns in suspension in the high heat input zone of the pulverized coal fire while the heavier fuel fraction falls out in the lower furnace. A dump grate stoker located in the neck of the ash hopper allows more complete burnout of the heavier fuel particles before they are discharged into the ash system (Fig. 19). RDF has been successfully co-fired in B&W boilers at Lakeland, Florida; Ames, Iowa; and Madison, Wisconsin.

RDF has also been successfully co-fired in B&W Cyclone furnaces where the finely processed and sized RDF is injected into the Cyclone secondary air stream moving tangentially inside of the Cyclone barrel. (See Chapter 15.) This method of RDF combustion has been used in Baltimore, Maryland.

Dedicated RDF-fired boilers

From this supplemental fuel experience, RDF then became the main fuel for boilers specifically designed to generate full load steam flow when burning RDF (Fig. 20). In some cases where steam flow was required even when refuse was not available, the boiler was

Fig. 19 Typical B&W RB-type utility boiler firing RDF as a supplementary fuel.

Fig. 20 Typical RDF refuse-to-energy system.

designed so that it could also reach full load on wood, coal or natural gas. More commonly there would only be auxiliary gas or oil burners for startup and shutdown.

The first boilers in the world to fire RDF as a dedicated fuel were B&W units which began operation in 1972 in Hamilton, Ontario, Canada. The first of such boilers in the U.S. went into operation in 1979 in Akron, Ohio. The boiler design was highly influenced by the proven technology of wood-fired boilers with respect to their fuel feed system, stoker design, furnace sizing, and overfire air system. The transfer of this technology from wood firing to RDF firing was successful in many areas, but in other areas design adjustments were needed to accommodate the unique aspects of RDF.

The operating experience from the first generation designs at Hamilton, Akron and other plants led to second generation designs with improved RDF processing systems, fuel feed systems and boiler design. Specific improvements included the first fuel feeder designed specifically for RDF and the use of alloy weld overlay in the lower furnace for corrosion protection.

The third generation of facilities is essentially today's state-of-the-art design. (See Fig. 21.) This boiler design has an enhanced overfire air system to significantly improve combustion efficiency. These third generation designs also incorporate dramatically improved fuel processing systems.

RDF processing

The first generation RDF processing systems were referred to as crunch and burn systems. The incom-

Fig. 21 Third generation RDF unit and fuel feeding system.

ing refuse first went to a hammer mill type shredder that produced an RDF with 6 by 6 in. (152 by 152 mm) top size. Ferrous metal was removed by magnetic separators. There was no other material separation and many undesirable components entered the boiler such as shredded particles of glass that became embedded in wood and paper resulting in a very abrasive fuel entering the boiler in suspension. Following the practice of wood-fired boilers, the RDF was generally stored in a hopper or bin. RDF, however, is much more compactible than wood and in nearly every case, significant problems were encountered getting the RDF out of the storage bins.

Second generation RDF processing systems recognized and corrected some of the problems. The shredder for final fuel sizing was moved to the back of the processing system and a rough sizing shredder was used as the first piece of equipment in the system. This reduced, but did not eliminate, the problem of abrasive particles embedding in the fuel. Size separation equipment was introduced, generally removing the small size fraction which is less than 1.5 in. (38.1 mm) composed mostly of broken glass, ceramics and dirt, which was sent to landfill. RDF was stored on the floor rather than in bins or hoppers and was moved by front-end loaders to conveyor belts. This greatly improved the reliability of fuel flow to the boiler.

In third generation RDF processing systems (Fig. 22) the first piece of equipment became a flail mill or similar equipment whose main function was to break open the garbage bags. The refuse is still size-separated using a trommel disk screen with the minus 1.5 in. (38.1 mm) size destined for landfill. Generally, a device such as an air density separator is added to collect the light fraction (paper, plastics, etc.) from this stream to achieve maximum heat recovery. Where it is economically attractive, separation of aluminum and other non-ferrous metals is added to the plus 1.5 in. (38.1 mm.) minus 6 in. (152 mm) stream.

RDF yield

RDF yield is defined as the percentage of RDF produced from a given quantity of MSW. For instance, a 70% yield means that 70 t (63 t_m) of RDF are produced for every 100 t (90 t_m) of incoming MSW. The ash content of RDF is directly related to the yield of the processing system. In a processing system with a lower yield, the portion of the MSW that is rejected is gen-

Fig. 22 Third generation RDF processing system.

erally high in ash and inerts content and, therefore, the resulting RDF is low in ash content. When an RDF processing system is designed to obtain a higher yield, more of the ash is carried over into the RDF fuel fraction and the ash content is increased.

The RDF heating value is inversely related to the yield; the lower the yield, the higher the heating value. A sophisticated RDF processing system will have multiple stages of material separation that remove a very large percentage of the metals, inert material, and high moisture organic material. Since a relatively large portion of the incoming MSW is removed by this processing system, the RDF yield is significantly lower than the yield produced by a less sophisticated crunch and burn system. The resultant RDF, however, will have a high heating value corresponding to its low percentage of non-combustible material (ash) and high-moisture organic material.

A typical MSW might have a composition comparable to the reference waste shown in Table 4. The majority of the waste is combustible materials, which have ash contents ranging from approximately 4% for wood to 12% for glossy magazine paper. The glass frac-

tion, yard waste and mixed combustibles may also contain varying quantities of sand, grit and dirt. The predicted composition of the RDF will vary depending on the type of processing system and the resulting yield. Table 5 shows how the ash content in the fuel and the heating value of the fuel will vary as the RDF yield varies with different processing systems. Two cases are considered, one which assumes no front end recycling (curbside recycling or separate recycling facility), and a second case which assumes that such a system is in place in the community.

RDF quality

RDF used to supplement pulverized coal in utility boilers should be very low in ash; contain the least possible amount of ferrous metal, aluminum, and other nonferrous metal; and be small enough in particle size to be fed pneumatically to the boiler. The processing system for such a fuel would generally be a very low yield system, between 40 and 60%.

RDF for dedicated traveling grate stoker boilers should be low in ash; as free as possible of ferrous metal, aluminum and other nonferrous metals; and have a particle size distribution that is considerably larger than the particle size of RDF for use in Cyclone or pulverized coal boilers. The processing system for such a fuel will have a higher yield, around 70 to 85%.

RDF produced in a crunch and burn system, in which solid waste is shredded and only the ferrous metal removed, has a yield of about 93%; an inherently high ash content; and contains 100% of the aluminum, other non-ferrous metals, glass, stones and ceramics in the original MSW. The large quantities of aluminum, glass, and other inerts that remain in the RDF will result in higher wear on the stoker and lower furnace. The economic advantage of installing a less sophisticated crunch and burn processing system is generally offset by the need to provide a more conservatively designed stoker and furnace as well as a larger ash handling system.

RDF processing systems

An optimum RDF processing system for a dedicated boiler application achieves the highest yield with the

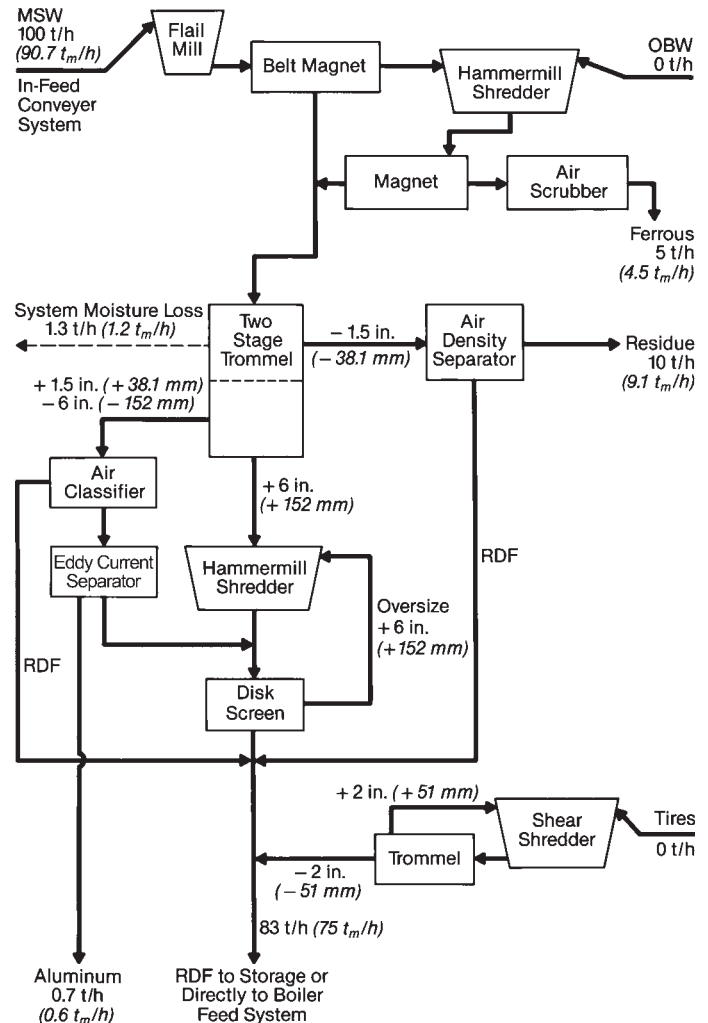

Fig. 23 Components of a complete RDF processing system.

highest heat recovery, while removing ferrous, aluminum and other non-ferrous materials, and glass. Such a system (Fig. 23) includes the following:

In-feed conveyors From the tipping floor, the solid waste is fed by front-end loaders or excavators to steel pan apron conveyors which feed the flail mill in-feed conveyors.

Initial size reduction The flail mill tears open the plastic garbage bags, coarsely shreds the refuse, and also breaks glass bottles to a size of approximately 1.5 in. (38.1 mm) or less.

Ferrous metal recovery Ferrous metal is extracted from the coarsely shredded MSW in each line by a single-stage overhead magnet. Recovered ferrous metal is moved to a ferrous air classifier where tramp materials such as paper, plastics or textiles are removed, thereby providing a clean ferrous product. A ferrous recovery of 90% is possible.

Size classification and final size reduction After ferrous removal, shredded waste is fed into a rotating trommel screen, a size separating device about 10 ft (3.0 m) in diameter by 60 ft (18.3 m) long. The trommel performs the following functions:

1. removes glass, sand, grit and nonferrous metal less than 1.5 in. (38.1 mm) in size, and

Table 5

RDF Yield Versus Ash Content and Fuel Heating Value

Mode	RDF Yield %	Ash	Btu/lb	(kJ/kg)
Without front-end recycling:				
Mass burn	100%	23.64	4814	(11,197)
Crunch and burn	93%	19.87	5146	(11,970)
RDF	83	11.72	5641	(13,121)
	to 70%	to 8.87	to 5834	(13,570)
With front-end recycling:				
Mass burn	100%	19.58	5513	(12,823)
Crunch and burn	93%	17.16	5898	(13,714)
RDF	85	9.91	6328	(14,719)
	to 71%	to 6.59	to 6491	(15,098)

2. removes the minus 6 in. (152 mm), plus 1.5 in. (38.1 mm) fraction and contains the bulk of the aluminum cans.

The trommel oversize material, plus 6 in. (152 mm), is then shredded in a horizontal secondary shredder. Because the secondary shredder is a major consumer of energy and has high hammer maintenance costs, the RDF process is specifically designed to reduce the secondary shredder's load by shredding only those combustibles too large for the boiler. Particle size is primarily controlled by the design of the secondary shredder grate openings. Additional particle size control may be achieved by adding a disc screen downstream of the secondary shredder to recycle any oversized material back to the secondary shredder.

Separation of glass, stones, grit and dirt Trommel undersize material, minus 1.5 in. (38.1 mm), passes over an air density separator (ADS) designed to remove dense particles from less dense materials through vibration and air sweeping. This device can efficiently remove glass, stones, grit and dirt, as well as nonferrous metals. The light fraction, which can range from approximately 50 to 90% of the ADS feed, consists essentially of combustibles with high fuel value which are recovered and blended into the main fuel stream.

Aluminum can recovery To optimize aluminum can recovery, an air classifier is provided for the plus 1.5 in. (38.1 mm), minus 6 in. (152 mm) undersize fraction. The air classifier removes the light organic portion of the stream, allowing aluminum cans to be more visible for hand pickers. The air classifier heavy fraction drops onto a conveyor moving at approximately 2.5 ft/s (0.76 m/s) with numerous hand-picking stations on either side of the belt. Cans go into hoppers and, by conveyor, to a can flattener. A pneumatic conveyor then transfers the flattened cans into a trailer. An eddy current separator, for the removal of aluminum cans, can replace hand picking if the expected amount of cans is high enough to justify the additional capital cost. Aluminum recovery of 60% is possible with hand picking, while up to 90% recovery is possible with the eddy current separator.

Oversized bulky waste (OBW) The OBW shredder is generally a horizontal hammer mill used to shred ferrous metal recovered by the RDF processing lines and pre-separated oversized material which includes white goods such as refrigerators, washing machines, furniture and tree limbs. The ferrous metal is magnetically recovered and given a final cleaning by an air scrubber to remove tramp materials. The nonferrous material is integrated into the RDF stream.

Tire shredding line If there is a sufficient supply of tires, a separate tire shredding line can be included. A shear shredder, used specifically for shredding tires, can shred 500 passenger car tires per hour. The shredder includes a rotary screen classifier (trommel) for returning shredded tire chips above 2 in. (51 mm) back to the shredder. A tire chip 2 by 2 in. (51 by 51 mm) or less is the final product which is then blended in with the RDF stream.

RDF storage building RDF from each processing line is conveyed to an RDF storage building. From there,

it is either fed directly to the boiler or fed directly to a shuttle conveyor and storage pile. When RDF feed is direct to the boiler, excess RDF from the boiler feed system is returned to the RDF storage building. RDF not being fed directly to the boiler is retrieved from the storage pile by a front-end loader and loaded onto inclined conveyors which transport the RDF to the boiler feed system.

Fuel feed system: metering feeders

A successful RDF metering feeder must meet the following design criteria:

1. controlled fuel metering to meet heat input demand,
2. homogenization of material to produce even density,
3. adequate access to deal with oversized material,
4. maintainability, in place, and
5. fire detection and suppression devices.

A reliable RDF metering feeder (see Fig. 21) is a key feature of the second generation RDF boiler design. One feeder is used for each air-swept fuel distributor spout. Each feeder has an upper feed bin which is kept full at all times by an over-running conveyor to ensure a continuous fuel supply. The fuel in this hopper is transferred to a lower hopper by a hydraulic ram. The ram feed from the upper hopper is controlled by level control switches in the lower hopper. The RDF is fluffed into a uniform density by a variable speed inclined pan conveyor which sets up a churning motion in the lower hopper. The pan conveyor delivers a constant volume of RDF per flight which is carried up the pan conveyor and deposited into the air-swept spout. The rate at which the fuel is deposited into the spout is based on fuel demand.

Air-swept distributor spouts

Air-swept fuel spouts, used extensively in the pulp and paper industry, proved to be equally effective for RDF firing. (See Chapter 28.) Lateral fuel distribution on the grate is achieved by locating multiple spouts across the width of the furnace. Longitudinal distribution is achieved by continuously varying the pressure of the air sweeping the spout floor. A major feature of this design is its simplicity.

Traveling grate stoker

To date, only traveling grates have been used for spreader-stoker firing of RDF. These grates move from the rear of the furnace to the front, into the direction of fuel distribution. A single undergrate air plenum is used. There is a wealth of experience worldwide with traveling grate stokers burning a myriad of waste and hard to burn fuels. The parameters for unit design shown in Table 6 were developed from this experience and the uniqueness of the RDF. (See also Chapter 16.)

On mass-fired stokers, a large volume of fuel at the front slowly burns down to a small volume of ash at the back. For an RDF stoker the key is to maintain an even 8 to 10 in. (203 to 254 mm) bed of fuel and ash over the entire stoker area. Grate problems are usually due to a shallow ash bed or localized piling of fuel. Operator tendency, when confronted with poor metering and/or fuel distribution, is to run the grates

Table 6
Stoker Design Criteria (English units)

Parameters	RDF	Wood
Grate heat release, 10^6 Btu/h ft ²	0.750	1.100
Input per ft of grate width, 10^6 Btu/h	15.5	29
Fuel per in. of distributor width, lb/h	450	1000
Feeding width as % of grate width	45 to 50	45 to 50
Grate speed, ft/h	25	N/A

faster. While this technique can minimize bed upset, it will shorten grate life due to higher wear rates and the overheating of the grate bars. With the recommended ash bed thickness, tramp material is minimized, grate temperatures are lowered, wear is reduced, and grate life is increased. To achieve this optimum ash bed requires controlled metering of the RDF and proper distribution of the fuel to the grates, as previously described.

A second problem is the accumulation of melted aluminum and lead on the grate. The best solution is total removal of these metals from the fuel stream. If this is not practical, experience has shown that maintaining proper ash bed thickness will cause the aluminum and lead to solidify in the ash bed rather than on the grate.

Fluidized-bed combustion

Beginning in the 1980s, fluidized-bed combustion technologies, both bubbling bed and circulating bed, had proven themselves to be efficient and cost-effective technologies for the combustion of waste fuels such as biomass, sludge, and waste coals. (See Chapters 17 and 30.) In the mid-1990s, there was growing interest in applying these fluidized-bed technologies to the combustion of RDF based upon higher efficiency, reduced emissions, and lower capital costs. While a number of waste-to-energy facilities were installed that utilized fluidized-bed technology, few of these facilities were able to achieve these high expectations due to several unique characteristics of RDF:

1. The quality and particle size of RDF is more critical for fluidized-bed combustion than for stoker firing to ensure fluidization of the fuel within the bed and to avoid plugging of the bed drain system. The fuel processing system needed to produce RDF suitable for fluidized bed combustion has a higher capital cost plus higher operating and maintenance costs.
2. A coal-fired fluidized-bed power generation facility can have a lower capital cost than a pulverized coal facility due to the in-bed capture of sulfur dioxide. This eliminates the need for a separate flue gas scrubbing system. The combustion of RDF, however, produces HCl as well as sulfur dioxide (SO₂) and a fluidized-bed boiler can not capture a sufficient amount of the HCl to meet current emissions limits. Therefore, a separate flue gas scrubbing system is required with significant capital and operation/maintenance costs.
3. Furnace and superheater tube corrosion is a major concern for any refuse-fired boiler; erosion is a

major concern for a fluidized-bed boiler. One form of protection against corrosion in a refuse-fired boiler is the formation of an oxide layer on the surface of the tubes. This oxide layer acts as a barrier against continual contact between the corrosive flue gas and the tube material. The erosive action of the bed material in a fluidized-bed boiler will continuously remove this protective oxide layer as it is being formed, thereby accelerating the corrosion rate.

Fluidized-bed combustion technology is capable of firing RDF. However, the advantages of the technology must be carefully weighed against its disadvantages.

Lower furnace design configuration

The lower furnace designs of early RDF boilers were largely based upon technology used for wood-fired boilers. This included modest overfire air (OFA) systems with multiple small diameter nozzles designed for 25 to 30% of the total air supply, straight wall furnaces, and carbon reinjection systems. The result was less than desired combustion performance due to inadequate turbulent mixing in the furnace. Today's RDF units are designed with fewer large diameter OFA nozzles designed for 50% of the total air supply with nominal operation at 40%. This design has proven itself capable of injecting OFA deep into the combustion chamber for improved turbulent mixing of air with combustibles released from the grate. The Controlled Combustion Zone (CCZ) lower furnace design with twin arches for wood and biomass firing (see Chapters 16 and 30) has also been applied to some limited RDF applications.

Furnace exit gas temperature

Gas temperatures leaving the furnaces of first and second generation designs were higher than anticipated. There were not enough data on RDF firing to accurately predict the relationship between furnace surface area and furnace exit gas temperature. Compounding this problem was a continual increase in the heating value of the RDF due to changes in the composition of the raw refuse and the development of more efficient processing equipment. To achieve the desired furnace exit gas temperatures, the size of the third generation furnace has increased significantly. The furnace width and depth are set by the size of the stoker, therefore the furnace height has increased to achieve the required furnace exit gas temperatures.

Ash handling systems

Much of the non-combustible material in the RDF system is removed before it is fed to the boiler. Although systems vary, there is generally some effort made to remove ferrous metals and aluminum, both of which can be troublesome once they reach the stoker grates. Non-combustibles and most of the ash from combustion collect on the traveling grate stoker and discharge off the front into a submerged chain conveyor system.

The submerged chain conveyor (Fig. 24) is a mechanical conveyor that consists of a water-filled trough and a dry return trough, with two endless chain

Fig. 24 Submerged chain conveyor for RDF stoker ash.

strands with flights connected between the strands. The return trough can be either above or below the water-filled trough. Ash from the stoker discharge chute drops into the water-filled trough. The water absorbs the impact of any larger ash pieces, quenches the ash, and provides a gas-tight seal with the stoker discharge chute.

The chains are usually driven by a variable speed drive to handle varying ash rates. The ash residue is conveyed from the bottom of a water-filled trough up an incline section where the ash dewateres and discharges directly into a truck, a storage bin, or onto another type of conveyor for final transport and disposal. Because this conveyor uses a dragging action to convey the ash, it is not used on mass-fired units where it can have problems in dragging the large non-combustible items up the incline section.

Fine ash from the boiler siftings hopper, flyash from the boiler, economizer and air heater hoppers, and

flyash from the scrubber, baghouse or precipitator hoppers are all handled the same way as previously discussed for mass-fired boilers.

Retrofits to RDF

Most dedicated RDF boilers are new installations. However, it is possible to retrofit existing boilers to become dedicated RDF boilers. To be candidates, the existing boilers must be conservative designs for solid fuels, such as wood or coal. Typically, these are older units which are underutilized or used as standby units. These plants are often located near large metropolitan areas, sources of large quantities of refuse. The conversion of such an older power plant could represent a cost-effective solution to a community's refuse disposal problems.

B&W has converted several such boilers from coal-fired to dedicated RDF. Each retrofit is unique in that each of the coal-fired boilers was of different design and originally supplied by different manufacturers. Each retrofit was also the same in that all were designed to the same standards as new RDF units.

The principal modification involves enlarging the furnace to obtain the proper furnace volume for combustion. Although coal-fired boilers have conservatively sized furnaces, refuse firing requires even larger volumes. This is achieved by removing the existing stoker and lower furnace and installing new membrane furnace wall panel extensions (Fig. 25). The new lower furnace is protected from corrosion using either Inconel weld overlay or Inconel bimetallic tubes.

Fig. 25 Coal-fired unit converted to RDF.

Other pressure part modifications could include:

1. converting the superheater to a parallel flow design while adding the proper metals for corrosion protection,
2. modifying the boiler, economizer and air heater surface for the proper heating surface distribution and to meet refuse standards for velocities, tube spacing, etc., and
3. possibly adding screen surface to lower the flue gas temperature entering the superheater.

In some cases, the coal stoker can be reused for RDF firing; in other cases it must be replaced. In either case the grate release rate, and other design criteria, must be set to the same design standards as new refuse boilers. Properly executed, the retrofit of an existing boiler to RDF firing will result in an RDF boiler as conservative as a new RDF boiler and capable of operating equally well.

Boiler components

Superheater

Superheater design is critical in both mass burn and RDF-fired refuse boilers because of the highly corrosive nature of the products of combustion. This is compounded in the U.S. by the desire for the highest possible steam temperature and pressure to maximize income from power production sales while still disposing of refuse in an environmentally safe manner. B&W has pioneered both the 900 psig (6.2 MPa) 830F (443C) and 1300 psig (8.96 MPa) 930F (499C) high pressure, high temperature steam cycles for refuse boiler application. This noteworthy increase in pressure and temperature over the more conventional refuse boiler steam conditions of 600 psig (4.14 MPa) and 700F (371C) has resulted in a significant improvement in cycle efficiency.

To accomplish this improvement, the superheater must be specifically designed for corrosion protection. Superheater corrosion is a function of many variables including flue gas temperature, flue gas velocity, tube spacing, tube metal temperature, tube metallurgy, and ash cleaning equipment. Each of these variables must be taken into consideration to avoid rapid superheater corrosion, even if the superheater steam outlet temperature is relatively low. For example, specifying only a low furnace exit gas temperature will not assure long superheater life.

Of these criteria, tube metal temperature and tube material are most critical. To obtain satisfactory refuse boiler superheater performance, two key design features are needed:

1. a parallel flow superheater design as shown in Fig. 26 where the coolest steam conditions are exposed to the hottest gas temperatures and the hottest steam temperatures are matched with the coolest gas temperatures. The result is a design with the lowest maximum superheater metal temperatures.
2. use of Incoloy tube material in the highest tube metal temperature sections of the superheater. Carbon steel is still used in the superheater sections with lower superheater metal temperatures.

Fig. 26 Parallel flow superheater (SH).

B&W refuse boilers were the first to demonstrate successful commercial operation at the 900 psig (6.2 MPa), 830F (443C) steam cycle with the first three units going into operation at the Westchester County, New York refuse-to-energy facility in 1984. As of 2004, there were 21 B&W refuse boilers in operation at these steam conditions with more than 320 cumulative years of operating experience.

B&W extended this leadership position in superheater design in 1992 with the development of the first refuse boiler design to use the 1300 psig (8.96 MPa) and 930F (499C) steam cycle. This design was based on laboratory corrosion research and full scale superheater test sections installed in operating refuse boilers. In one test, two full scale superheater sections, composed of a variety of tube metallurgies, were installed in an operating 900 psig (6.2 MPa), 830F (443C) design refuse boiler with steam flow through the sections controlled to simulate 1000F (538C) operation. One section was removed after one year of operation and the second after 26 months. This test provided the basis for tube metallurgy selection for the 1300 psig (8.96 MPa), 930F (499C) design. In 1994, two mass-fired refuse boilers located in Falls Township, Pennsylvania, were placed into operation generating superheated steam at 1300 psig (8.96 MPa) 930F (499C). These boilers continue to operate successfully.

In addition to corrosion concerns, the superheater must be designed to minimize fouling and the potential for erosion due to excessively high flue gas velocities. Maximum design velocity is 30 ft/s (9.1 m/s), but in practice it is usually in the 10 to 15 ft/s (3 to 4.6 m/s) range. Minimum superheater side spacing is 6 in. (152 mm).

Boiler design

The lower furnace design, refuse stokers and refuse feed systems are markedly different for mass-fired and RDF boilers. However, the design requirements for the upper furnace, generating surface and economizer are the same. This is also true for auxiliary equipment such as burners and ash cleaning equipment.

Upper furnace design The upper furnace must be sized to provide adequate heat transfer surface to reduce the flue gas temperature entering the superheater to an acceptable level. This helps minimize fouling in the superheater and maintain low superheater tube metal temperatures to minimize corrosion. A certain amount of furnace volume is required for complete burnout of the fuel in the furnace and minimum CO emissions. The required volume should be measured from the point where all the combustion air has entered the furnace (the highest level of overfire air ports) to the point where the flue gas enters the first convective heating surface (at the tip of the furnace arch at the bottom of the superheater). Measured in this manner, the required furnace volume per unit of heat input is the same for both mass-fired and RDF boilers.

The furnace must also contain sufficient heating surface to lower the flue gas temperature to help reduce fouling and corrosion in the superheater and boiler bank. The gas temperature should be limited to 1600F (871C) entering the superheater and 1400F (760C) entering the boiler bank. Lower temperature values may be appropriate in certain geographic areas where the refuse composition is known to be highly corrosive. As a general rule, the furnace size is set by volumetric requirements in smaller capacity boilers and by maximum gas temperature limits in larger capacity boilers.

Boiler generating bank Refuse boilers in operation use both the one-drum and two-drum design. In the two-drum design there is both a steam drum (upper drum) and a lower drum, interconnected by the boiler generating bank tubes.

In the one-drum design the steam drum is located outside of the flue gas stream; there is no lower drum. The steam generating bank tubes are shop-assembled modules. These modules may be of either the vertical longflow (see Fig. 12) or a vertical crossflow design. Minimum side spacing in the two-drum design and for the generating bank modules used with the one-drum design is 5 in. (127 mm). Maximum design flue gas velocity is set at 30 ft/s (9.1 m/s).

Economizer The economizers can be either vertical longflow or horizontal crossflow. Economizer side spacing should be no less than 4 in. (102 mm) with a maximum flue gas velocity of 45 ft/s (13.7 m/s).

Air heater

Air heaters may be used for two reasons: 1) to supply preheated air to help dry and ignite the refuse on the stoker, and/or 2) to increase thermal efficiency where high feedwater temperatures preclude designing to lower exit gas temperatures with economizers. RDF-fired units have typically used air heaters to preheat the combustion air to the 300 to 350F (149 to 177C) range. Both tubular and regenerative air heaters have been used successfully. Due to air leakage into the air heater and the potential for fouling, regenerative types have been limited to the outlet side of hot electrostatic precipitators where the flue gases are relatively clean.

When either tubular or regenerative air heaters are used, the design and arrangement should minimize

the potential for low-end temperature corrosion. To some extent, the surface arrangement in a tubular air heater will maintain adequate protection. Steam coil air heaters are required at the air inlet, on either type, to preheat the incoming ambient air and maintain the average metal temperature above acid dew points. (See also Chapter 20.)

Ash cleaning equipment

To maintain the effectiveness of all convective heating surfaces and to prevent pluggage of gas passages, it is necessary to remove ash and slag deposits from external tube surfaces. Steam or air sootblowers are most commonly used. Saturated steam is preferred for its higher density and better cleaning ability. One disadvantage of sootblowing is that localized erosion and corrosion can occur in areas swept too clean by the blowing medium. This problem can be addressed by installing tube shields on all tubes adjacent to each sootblower for localized protection.

A mechanical rapping system (Fig. 27) can be used to complement the sootblowers. In this system, a number of anvils strike designated pins to impart an acceleration through the superheater tube assembly. The purpose is to remove the bulk of the ash while leaving a light layer of ash on the tubes for corrosion protection. Mechanical rapping systems will not eliminate the need for sootblowers, but will reduce the number of sootblower cleaning cycles required.

Auxiliary input burners

Auxiliary fuel burners are used to maintain furnace temperature during startup, shutdown, and upset conditions to minimize the release of unburned hydrocarbons. In most cases, the auxiliary fuel (oil or gas) burners are designed for only 25 to 30% of the boiler's maximum heat input.

When not in service, the typical gas- or oil-fired burner requires some amount of air flow through the idle burner for protection against overheating. Because this air leakage represents an efficiency loss,

Fig. 27 B&W mechanical rapping system for cleaning superheaters.

and because these burners are used infrequently, a special design auxiliary input burner (AIB) is used for refuse boilers. The AIB is designed with a retractable burner element which is inserted toward the furnace when in use, and retracted when out of service. There is also a movable ceramic shutoff damper which provides protection against furnace radiation and debris when the burner is out of service. When the burner is put into service, this ceramic damper is retracted to one side and the burner element is inserted through an opening in the damper (Fig. 28).

Upper furnace maintenance platforms

Because refuse is a high fouling fuel, it is necessary to have good access to the convection sections. Maintenance platforms (Fig. 29) are often used to allow access to the superheater area for inspection and

maintenance. Either retractable or light weight aluminum support beams are inserted into the furnace from access doors in the front wall to the superheater arch, where the beams are locked in place. Corrugated decking material is then inserted into the furnace through special side wall access doors, and arranged on top of the support beams. This system provides both a platform for working in the superheater and upper furnace and some overhead protection to those working in the lower furnace.

Air pollution control equipment

Various boiler fuels have specific components unique to that fuel. Some of these components, such as sulfur, create specific air pollution emissions that require unique boiler designs or specific air pollution control equipment. These fuels, such as high sulfur coal, are homogenous. This means the fuel will be the same in the future as it is today, and will be the same from one day to the next.

Refuse is a nonhomogenous fuel. It not only changes over the long term, but can change from day to day. Nearly every component of a fuel that can result in an unwanted air pollutant is present in refuse. However, in the early 1980s when the number of refuse-fired boilers began to rapidly grow in the U.S., the only emissions requirements were on particulates, NO_x and SO_x . Refuse boilers, due to their relatively cool burning systems and the generally low level of fuel bound nitrogen, are low NO_x generators. There are also very low levels of sulfur in refuse. Therefore, early boilers were generally equipped only with an electrostatic precipitator (ESP) for particulate control. As more boilers went into operation and further air emissions data were obtained, additional emissions requirements were applied. Initially, hydrochlorides were targeted for control. Soon the various state air pollution agencies set regulations for the control of dioxins and furans as well as a long list of heavy metals.

Dry systems

Dry scrubbers, used for years to control SO_2 emissions from coal-fired units, were found to be equally effective in controlling HCl emissions from refuse units.

With the initial use of dry scrubbers, there was a split in the preferred particulate collection system between the ESP and baghouse. ESPs were used in earlier applications due to their more extensive history of proven performance. However, it has been fairly well documented that the layer of ash and lime that collects on the bags themselves improves sorbent utilization and increases the removal of SO_2 and HCl in a baghouse. This allows better capture of pollutants for the same lime slurry rates, or the same level of pollutant capture at slightly reduced lime slurry rates. Dry scrubbers and baghouses were also found to be very effective in controlling dioxin, furan and heavy metal emissions. Today, the preferred system for nearly all refuse boilers in North America is the dry scrubber/baghouse combination. (See Chapters 33 and 35.)

To enhance the capture of mercury contained in the flue gas, refuse-fired boilers are typically equipped

Fig. 28 Auxiliary input burner (out-of-service and in-service positions).

Fig. 29 Upper furnace maintenance platform.

with an activated carbon injection system that works in conjunction with a dry scrubber and baghouse. The process involves the injection of powdered activated carbon into the flue gas upstream of the dry scrubber. As the activated carbon mixes with the flue gas, it captures the mercury through adsorption. The activated carbon is then collected in the baghouse and removed along with the flyash.

NO_x and CO control

The permissible level of NO_x emissions has also been significantly reduced since the late 1980s. The lower NO_x limits can generally be achieved by installing an in-furnace ammonia or urea injection system. The ammonia injected into the furnace reacts with the NO_x contained in the flue gas to produce nitrogen and water. This form of NO_x control technology is known as selective non-catalytic reduction (SNCR) and can reduce the flue gas NO_x concentration by as much as 60%. In certain geographical nonattainment areas for NO_x emissions, selective catalytic reduction (SCR) systems may be required for even greater NO_x control.

The SCR systems have been demonstrated to achieve up to 90% NO_x reduction on fossil fuel boilers. However, the catalyst itself is fairly easily poisoned, and therefore rendered less effective, by a multitude of substances, all of which are found in refuse to various degrees. At this time it is not clear what the long-term life of the SCR catalyst would be on a refuse-fired boiler. (See Chapters 33 through 35.)

During this same time period, the emission requirements for CO have also been driven to lower levels. These requirements have been met by a combination of:

1. better overfire air system,
2. more control of undergrate air (more compartments with individual air control),
3. better combustion control systems,
4. larger furnace volumes, and
5. operator training.

Wet systems

Wet emissions control systems are also used. A typical wet gas cleaning system is designed for the removal of HCl, SO₂, hydrogen fluoride, mercury, dioxins and solid particle pollutants from MSW-fired systems. A sample process used in Europe includes six major steps:

1. an ESP collecting most of the particles,
2. a heat exchanger that cools the gas to recover energy before the first scrubber,
3. a first spray scrubber to quench the gas further to saturated conditions and remove HCl and mercury,
4. a second spray scrubber to remove SO₂,
5. a third spray scrubber to allow removal of the dioxins, and
6. final filtering modules to remove excess dust particles coming from the ESP and other scrubbers.

An optional condensing heat exchanger can be used for additional heat removal if a hot water heating system is associated with the plant. Water treatment units process the liquid bleeds and overflows to yield a cake containing the solids for disposal.

Inconel is a trademark of the Special Metals Corporation group of companies.

This facility features three 750 ton per day mass-fired units by B&W.

Chapter 30

Wood and Biomass Installations

The category of wood and biomass covers a wide range of material that can be used as a source of chemical energy. Wood encompasses a number of sources such as bark, wood sticks, sawdust, sander dust, over- and under-sized wood chips rejected from the pulping process, whole tree chips, and scrap shipping pallets. Biomass is anything that is or recently was alive such as straw, vine clippings, leaves, grasses, bamboo, sugar cane (called bagasse after the sugar has been extracted), palm oil, coffee grounds, and rice hulls from the food processing industry. All of these materials can be used as a fuel source to generate steam.

While wood and other biomass fuels were some of the first materials used as energy sources, their use declined around the early 1900s, when more consistent and easily transportable fossil fuels such as coal, oil and natural gas became more available. Nevertheless, there have always been applications where wood and biomass have been the preferred fuels. There has therefore been slow but steady progress in the development of equipment for firing these fuels.

Many factors have led to a recent, rapid development in this area. Some of these factors include the rising cost of certain fossil fuels, renewable energy options, development of new technology that allows better use of industrial byproducts, and the trend toward cogeneration in many industries. This includes industries that produce both electric power and process steam. Wood and biomass are used in many municipal combined heat and power (CHP) installations, particularly in Europe.

Biomass gasification is a relatively new technology being explored to supply fuel gas for power production by gas engines or gas turbines.

Equipment for chemical and heat recovery in the paper industry is discussed in Chapter 28. Equipment for using municipal solid waste as a fuel is discussed in Chapter 29. Stoker-related information is discussed in Chapter 16.

Steam supply for power production

Cogeneration in industry

Most heating requirements can be met with saturated steam at 150 psig (1.03 MPa) or less. Cogeneration, or the simultaneous production of electrical or

mechanical energy and heat energy to a process, has very high thermal efficiency. Thus, waste heat from electricity production becomes part of a usable process rather than being rejected into the atmosphere.

In a cogeneration facility, relatively high pressure superheated steam passes through a steam turbine or steam engine where energy is extracted. The exhaust steam is then used as a heat source in a process. The conversion efficiency, or the amount of heat absorbed in the steam turbine plus the heat absorbed in the process, versus the amount contained in the steam, approaches 100%. The overall thermal efficiency of a cogeneration process is closely approximated by the thermal efficiency of the boiler alone.

As well as providing high energy efficiency, there is a second and often more compelling reason for industries, especially the pulp and paper industry, to practice cogeneration. These industrial plants are often located far from economical and reliable sources of electricity and conventional fossil fuels in order to be close to their source of fiber, the forests. Cogeneration facilities equipped with wood-fired power boilers, for example, are therefore often justified.

Biomass-fired utilities

Changing economic conditions and environmental regulations have made utility plants fired by biomass fuels a practical source of electrical energy, in spite of their relatively high capital costs. Sometimes the plant is built with a condensing turbine and other times it is built beside or within a plant that can use exhaust steam. Economic conditions favoring such facilities include the unpredictable and sometimes high cost of conventional fossil fuels, the relatively low cost of wood waste and other biomass fuels, and the high cost to transport and dispose of biomass in a landfill.

Occasionally an installation is justified with regard to the high cost of emissions control equipment. Most wood and biomass fuels generate lower nitrogen oxides (NO_x) and sulfur dioxide (SO_2) emissions than conventional fossil fuels. In one installation in California, for example, it was found that the amount of NO_x produced by incinerating grapevine clippings and other biomass could be substantially reduced by burning the material in a wood-fired utility installation in a controlled manner. This produced environmental benefits

while generating electricity that would otherwise be produced by burning traditional fossil fuels.

The Babcock & Wilcox Company (B&W) operation in Europe completed a significant biomass-fired installation that burns straw in an ultra-supercritical power plant application. (See Fig. 1.) This straw-fired boiler consumes 105 MW_t of fuel producing 35 MW of electricity and 50 MW_t of heat. In this advanced design, carded (loosened by mechanical raking) straw is fed by screw feeders onto a water-cooled gasification grate where a high percentage of the energy content is released by pyrolysis and gasification. The remaining straw/carbon burns on a water-cooled vibrating grate. A bag filter removes more than 99% of particulates from the flue gas, and the plant operates within strict European emissions regulations.

Steam supply to process

Pulp and paper

The pulp and paper industry is the major consumer of biomass fuels because wastes such as bark, sawdust, shavings, lumber rejects and clarifier sludge are by-products of the pulping, paper-making and lumber manufacturing processes. There is a great amount of heat energy available in these products, making them useful energy sources. (See Figs. 2 and 3.)

The production of pulp and paper requires large quantities of mechanical energy for grinding, chipping, cooking and refining. To produce a marketable product, the pulp must be dried using steam or heated surfaces such as paper machine dryer rolls. These energy needs are met by using steam in a variety of equipment (steam engines or turbines, steam coil air heaters, dryer rolls, and/or indirect heaters) and by direct steam injection.

Fig. 1 Straw-fired ultra-supercritical boiler (courtesy Energi E2 A/S).

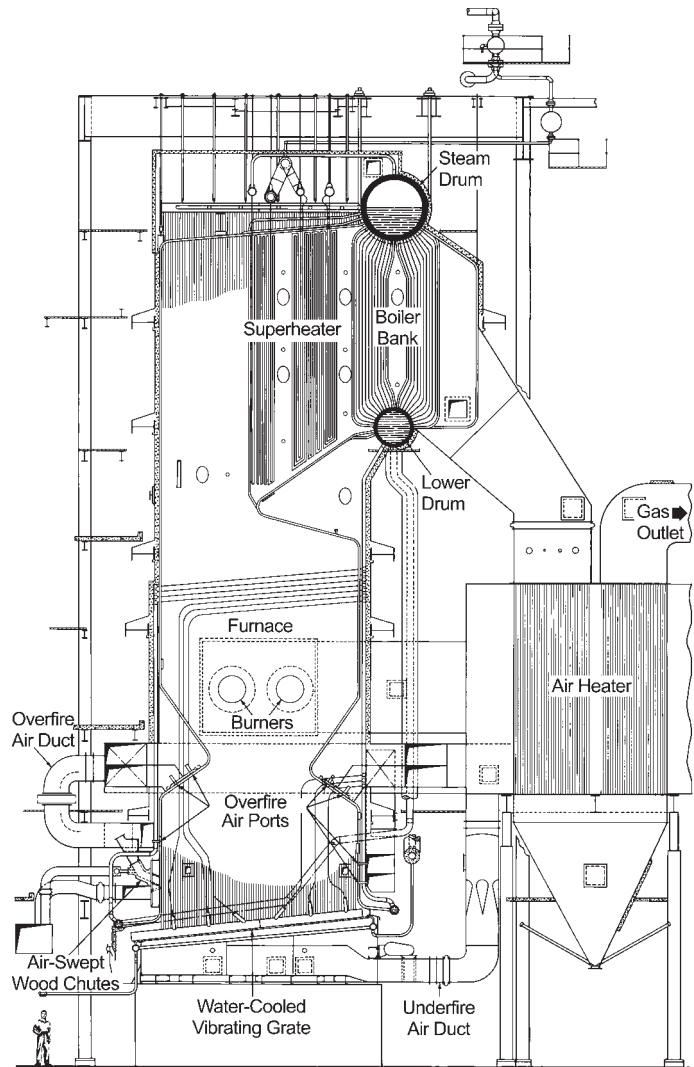

Fig. 2 Wood-fired two-drum Stirling® power boiler.

These requirements, coupled with the availability of the waste products, make boilers fired by wood and wood waste a logical choice for the pulp and paper industry. Most of the developments and improvements in equipment for these boilers have been driven by this industry's needs.

Food processing

The food processing industry also has energy needs that are provided by steam. Mechanical preparation, cooking, drying and canning all require a source of energy. Many foods leave behind waste byproducts rich in cellulose or other organic (hydrocarbon) material. Instant coffee production generates coffee grounds, sugar-making leaves bagasse from sugar cane, coconut preparation discards husks, rice has its hulls removed before packaging, and many types of nuts are sold roasted with their shells removed.

Many producers have installed boilers that burn such biomass materials, usually based very closely on equipment originally designed for the pulp and paper industry. These boilers produce steam that is then used as an energy source for the plant.

Fuels

Constituents

Wood and most biomass fuels are composed predominantly of cellulose and moisture. The high proportion of moisture is significant because it acts as a heat sink during the combustion process. The latent heat of evaporation (H_{fg}) depresses the flame temperature, contributing to the difficulty of efficiently burning biomass fuels.

Cellulose, as well as containing the chemical energy released during combustion, contributes fuel-bound oxygen. This oxygen decreases the theoretical air required for combustion and therefore the amount of nitrogen included in the products of combustion.

Most natural biomass fuels contain little ash. However, some byproducts, such as de-inking sludges, do

contain a great deal of ash, in some cases up to 50% ash on a dry basis. De-inking sludges are particularly difficult to burn because they usually have high moisture and ash contents and low fuel-bound oxygen content.

Burning wood and biomass

The following general guidelines for wood and biomass combustion have been developed from experience:

1. Stable combustion can be maintained in most water-cooled furnaces at fuel moisture contents as high as 65% by weight, as-received.
2. The use of preheated combustion air reduces the time required for fuel drying prior to ignition and is essential to spreader-stoker combustion systems. The design air temperature will typically vary directly with fuel moisture content.

Fig. 3 Multifuel single-drum, 141,000 lb/h (17.8 kg/s) steam flow, bottom-supported boiler with vibrating grate stoker.

3. A high proportion of the combustible content of wood and biomass fuels burns in the form of volatile compounds. A large portion of the combustion air requirement is therefore added above the fuel, as overfire air (OFA).
4. Solid chars produced in the initial stages of combustion of these fuels are of a very low density. Conservative selection of furnace size and careful placement of the OFA system are used to reduce gas velocity and keep char entrainment at an acceptable level. Typical furnace selection criteria include a grate heat release rate of 0.47 to 1.1 $\times 10^6$ Btu/h ft² (1.5 to 3.5 MW_t/m²) of grate surface area, a furnace liberation rate of 17,000 Btu/h ft³ (176 kW/m³) of furnace volume, and an upward gas velocity of 20 ft/s (6.1 m/s). This results in furnace residence times of approximately three seconds for larger units to enhance particulate burnout and minimize emissions.

Burning in combination with traditional fuels

Biomass can be burned on a traveling grate with stoker coal. The biomass is introduced to the furnace through a separate conveying system and either a separate windswept spout below the coal feeder or through a combination feeder. (See Chapter 16.)

Biomass can be burned with pulverized coal, oil or natural gas, using dedicated burners for the latter. In this case, the grate is selected for wood firing.

When burning biomass with substantial quantities of stoker or pulverized coal, the amount of ash from the coal is greater than the amount from the biomass. Therefore, the design parameters for the coal (slagging and fouling index) will govern the design.

When burning biomass with heavy fuel oil having high sulfur and vanadium content, the ash that forms on the convective surfaces can be tenacious and, once removed, can be very abrasive. It is preferred to design for low flue gas temperatures and low flue gas velocities, regardless of the specified contaminants in the heavy oil and in the biomass, as both flue gas parameters can vary widely over the typical range of boiler operating conditions. (See Chapter 10.)

Sludge burning

As mentioned above, paper mill sludges, especially de-inking sludges, are difficult fuels to burn. Their high moisture and ash content and low fuel-bound oxygen may limit their allowable proportion of the total heat input to the furnace.

Specific limits will vary with the sludge composition and combustion system. Higher sludge inputs for a given system can normally be achieved by combined firing with better quality fuels.

Wood waste mixed with sludge can prove difficult for the fuel handling system. Frequently, the sludge segregates from the other fuels (at transfer points on belt conveyors, for example) and can be fed preferentially to one feeder.

In spreader-stoker applications, the wet, dense sludge can pile up in one place on the grate very quickly. Therefore, when a portion of the fuel is sludge,

the boiler operator must continually inspect the grate to determine whether adjustments are required.

Combustion systems

Many methods have been developed to burn wood and other biomass fuels. The best known and most successful methods use the following equipment.

Dutch oven

A dutch oven is a refractory-walled cell connected to a conventional boiler setting. Water cooling is sometimes provided to protect and extend the life of the refractory walls. Wood and other biomass fuels are introduced through an opening in the roof of the dutch oven and burn in a pile on its floor. OFA is introduced around the periphery of the cell through rows of holes or nozzles in the refractory walls.

The principal advantage of the dutch oven is that only a small portion of the energy released in combustion is absorbed because of its high percentage of refractory surface. Therefore, it is able to burn high moisture fuels (up to 60% moisture). In addition, as the fuel is pile-burned, there is a high thermal inventory in the cell that makes the unit less sensitive to interruptions in the fuel supply.

The dutch oven has distinct disadvantages when compared to more modern methods. The unit operates best when at a steady load and when burning a consistent fuel. It does not respond quickly to load demand. The refractory is subject to damage from the following sources: spalling and erosion caused by rocks or tramp metal introduced with the fuel, rapid cooling from contact with very wet fuels, and overheating when very dry wood is fired.

The dutch oven cell must be shut down regularly to allow manual removal, or rake out, of the accumulated ashes. During this period, either load must be drastically reduced as is done with multiple cell units, or auxiliary fuel must be fired as is required for units equipped with a single dutch oven.

Pinhole grate

The pinhole grate (Fig. 4) is a water-cooled grate formed by cast iron grate blocks, sometimes referred to as Bailey blocks, that are clamped and bonded to the spaced floor tubes of a water-cooled furnace. The grate blocks have venturi-type air holes to admit undergrate air to the fuel on the grate. This grate is used in conjunction with either mechanical fuel distributors or air-swept fuel spouts. Both produce a semi-suspension mode of burning, wherein the finer portion of the fuel is burned in suspension and the heavier fraction accumulates and burns on the grate. The ash and foreign material that stay on the grate are removed by raking. Typically, 25% of the air for combustion of wood is introduced as OFA through nozzles in the lower furnace walls and 75% is undergrate air.

This combustion system can follow minor load swings by varying both the fuel flow and air flow, and is suitable for biomass fuels containing up to approximately 55% moisture. A small amount of refractory is used and maintenance requirements are low.

Fig. 4 Wood-fired boiler with pinhole grate.

The main disadvantage of this method is that the grate requires manual raking of the ashes. Therefore, biomass firing must be stopped on a regular basis. Manual raking also limits the depth of the furnace and therefore the steam capacity that can be economically built. Mechanical raking machines have been developed to increase the allowable furnace depth and to speed the raking process, while providing a certain degree of protection to the operator from hot gas, flames and hot ash.

Traveling grate

The traveling grate was introduced as an improvement over the pinhole grate. (See Fig. 5.) It is a moving grate that allows continuous automatic ash discharge and consists of cast iron or ductile iron grate bars attached to chains that are driven by a slow moving sprocket drive system. The grate bars have holes in them to admit undergrate air that is also used to cool the grate bar castings. The split between undergrate and overfire air flows depends largely upon fuel size, volatility and moisture content, while also meeting the grate cooling requirements. For coal firing, 60 to 85% of the air is typically supplied as undergrate with the balance used for OFA. For biomass firing, 25 to 50% of the air is typically supplied as undergrate. Rows of nozzles in the furnace front wall and rear wall are used for OFA. Fuel spreaders and burning mode are identical to those used with the pinhole grate. The main advantages of this grate are its abil-

ity to follow load swings and the automatic ash discharge that permits continuous operation on biomass fuels.

The traveling grate was originally developed for spreader-stoker firing of bituminous and subbituminous coals. With coal, the quantity of OFA required for efficient combustion can be as low as 15% of the total air. The quantity of ash in coal is also much higher than in wood. It is therefore possible to develop a relatively large bed of ash on the grate in order to protect the grate from high temperatures, and to help distribute the undergrate air flow. Lower moisture coal can often be burned without air preheating and rarely requires air temperatures in excess of 350F (177C).

The traveling grate, while an improvement over the pinhole grate, must be considered a compromise design for the burning of biomass because the use of preheated air and the usually low ash content of biomass reduce the cooling available to the grate. This grate has many moving parts that are subjected to the furnace heat, resulting in higher maintenance costs.

Vibrating grate

The vibrating grate allows intermittent, automatic ash discharge. The grate consists of cast iron grate bars or bare tube panels attached to a frame that vibrates on an intermittent basis, controlled by an adjustable timer.

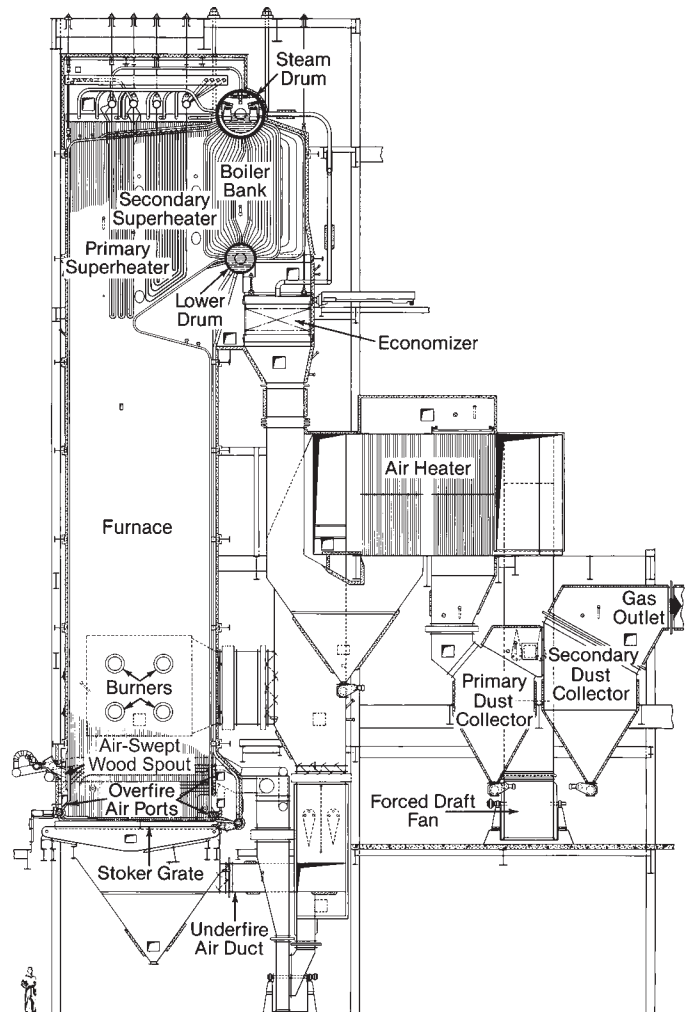

Fig. 5 Wood-fired boiler with traveling grate.

There are two major types that have been used for biomass fuels, one water-cooled and the other air-cooled.

The water-cooled vibrating grate (see Fig. 6) is used in conjunction with the semi-suspension firing mode. Because the grate is water-cooled, high temperature undergrate air, up to 650F (343C), can be used along with very high percentages of OFA and a relatively thin fuel bed. A key advantage of the vibrating grate is the low number of parts that are highly stressed, moving or in sliding contact. This results in reduced maintenance requirements. The vibration is intermittent and several vibration sequences (vibration frequency, duration, and time span between vibrating periods) are used. A common vibration sequence includes six cycles per second for a short duration of about two seconds every two minutes. The vibration time and the dwell time can be adjusted to suit the fuel characteristics. The vibrating action can help improve fuel distribution on the grate by causing fuel piles to

collapse. This style of biomass combustion system is being used very successfully at a number of installations for a wide range of wood fuel moisture contents.

The air-cooled vibrating grate can be used for applications similar to those suitable for the water-cooled vibrating grate, but the maximum allowable undergrate air temperature is 550F (288C), even with the use of stainless steel components. Because it can be installed with a horizontal grate surface, the air-cooled vibrating grate can be a very effective replacement for a traveling grate, when the traveling grate has been deemed unacceptable due to high maintenance or repair costs.

Furnace configurations

A variety of furnace configurations can be found in wood and wood-waste boilers. In the late 1970s, the controlled combustion zone or CCZ furnace was developed by B&W specifically for biomass combustion. As shown in Figs. 2 and 6, the CCZ design uses arches in the front and rear walls of the furnace to create a lower furnace zone in which combustion of biomass can be confined. OFA from nozzles located above and below the arches penetrates and burns off the volatile fuel released from the bed, as well as particles entrained in the upward flow. This furnace design incorporates a range of OFA systems that had multiple elevations of large ports and increased the OFA capacity to 40 to 50% of the total combustion air flow.

Tighter emission control regulations and advancing computational technology have stimulated the development and deployment of a straight-wall furnace design with fewer, larger OFA ports that can be more precisely located and operated. As shown in Fig. 7, the arches and multiple levels of OFA ports for the CCZ can be replaced with straight furnace walls and one level (sometimes two) of OFA ports. The B&W PrecisionJet™ OFA system has high velocity ports that include velocity dampers to fine-tune the combustion process. Computational models (see Chapter 6) permit the positioning and sizing of the higher velocity OFA ports to better complete the combustion process in a controlled fashion, thereby reducing NO_x, CO and particulate. OFA capacity of up to 60% of the combustion air flow can be used. As discussed in Chapter 16, a second option is a horizontal rotary overfire air system designed to create a double rotating circulation zone in the straight-wall furnace. (See Chapter 16, Fig. 13.) This can also increase turbulence and mixing of air and gaseous combustibles for enhanced performance. With a straight-wall design and fewer ports, these furnace configurations usually have lower initial capital costs.

Process recovery (PR) boilers (see Chapter 28) and coal-fired power boilers at pulp and paper mills have been retrofitted for wood and wood-waste firing capability as mill power and PR needs have evolved. Rising energy prices have also increased the benefit of higher internal power generation from waste product fuels. To accommodate the heat release rates discussed earlier, the furnace plan area of the original boiler must typically be enlarged to accommodate the grate area for the desired heat input. The new enlarged lower furnace is then tapered to connect with the origi-

Fig. 6 Water-cooled vibrating grate unit with CCZ furnace.

Fig. 7 Wood-fired boiler with straight furnace walls and overfire air.

nal upper boiler furnace to take full advantage of the original heating surfaces and boiler capacity. The same type of tapered furnace design may also be found where bubbling fluidized-bed combustion systems are retrofitted to PR or coal-fired boilers (see Fig. 8).

Dryers and pulverizers

If the biomass fuel available is particularly high in moisture, or if the capacity of an existing installation is to be increased, it is sometimes more economical to dry the fuel with boiler flue gas before firing it in the boiler furnace, rather than pressing the fuel to remove moisture or modifying the boiler for increased capacity. Dryers of the rotating drum type and cascading fuel type are available from several manufacturers. The dried fuel is then fired using one of the previously mentioned combustion systems.

Another means of burning biomass is by pulverizing/drying. This can be accomplished by mixing the biomass with hot gases removed from the boiler exit, pulverizing it in a fan/beater mill, and returning the mixture to the furnace through a burner. Milled peat is fired in several installations in the Nordic countries using this process. The milled peat, except for larger pieces, does not undergo much size reduction. Most other types of pulverizing systems have proven to require very high maintenance and to have poor availability and significant power consumption in biomass applications.

Fluidized-bed combustion

Fluidized-bed combustion has been successfully applied to a range of wood and biomass fuels and offers a number of features that may be advantageous in specific applications.

Only 2 to 3% of the bed is carbon; the remainder is

comprised of inert material (sand). This inert material provides a large inventory of heat in the furnace, thereby dampening the effect of brief fluctuations in fuel heating value on steam generation.

Fluidized beds typically operate at 1350 to 1650F (732 to 899C), a range considerably lower than combustion temperatures for spreader stoker units [2200F (1204C)]. The lower temperatures produce less NO_x and would be expected to provide the most benefit on high nitrogen wood and biomass fuels.

SO₂ emissions from wood and biomass firing are generally considered insignificant, but where sulfur contamination of the fuel stream is a problem, limestone can be added to the fluid bed to achieve a high degree of sulfur capture. Fuels that are typically sulfur contaminated include tire-derived fuel and coal.

The type of fluidized bed selected will be a function of the as-fired calorific value of the wood waste or biomass fuel. Bubbling bed technology is generally selected for fuels of lower calorific value. For fuels of higher calorific value, the circulating fluid bed may be suitable.

Designs for fluidized-bed combustion are discussed in Chapter 17. Bubbling fluidized beds have been applied to retrofit (Fig. 8) and new installations (see Chapter 17, Fig. 10).

Boiler component design for wood and biomass burning

Grate

The grate forms the furnace floor and provides a surface on which the larger fuel particles burn. The grate may be air-cooled or water-cooled and stationary or arranged for automatic, continuous ash removal. Most grates consist of some form of cast iron or cast alloy grate bars. (See Chapter 16.)

Fig. 8 Retrofit of process recovery boiler for wood-firing capability.

Fuel distributor

The two most common devices for introducing fuel into the furnace for semi-suspension firing are mechanical distributors and air-swept spouts. They are both designed to distribute fuel as evenly as possible over the grate surface.

The mechanical distributor uses a rotating paddle wheel to distribute the fuel. The speed of the wheel is varied to suit the fuel characteristics. In some installations, a continually varying speed is used to ensure good fuel distribution.

The air-swept spout uses high pressure air that is continuously varied by a rotary damper to distribute the fuel. Adjustments to the supply air pressure are made by the operator as the characteristics of the fuel change. The trajectory of the fuel leaving the spout is altered by an adjustable ramp at the bottom of the spout.

Burners

Burners are sometimes used to burn all or a portion of the biomass fuel. The burners are somewhat similar in design to a pulverized coal burner. (See Chapter 14.) Fuels that can be fired in a burner include sander dust, sawdust of less than 35% moisture content, and the fine material collected from a fuel dryer. Due to the possibility of inconsistent fuel flow and quality, a continuously operated auxiliary fuel pilot flame is recommended.

Furnace

A properly designed furnace has two main functions. The first is to provide a volume in which the fuel can be burned completely. The second is to absorb sufficient heat to cool the flue gas to a temperature at which the entrained flyash will not foul the convective surfaces. This must be accomplished while matching the dimensions of the grate and while providing sufficient clearance dimensions from auxiliary burners to prevent flame impingement on furnace walls.

Modern boilers are typically of membrane wall construction, but in certain limited cases, such as installations in developing countries, reverting to a tube and tile type of furnace construction may be appropriate. In such circumstances, the frequent maintenance requirement is outweighed by the reduction in first cost and the ease of operation due to the higher temperatures in the furnace.

Superheater

The sizing of the superheater on a wood-fired boiler can be complicated by several factors. For a given fuel being fired, the setting of the surface depends on the final steam temperature and on the control range required. The side and back spacing are selected to minimize fouling and erosion potential. (See Chapters 19 and 21.)

However, a wood-fired boiler rarely burns a consistent fuel. Variable moisture content and fuel analyses affect the steam-to-flue gas ratio, and a variety of auxiliary fuels, e.g., oil, gas or coal, may be available. Therefore, when designing a superheater, the full range of operating conditions must be completely understood.

Constituents in the ash can affect superheater design. For example, high levels of chloride are often

found in bark from logs floated in sea water and can require the use of high alloy materials such as 310 stainless steel to minimize the corrosion rate of the superheater tubes in the high temperature zones.

Boiler bank

Due to the relatively high ratio of flue gas flow to steam flow and the relatively low pressures and temperatures at which most wood-fired boilers are operated, a large amount of saturated (boiling) surface is required. Furthermore, due to relatively low adiabatic flame temperatures, the amount of heat absorption in the furnace is usually low compared to fuels such as oil or natural gas. Therefore, a large portion of the total heating surface in a wood-fired boiler is usually provided as boiler bank.

In some cases, the amount of furnace surface is augmented by water-cooled screens in front of superheaters to lower flue gas temperatures entering the superheater and to protect it from thermal radiation or from the active burning areas in the furnace.

The amount of boiler bank surface is usually very substantial. This surface can be arranged as cross flow surface as normally found in a two-drum Stirling boiler (see Fig. 2), or may be arranged for longitudinal flow as found in a smaller bottom-supported Towerpak® boiler. (See Fig. 9.)

Because wood fuels frequently contain sand and other mineral matter in addition to the ash, flue gas velocities in the convection pass or boiler bank must be kept low, typically below 60 ft/s (18.3 m/s).

Economizer

In most cases, when an economizer is required to reduce the back-end temperature to a specified level, it is located between the boiler bank and the tubular air heater. The economizer is designed to reduce the flue gas temperature to that required at the air heater gas inlet.

Occasionally, the positions of the economizer and air heater need to be reversed. For example, it may be necessary to provide a higher gas temperature to the air heater as part of an installation that includes a fuel dryer. The dryer needs the hotter gas to remove moisture from the fuel. This same system may also be required to maintain a specified exit gas temperature entering the stack even when the dryer (and its thermal load) is out of service for maintenance or repair. For such a system to work effectively under both operating conditions, the economizer needs to be the final heat trap. In addition, a bypass, preferably on the economizer gas side, is needed to permit exit gas temperature control.

In the above example, it should be remembered that the economizer gas exit temperature would be lower when burning dry fuel from the dryer and would be higher with the dryer out of service, if no control method was provided.

There are no special mechanical design considerations for economizers on wood-fired units, other than to limit the flue gas velocity. In virtually all cases, a continuous bare tube economizer is used. (See also Chapter 20.)

Fig. 9 Towerpak® boiler with longitudinal flow boiler bank.

Air heater

Due to the requirement to provide hot air to burn all but the driest of wood fuels, wood-fired boilers are usually equipped with air heaters. Because of the ash, sand and char in the flue gas, a recuperative type is normally selected, usually tubular. (See Chapter 20.) It is B&W practice to provide the tubes on square or rectangular pitch, rather than on triangular pitch, to lower air-side resistance and allow easier maintenance.

The common arrangement is for the flue gas to pass through the tubes and for the air to flow around the outside of the tubes. A two-gas pass design is favored for economic reasons. The low flue gas velocity in the hopper and the 180 deg change in direction also promote the separation of large, heavier particles of char and sand. The tubular air heater, when arranged for two gas passes, can act as a low efficiency (approximately 50%) mechanical dust collector.

Experience has shown the use of 2.5 in. (63.5 mm) outside diameter (OD) tubes to usually be the most cost effective. Available space limitations may require the use of smaller 2 in. (50.8 mm) OD tubes. In cases with a history of plugging by contaminants in the flue gas, it may be necessary to use 3 in. (76.2 mm) OD tubes.

Auxiliary equipment

Fans Wood-fired boilers require forced draft (FD), induced draft (ID) and usually overfire air (OFA) fans. (See Chapter 25.)

Forced draft fans require no special design considerations other than determining the required capacity and static pressure. The design may be determined by wood firing alone, wood firing in combination with auxiliary fuel, or auxiliary fuel alone, depending on the quantity and pressure of air required for each of these conditions. Normal test block margins for FD fans are sufficient. Usually these fans are controlled to maintain a constant pressure at the tubular air heater air outlet plenum.

ID fans must be designed to take into account the abrasiveness of the flue gas, the quantity of flue gas to be handled, the draft losses to be overcome, and the temperature of the flue gas. The abrasiveness of the flue gas depends on the type and efficiency of the dust collection equipment installed and whether the fan is located before or after this equipment. The ID fans are used to control the furnace pressure to a set point, usually at -0.1 to -0.5 in. wg (-0.025 to -0.12 kPa).

The quantity of gas and the draft loss used to specify the ID fan must take into account not only the expected operation of the boiler, but also possible wide variations in heating value, theoretical air, and moisture content of the fuel.

OFA fans are often exposed to severe service, as typically the air to be brought to 30 in. wg (7.5 kPa) has already been heated in the tubular air heater to as high as 650F (343C) before reaching the fan inlet. When specifying an OFA fan, it is particularly important to specify the maximum air temperature that it must be capable of handling.

Sootblowers Because biomass-fired boilers are susceptible to ash and carbon carryover, the convective heat transfer surfaces must be designed to accommodate sootblowers. Retractable sootblowers must be used for the superheater and high temperature boiler bank surfaces. Rotary sootblowers can be used for the low temperature boiler bank areas and the economizer, but retractable sootblowers are preferred, provided there is sufficient space. Traveling rake type sootblowers are typically used above the tubular air heater tubesheets on the flue gas side. (See Chapter 24.)

These sootblowers use either saturated or superheated steam to clean the gas lanes between the tubes. Blowing pressures are typically 150 to 250 psi (1034 to 1724 kPa) and the blowing sequence is usually initiated once per working shift. The high pressure jet of steam from the sootblower nozzle cleans the tube surfaces with a set radius around the sootblower lance depending on sootblower design [usually about 5 ft (1.52 m)].

The ash is typically nonsticky and is relatively easy to remove by sootblowing. If allowed to accumulate, the ash can plug gas passages, cause flow unbalances, affect boiler circulation and heat transfer, and ultimately lead to a forced outage of the boiler. If unburned carbon particles are allowed to accumulate, they can create a fire potential, particularly in the back-end equipment.

Fuel handling systems Biomass fuel systems can be quite complicated and maintenance-intensive due to the varying characteristics of the fuel. Typically, the fuel is continuously conveyed from storage to small surge bins at each fuel distributor that are kept full, with any over-

feed returned to storage. The surge bins are equipped with variable speed screw feeders or chain feeders to control the rate of biomass fuel fed into the furnace.

These variable speed feeders must be capable of operation over a turndown range of four-to-one on automatic control. They must also be able to operate at very low speeds during startup conditions to build a fuel bed on the grate. The feeder drives must be of sufficient horsepower to allow the feeder to be started when the surge bin is full of fuel.

Upstream of the surge bins, it is common to have a large live-bottom storage bin with four to eight hours of biomass fuel inventory. This is to avoid interruptions in the fuel feed to the boiler when there are problems with the outside fuel handling equipment. (See Chapter 12.)

For many biomass fuels, special fuel preparation equipment may be needed to provide effective overall combustion. As an example, for the straw-fired unit shown in Fig. 1, the straw bale is carded or raked to loosen the straw before it is fed to the grate by screw feeders.

Ash handling Ash handling systems on biomass-fired boilers can be divided into two main areas, bottom ash and flyash.

Bottom ash is the ash that is raked or conveyed off the grate, plus the ash that falls through the grate bar holes into the undergrate hopper, called a riddlings or siftings hopper. Bottom ash consists mainly of sand and stones. The ash at the grate discharge is typically collected using a submerged drag chain conveyor with a dewatering incline at the discharge end. The siftings can be collected with drag chain or screw conveyors.

Flyash is the fine ash and unburned carbon that is collected from all the boiler bank, economizer, air heater and emissions control equipment hoppers. The ash handling equipment can be drag chains, screw conveyors or wet sluicing systems. Because the flyash contains a high percentage of hot carbon, it is important that rotary seal valves be used at each hopper discharge to prevent air infiltration that could create a fire in the hopper. For the same reason, all ash conveyors should be sealed.

In some instances, the flyash from the boiler bank and air heater hoppers is reinjected into the furnace to lower the unburned carbon loss and to reduce the quantity of material that must be disposed. However, the high maintenance requirements of these systems have limited their use.

Air systems

Air systems can be categorized as undergrate or underfire air and overfire air.

Undergrate air is typically low pressure [3 in. wg (0.75 kPa)] and, depending on the type of grate used, can be anywhere between 40 and 60% of the total air required for combustion. The purpose of undergrate air is to help dry the fuel, promote the release of the volatiles, provide the oxygen necessary for the combustion of the devolatilized char resting on the grate and, in the case of an air-cooled grate, cool the grate bars. The pinhole grate and vibrating grate can be provided with multiple undergrate air compartments

with separate dampers for the operator to bias the undergrate air to the area of the furnace where the fuel is concentrated. Traveling grates can be provided with only one compartment per drive section.

OFA system capacities are varied and can range from 25 to 60% of the total air. Varying air port or nozzle sizes and air pressures are used to obtain adequate penetration of the air into the rising stream of volatiles from the grate. Typically, modern OFA nozzles are 3 to 6 in. (76.2 to 152.4 mm) in diameter or rectangular with velocity dampers (PrecisionJet™) and use air pressures up to 20 in. wg (4.98 kPa). Levels of nozzles are controlled independently such that the OFA can be varied with load and fuel characteristics. Where very high temperature OFA is used and it constitutes more than 40% of the total air flow, it is usually economical and energy efficient to provide a high pressure FD fan, rather than a low pressure FD fan plus a large high pressure OFA fan. The OFA ports can be designed to provide a double rotating circulating zone to further enhance combustion. (See Chapter 16.)

Emissions control equipment

Dust collector Mechanical dust collectors are used after the last heat trap on the boiler to collect the larger size flyash particulate, sometimes as protection for the ID fan. They typically consist of multi-cyclone tubes enclosed in a casing structure. The tubes consist of outer inlet tubes with spin vanes and inner tubes used without recovery vanes. The dust collector efficiency is in the range of 65 to 75% at an optimum draft loss of 2.5 to 3.0 in. wg (0.62 to 0.75 kPa). Due to the abrasive nature of the flyash, the outer collection tubes and cones are made of high hardness (450 Brinell) abrasion resistant material. (See Chapter 33.)

Precipitator Electrostatic precipitators are typically used after the mechanical collector to reduce the particulate concentration in the flue gas and to meet environmental requirements. Due to the high carbon content in the flyash, it is important to reduce the fire potential in the precipitator. It is necessary to ensure no tramp air enters the precipitator and that the flyash is continuously removed from the hoppers. Hopper level detectors and temperature detectors alert the operator.

Installations can be equipped with fire fighting apparatus such as steam inerting. Other suppliers recommend de-energizing the precipitator if a predetermined oxygen content in the flue gas is exceeded.

Fabric filter or baghouse Due to the fire potential, baghouse collectors have been rarely used for biomass fuels to date.

Wet scrubbers Wet scrubbers have also been used to control particulate emissions on biomass-fired boilers. Their main disadvantages are the high flue gas pressure drop, which increases the ID fan horsepower requirements, and high water consumption. Also, there is the need for a wet ash collection system and a water separation and clarification system. Wet scrubbers have given way to electrostatic precipitators as the preferred means of final flue gas cleanup, provided there is no need for a scrubber to reduce SO₂ emissions from auxiliary fuels.

Wet scrubbers with numerous small spray nozzles in a chamber can be used where low pressure drop and low water consumption are required. This is particularly well suited to retrofit applications where the scrubber can replace the mechanical dust collector for improved collection efficiency.

Environmental impact

Particulate emissions

About 80 to 95% of the total ash residue produced by a bark- and wood-fired spreader stoker is in the form of gas-borne particulate. This particulate is composed of a number of materials, including ash, sand and contaminants introduced during fuel handling, unburned char from the furnace, and salt fume (usually present only where logs are seawater flumed).

The ash content of wood and bark fuels is low (0.2 to 5.3%, dry basis). Therefore, if fuel ash contaminants are not appreciable, the particulate will usually contain high percentages of unburned char.

The particulate loading in the flue gas exiting the boiler is influenced by factors related to both combustion and aerodynamics. Combustion-related factors affect particulates by determining the degree of burnout for the entrained char. They include plan and volumetric heat release rate (two design parameters that affect furnace temperature), residence time, and consequently, char burnout.

The importance of aerodynamic factors is based on the fact that bark- and wood-fired spreader-stoker units are designed to operate with some degree of suspension burning. Variables that would tend to increase the ratio of furnace velocity to mean char particle size would therefore tend to increase flue gas particulate loading.

Some of these factors include fuel moisture and fines content, boiler plan area, air staging, and excess air level.

For wood and bark fuels not containing appreciable quantities of sand, particulate loading at the air heater exit of a modern spreader-stoker unit would typically be in the range of 1 to 3 grains/DSCF (2.4 to 7.2 g/Nm³).

Nitrogen oxides

NO_x emissions from wood and bark firing are low compared with those from traditional fossil fuels. Combustion temperatures in wood firing are sufficiently low, and little thermal NO_x is formed from the nitrogen in the combustion air. Corresponding NO_x emissions are therefore predominantly a function of the fuel nitrogen content. (See also Chapter 34.)

Conversion of fuel bound nitrogen to NO_x is dependent

on a number of operating conditions including excess air, air staging, heat release rate, and fuel sizing and moisture content. Empirical studies have also found NO_x to vary inversely with fuel moisture content, although the magnitude of this correlation is less significant.

All factors considered, NO_x emissions from stoker firing of most wood and bark vary between 0.1 and 0.35 lb/10⁶ Btu (0.04 to 0.15 g/MJ) heat input, expressed as nitrogen dioxide. Fuel contaminants that may introduce nitrogen compounds (glues and chemicals, for example) should receive special consideration.

Sulfur dioxide

Wood and bark typically contain 0.0 to 0.1% elemental sulfur on a dry basis. During the combustion process some of this sulfur can be converted to flue gas SO₂, but the conversion ratio is typically low (10 to 30%). Because the quantities of both wood sulfur and flue gas SO₂ are near the low end detection limit of corresponding analytical instruments, correlation of the two is not practical.

Typically, SO₂ emissions for stoker-fired wood and bark fuels do not exceed 0.03 lb/10⁶ Btu (0.01 g/MJ) heat input. Special consideration should be given to fuels where sulfur bearing contaminants may be present.

Carbon monoxide

Of all emissions commonly associated with wood and bark firing, carbon monoxide (CO) is usually the most variable. As a gaseous product of incomplete combustion, CO is dependent on time, temperature and turbulence considerations.

At normal excess air levels, consistency of both fuel heating value and fuel distribution are considered the most important determinants of CO emissions. Typically, test data showing the highest standard deviation in CO correspond to the highest mean CO.

Conditions of high excess air, low excess air, high fuel moisture and reduced load (<70% of the maximum continuous rating) have all been demonstrated to increase flue gas CO concentration.

Modern spreader-stoker units firing wood and bark only, and operating at steady-state conditions, typically emit CO in the range of 0.05 to 0.5 lb/10⁶ Btu (0.04 to 0.22 g/MJ) heat input.

Volatile organic compounds

Volatile organic compounds (VOCs) are also gaseous products of incomplete combustion. As such, the emission of VOCs during wood firing is influenced by the same factors affecting CO.

Typically, VOC emissions while stoker-firing wood and bark fuels do not exceed 0.05 lb/10⁶ Btu (0.02 g/MJ) heat input, expressed as methane.

Combined heat and power plant with straw-fired ultra-supercritical boiler (courtesy of Kastrup Luftfoto A/S, Denmark).

Chapter 31

Marine Applications

The ingenuity of many inventors and engineers has been devoted to the application of fossil fuel-fired steam boilers and engines to ship propulsion. The need for higher power, lower weight and smaller volume designs for ships drove many of the boiler system advances that ultimately appeared in stationary boilers designed and used today.

The primary propulsion systems in ships today, however, have progressed to diesel engines, gas turbines and even nuclear power systems in naval applications. (See Chapter 46.) Nevertheless, there remain requirements aboard new ships to produce steam for a variety of needs. In addition, a large existing population of contemporary ships, such as the LASH (lighter aboard ship) class container ships (Fig. 1), continues to use steam boilers as their primary source of power. Finally, increasing fuel costs have led to investigations of burning coal-water mixtures, coal-oil mixtures and other fuels in steam-based systems for use in the future.

The Babcock & Wilcox Company (B&W) marine boilers have established a reputation for dependability and efficiency. The history of these boilers reflects sound principles of design and fabrication. Since the first installation in the S.S. *Monroe* in 1875, B&W boilers have been installed in more than 4000 ships of the United States (U.S.) Navy and the Merchant Marine.

During World War I, B&W boilers were installed in 50 mine sweepers, 100 destroyers, and 500 Shipping Board vessels. During World War II, B&W boilers were furnished to the Navy for all but two battleships (such as the U.S.S. *Missouri*, shown in the chapter frontispiece), all the cruisers, all aircraft carriers (see U.S.S. *John F. Kennedy* in the chapter frontispiece), 90% of the destroyers, 33% of the destroyer escorts and numerous miscellaneous small craft.

General design considerations

Steam generating equipment for marine service is designed in accordance with the principles and considerations that apply to stationary units with modifications to meet specific requirements for operation at sea. The boiler must fit within a minimum engine room space, yet be accessible for operation, inspection and maintenance. Although lightweight, it must be sufficiently rugged to operate dependably under adverse sea conditions and to absorb vibration and forces resulting from rolling and pitching in heavy seas or from shocks that may result from accidental causes

such as groundings and collisions. Special steam drum design requirements must be met to accommodate *roll* of the ship from side to side, *pitch* variations from bow up to bow down, permanent *list* to either side and permanent *trim* to either bow or stern. In the case of naval vessels, the shock effects of the detonation of explosives must also be considered. Operation over a wide load range with operating characteristics compatible with a high degree of automation is also required. Finally, the factors used in both the thermal and structural design must be conservative so that continuous operation over extended periods of time will be provided with minimum maintenance. These factors combined with the use of several different fuels have led to a variety of B&W marine boiler designs.

Integral Furnace naval boiler

The Integral Furnace naval type boiler (Fig. 2) is fitted with welded high strength, low weight stainless or low-alloy steel casings. Furnace roof, side and rear walls are water-cooled by 2 in. (50.8 mm) outside diameter (OD) close-spaced tubes. Front (burner) wall and floor are usually refractory, but some recent boilers have water-cooled front walls. Steam drum diameters range from 54 to 60 in. (1.37 to 1.52 m) and water drums vary from 27 to 36 in. (0.69 to 0.91 m). Two to four rows of 2 in. (50.8 mm) OD tubes form the superheater screen. The superheater has 1.00 or 1.25 in. (25.4 or 31.8 mm) OD tubes arranged in a maximum of 8 rows deep with provision for complete drainability. The boiler bank is usually inclined and

Fig. 1 S.S. *President Tyler*, LASH Class container ship (courtesy of American President Companies, Ltd.).

Fig. 2 Two-drum boiler, naval type.

has from 18 to 23 rows of 1.00 in. (25.4 mm) OD tubes. For maximum efficiency, the boiler is fitted with a stud-tube economizer and in some cases, steam air heaters.

Range in size, steam output:

To 350,000 lb/h (44.1 kg/s) in no fixed increments

Operating pressure:

Up to 1200 psig (8.27 MPa)

Steam temperature:

Saturation to 1000F (538C)

Fuel:

Navy special fuel oil (residual)

Multipurpose fuel oil

Operational control:

Manual to complete automatic, combustion and feedwater regulation.

Draft loss at maximum output:

Up to about 75 in. wg (18.7 kPa) total through all components

Dimensions outside setting:

Smallest – 14 ft 2 in. high × 15 ft 1 in. wide × 10 ft 6 in. deep (4.32 m × 4.60 m × 3.20 m)

Largest – 21 ft 5 in. high × 18 ft 11 in. wide × 16 ft deep (6.53 m × 5.77 m × 4.88 m)

Indicated field of application

The primary use of these boilers is for combat or auxiliary naval vessels or special installations.

General comments

The nature of the construction and the rating at which these boilers operate limit their use to naval or high speed naval auxiliary vessels requiring maximum power in minimum space. They are designed for maximum efficiency at cruising speed, and some attainable efficiency is sacrificed to develop high power-to-weight and power-to-boiler volume ratios. The construction in-

cludes lightweight tubes, high-tensile drum plates, and other special features to minimize weight.

Integral Furnace merchant boiler

The Integral Furnace merchant boiler became the marine industry standard after World War II. The boilers were originally designed as tangent tube (Figs. 3 and 4) and refractory construction (water-cooled furnace) and more recently, membrane furnace construction (water-cooled, welded-wall furnace). Both types have a single gas pass with a 2 row, 2 in. (50.8 mm) OD screen before the superheater, steam drum diameters ranging from 54 to 72 in. (1.37 to 1.83 m) and water drums from 30 to 36 in. (0.76 to 0.91 m).

The tangent tube furnace is water-cooled by closely spaced 2 in. (50.8 mm) OD tubes on the side, roof, front and rear walls. Recent designs have sloped and bare furnace floor tubes with consequent reduction in exposed refractory. In designs with refractory floors, the tubes are usually buried in the floor to reduce refractory temperature and increase refractory life.

The membrane furnace is water-cooled by welded-wall construction consisting of 2.75 in. (69.9 mm) OD tubes on 3-9/16 in. (90.5 mm) centers. This applies to the furnace floor, front, rear and side walls. The floor is covered with firebrick to protect the tubes from overheating.

In either style boiler, an inclined or vertical boiler tube bank, composed of 2 to 4 rows of 2 in. (50.8 mm) OD screen tubes and 17 to 24 rows of 1.25 in. (31.8 mm) OD generating tubes, may be used. The superheater consists of either horizontal or vertical 1.25 in. (31.8 mm) OD tubes and has one or two access cavities to facilitate water washing, cleaning, inspection, and maintenance of the superheater and boiler bank. A single cavity is normally provided when the fouling characteristics of Bunker C oil are average, and two

cavities are used when fouling characteristics are more severe. The boiler is generally equipped with steam atomizing burners, retractable sootblowers, and an air heater or an economizer.

Indicated field of application

These designs are primarily used for propulsion power, although they are also used without a superheater for auxiliary or heating service in the smaller sizes where space is at a premium, a compact lightweight design is needed, and feedwater is of good quality.

Range in size, steam output:

To 400,000 lb/h (50.4 kg/s) in no fixed increments

Operating pressure:

up to 1200 psig (0.69 to 8.27 MPa)

Steam temperature:

Saturation to 1000F (538C)

Fuel:

Oil (light fractions to heavy residuals) and liquified natural gas (LNG)

Operational control:

Manual or completely automatic, including feedwater flow, combustion and steam temperature controls

Draft loss at maximum output:

From 15 to 30 in. wg (3.7 to 7.5 kPa) total through all components

Dimensions outside setting:

Smallest – 7 ft 8 in. high × 5 ft 5 in. wide × 5 ft 6 in. deep (2.34 m × 1.65 m × 1.68 m)

Largest – 41 ft 6 in. high × 34 ft 3 in. wide × 24 ft 1 in. deep (12.65 m × 10.44 m × 7.34 m)

General comments

Designs of this type are suitable for vessels where large power plants must be installed in a minimum of space, and where weight saving is a vital consideration. Many possible variations in configuration permit application under limited space conditions. Mass action retractable sootblowers are recommended for the superheater zones.

Reheat boilers

Although reheat boilers have not been extensively used in the marine industry, there have been several applications. In considering a reheat boiler for shipboard applications, one design feature must be considered. That feature is the protection of the reheater tubes when the main propulsion turbine is in astern operation or stopped. B&W has designed the boiler with damper and bypass systems, as well as with extensive screen tube protection systems in front of the reheater.

The marine reheat boiler is of the two-drum divided inclined boiler bank type, capable of burning fuel oil or natural gas. Other than the reheater, reheat screen, baffle wall and damper system, the reheat boiler is similar to the tangent tube boiler.

Coal-fired marine boilers

Up until the late 1970s, coal-fired marine boilers put into service were for vessels on the Great Lakes.

Fig. 3 Two-drum Integral Furnace boiler with vertical superheater.

Fig. 4 Two-drum Integral Furnace boiler with horizontal superheater.

These units were built in the late 1950s, and were for relatively low-pressure and low-temperature conditions. The boiler designs were either the sectional header type or the two-drum type. This two-drum boiler had the same physical appearance as many of the newer oil-fired two-drum boilers. However, because coal firing requires a much lower furnace heat release rate than oil firing for proper combustion, the result was less steam generating capacity for the same ship-board space availability.

As with a land-based unit, boiler design begins with the stoker. The maximum stoker grate release rate for good operation and for prevention of grate overloading is $750,000 \text{ Btu/h ft}^2$ ($2.37 \text{ MW}_t/\text{m}^2$) of grate surface. Another requirement for good stoker operation, particularly when flyash and unburned carbon are re-injected into the furnace, is a limit of input to the stoker of $13 \times 10^6 \text{ Btu/h ft}$ ($12.5 \text{ MW}_t/\text{m}$) of stoker width. Exceeding this limit can cause poor fuel distribution on the grate, resulting in uneven burning.

The furnace volume should be set so that the furnace liberation does not exceed $30,000 \text{ Btu/h ft}^3$ ($0.31 \text{ MW}_t/\text{m}^3$). Adherence to this value will ensure sufficient residence time in the furnace to properly burn the fuel and minimize slagging and fouling.

The coal-fired marine boiler has a totally different appearance than that of the customary oil-fired marine boiler. The furnace extends considerably below the centerline of the lower drum. This dimension, commonly called the setting height of the furnace, is the dimension from the top of the stoker to the centerline of the water drum. Generally, on units of this capacity, setting heights range from 16 to 20 ft (4.9 to 6.1 m).

This boiler has been specifically designed to make full power by either burning 100% coal or 100% oil. When burning coal and with a grate release rate of $750,000 \text{ Btu/h ft}^2$ ($2.37 \text{ MW}_t/\text{m}^2$), the approximate turndown ratio of the stoker will be 3:1. However, with the oil burners, the turndown ratio can be as high as 16:1. Therefore, if required during maneuvering modes of operation, the boiler can be readily fired by oil and have the full flexibility and response time needed for this condition. The design operating conditions are 875 psig (6.03 MPa) and 900F (482C) with steam capacity ranging from 60,000 to 150,000 lb/h (7.6 to 18.9 kg/s).

Additional features of this design address other impacts of coal and its associated ash loading. Retractable sootblowers, hoppers, dust collection equipment and flyash re-injection are all included.

Auxiliary package marine boilers

As the marine industry has shifted its emphasis from main steam propulsion systems to diesel propulsion, the need developed for a simple, low-cost, self-contained auxiliary boiler.

B&W developed an Integral Furnace, two-drum D-type package boiler (FMB) that could operate as a stand-alone unit or in conjunction with a diesel or gas turbine exhaust waste heat boiler.

The boiler in Fig. 5 represents the marine package design conforming to the requirements of U.S. Coast

Guard (USCG) and American Bureau of Shipping (ABS) Rules. The unit is shop-assembled, including furnace and firing equipment. It is not intended for ship propulsion, but as a means of supplying auxiliary steam.

The boiler incorporates a compact vertical bank of 2 in. (50.8 mm) OD tubes arranged between and terminating in an upper and lower drum. The tube ends are expanded into tube seats that are grooved to obtain maximum tightness.

A 54 in. (1.37 m) nominal diameter steam drum is required to promote water level stability even during wide variations in load, and helps to ensure dry, saturated steam. The requirements for this drum include satisfactory operation under the following conditions:

- 30 degree roll to each side for a 15 second period,
- 10 degree pitch from bow up to bow down for a 6 second period,
- 15 degree permanent list to either side, and
- 5 degree permanent trim to either the bow or stern.

Under any of these adverse conditions, the downcomers and boiler bank generating tubes will not uncover.

The furnace and boiler are covered by a 20 gauge (0.9 mm) nonpressurized galvanized steel ribbed lagging except in areas such as the steam drum joints and bent tube portions of the walls, which are covered by a 12 gauge (2.7 mm) carbon steel casing.

The boiler furnace unit is arranged for upward expansion and is mounted on a welded structural base frame, ready for positioning on the ship's foundations. The unit has a furnace with a refractory covered flat floor, and a boiler bank. The furnace side wall, roof, floor and rear wall are completely water-cooled and form an integral part of the boiler circuitry. One burner is used in the refractory front wall.

Water-cooled furnace wall tubes, comprising the side wall, roof and floor, are of membrane construction. The rear furnace wall is 2 in. (50.8 mm) OD flat-studded tubes on 4 in. (101.6 mm) centers. A 10 gauge (3.4 mm) steel inner casing backs the flat-studded wall. The furnace wall tubes receive their flow from the lower drum

Fig. 5 Auxiliary package marine boiler.

and discharge the steam-water mixture into the steam drum. The 2.75 in. (69.9 mm) OD furnace, roof and floor tubes are a part of the furnace side wall circuitry. The furnace front wall (burner wall) is of refractory anchored construction and is backed by insulation and a gas-tight casing.

These marine auxiliary package boilers are designed to provide unattended operation with controls that are fully automatic after the boiler is on line.

Range in size, steam output:

To 100,000 lb/h (12.6 kg/s) in no fixed increments

Operating pressure:

225 psig (1.55 MPa)

Steam temperature:

Saturation only

Fuel:

Oil, light fractions to heavy residuals

Dimensions outside setting:

Overall width is 12 ft 6.25 in. (3.82 m), overall height (base to face of steam outlet flange) is 16 ft 9.75 in. (5.12 m) with drum centers at 12 ft 10 in. (3.91 m). These dimensions are constant for all boiler sizes. The length is variable to establish the various boiler sizes and ranges from about 12 to 18 ft (3.66 to 5.49 m).

Waste heat marine boilers

With the use of diesel or gas turbine propulsion systems, such as aboard the LaJolla class ship, shown in Fig. 6, it is often advantageous to incorporate a waste heat (exhaust gas) boiler system that, in addition to an auxiliary boiler, supplies saturated steam and improves overall plant efficiency.

The waste heat boiler system is composed of a forced circulation, spiral wound, finned tube or studded tube boiler (Fig. 7); auxiliary steam drum; and control equipment.

The waste heat boiler unit is arranged for upward expansion and is ready for positioning on the ship's foundation. It is designed to operate under either a wet or dry condition and can serve as a muffler or sound reducer whether filled with water or in a dry state.

The horizontal waste heat boiler uses the B&W continuous stud tube extended surface or a spiral wound, finned type surface. The elements including the inlet and outlet headers are located inside a welded gas-tight casing, arranged for bottom support. This boiler consists of 1.5 in. (38.1 mm) OD steel tubes and studs or fins.

The boiler elements, headers, casing, integral support steel and framing angles are shop-assembled. The tubes are supported by tube support plates. The unit is single-cased and of welded construction. The casing provides a gas-tight seal and is fitted with access panels for inspection purposes. Support of the exhaust gas boiler is on the ship's structural members.

A 36 or 42 in. (0.91 or 1.07 m) nominal diameter auxiliary steam drum is provided to meet anticipated list and trip operating conditions as well as to promote water level stability. The effect of shrink and swell is controlled by forced circulation with a minimum 4:1 circulation ratio, cyclone steam separators and the large diameter steam drum.

Fig. 6 M.V. Potomac Trader, LaJolla Class vessel with diesel propulsion plus waste heat and auxiliary steam boilers (courtesy Penn-Attranco Corp.).

One mode of operation has an auxiliary boiler operating in conjunction with the waste heat boiler system. (See Fig. 8.) The main diesel engine exhaust gas is directed to the waste heat boiler. The gas then enters the boiler and crossflows over the in-line extended surface to the waste heat boiler exit where it is then sent to the stack.

The auxiliary boiler feed pump supplies condensate to the auxiliary boiler steam drum. The circulating pumps take suction from the auxiliary boiler lower drum and feed the waste heat boiler. Flow is upward through the waste heat boiler to its outlet where the resulting steam-water mixture is conducted through piping to the auxiliary boiler's steam drum. All steam for ship services is drawn through the auxiliary boiler's cyclone steam separators so that the auxiliary boiler acts as the steam drum of the exhaust gas boiler. The auxiliary boiler will fire automatically to maintain the steam pressure within an adjustable band.

The alternate mode of operation for this system, with the auxiliary boiler, has the boiler feed pump supply condensate to the auxiliary steam drum. The circulating pumps take suction from the auxiliary steam

Fig. 7 Waste heat marine boiler.

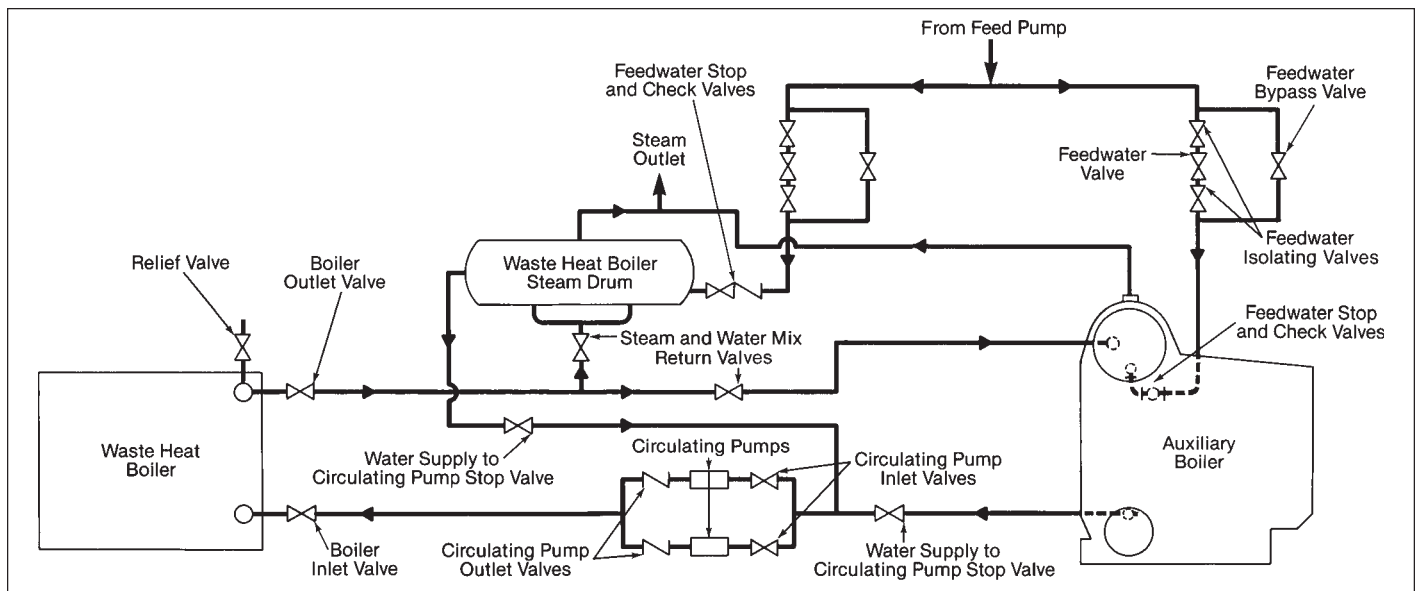

Fig. 8 Shipboard steam system combining auxiliary boiler and waste heat boiler.

drum and feed the waste heat boiler. Flow is upward through the boiler to its outlet, where the resulting steam-water mixture is conducted through piping to the auxiliary steam drum. The auxiliary boiler may be isolated and unfired in this condition for maintenance or to accommodate steam demand. It may also be fired automatically to maintain the steam pressure within an adjustable band.

Marine boiler design

The techniques used in the design of marine boilers are similar to those applied to stationary units (Chapters 19, 20 and 21). However, the design of marine boilers is also subject to constraints and requirements that are specific to marine plants. These include space conditions, fireroom configuration, list and trim, pitch and roll, and ship maneuverability. In addition to the codes and standards used for stationary boilers (i.e., ASME, ANSI), other codes apply. Examples include the United States Coast Guard Marine Engineering Regulations, subchapter F and other subchapters, American Bureau of Shipping (ABS) Rules, and Lloyd's Register of Shipping Rules.

Design procedures and guidelines for marine boilers are generally set in the Society of Naval Architects and Marine Engineers (SNAME) Technical Bulletin No. 3-32 (*Furnace Performance Criteria for Gas, Oil and Coal Fired Boilers*, 1981) and No. 3-11 (*Marine Steam Plant Heat Balance Practices*).

Fuel characteristics can have considerable bearing on the design. Regardless of whether oil or coal is used, the chemical analysis and ash characteristics are particularly important and should be specified so that heat transfer surface can be arranged to minimize corrosion and deposition from ash and slag.

Boiler design for a particular application starts by establishing the dimensions and arrangement of the furnace. Within this volume the desired fuel-burning equipment can be installed and the fuel burned effi-

ciently, without exceeding allowable furnace heat absorption rates. This is a major concern where small furnaces are needed to fit into restricted shipboard engine room space.

The furnace arrangement and dimensions generally establish the overall size of the boiler bank. Therefore, the first step in designing a new boiler is to prepare a preliminary layout of a suitable furnace. To do this, the amount of fuel to be fired is calculated based on the required steam flow, pressure and temperature, as well as on feedwater temperature and efficiency. It is then possible to estimate the type and number of burners to be used, the allowable pressure drop through the burners for good combustion conditions, the size and shape of the furnace to properly accommodate the burners for good combustion, and the allowable furnace heat absorption rate.

Oil burners

The type and number of oil burners selected depend on the fuel rate and the allowable air resistance. The number is usually not less than two, so that at least one burner operates at all times, even when changing sprayer plates or cleaning atomizers of the idle burners. Many types of oil burners are available. The burners described in Chapter 11 are for stationary boilers and are for burning natural gas and oil, as well as other gaseous type fuels or mixtures.

Marine burners are generally designed solely for burning oil. Since World War II, three types or sizes of registers were applied to most merchant marine and naval vessels. They were the Iowa, Saratoga and Progress types and covered oil flow rates up to 7000 lb/h (0.9 kg/s) or 130×10^6 Btu/h (38.1 MW_t) input per register with excess air of 10 to 20%.

With the pursuit of more efficient steam propulsion systems in the 1970s, B&W developed a low excess air burner (5 to 10%) to be used on merchant ships. These burners were designed to burn natural gas or oil up to 130×10^6 Btu/h (38.1 MW_t) input. The burners are

available in throat sizes from 15 to 30 in. (381 to 762 mm) (Fig. 9) and have pressure drops of 8 in. wg (2 kPa) at normal operating conditions.

Prior to 1970, most steam ships used a mechanical atomizer. However, B&W developed and introduced the wide range Racer® steam atomizers or sprayer plate. This steam atomizing sprayer plate provided coverage over the full range of operation. The properly sized and selected sprayer plate will cover the range from minimum to the designed maximum overload firing rate as long as atomizing steam is available. This steam atomizer and burner are capable of operating at extremely low firing rates without loss of good combustion or ignition as long as proper fuel oil temperature and proper air flow (air/oil ratio) are maintained.

When maneuvering, or at any time during port operation or normal operation at sea, it should not be necessary to secure burners unless the steam demand is less than that produced with all burners in service at the minimum fuel oil pressure. During normal operation, all burners should be kept in use for all rates of operation.

For all fuel oil pressures, the atomizing steam pressure should be constant and should be maintained at 135 psig (0.93 MPa) at the burner. Due to the pressure drop between the atomizing steam header and the burner, this is equivalent to a steam pressure of approximately 150 psig (1.03 MPa) at the atomizing steam header.

When burning heavy residual fuel oil, certain minimum clearances are required around the burners to prevent flame impingement and carbon deposits. To assure complete combustion of the fuel, the furnace depth is usually limited to a minimum of 6 ft (1.83 m), although both diesel and bunker oils have been burned successfully in furnaces 5 ft (1.52 m) or less in depth.

Furnace heat absorption

In the marine field, the heat release rate per unit furnace volume is frequently used for comparing boilers without regard to similarity of design. This ratio is not an important design criterion as it provides only an approximation of the time required for the products of combustion to pass through the furnace. However, it may be used to indicate the operating range for which the firing equipment is to maintain satisfactory combustion conditions. In naval vessels, the availability of suitable oil burners has permitted the installation of high capacity lightweight boiler units with heat released at a rate of 200,000 Btu/h ft³ (2.07 MW_t/m³) of furnace volume at cruising conditions and more than 1,000,000 Btu/h ft³ (10.3 MW_t/m³) at the maximum evaporative condition with satisfactory results. For merchant ships, arbitrary limits of 75,000 to 90,000 Btu/h ft³ (0.77 to 0.93 MW_t/m³) at the normal rate of operation are commonly specified.

A more meaningful criterion of furnace design is the heat absorbed by the cold surfaces of the furnace, expressed as the amount of heat absorbed per square feet of radiant heat-absorbing surface as discussed in Chapter 19. The considerations described also apply to marine units, with particular emphasis on the de-

termination of the furnace exit gas temperature to assure satisfactory superheater design and to establish the heat absorption by the furnace wall tubes for adequate circulation margins.

Marine boilers operate with higher heat input rates per square foot of boiler and superheater surfaces than stationary boilers designed for the same steam outputs. They have less heating surface and smaller overall dimensions. Flame temperatures more closely approach the adiabatic temperature, and furnace exit gas temperatures are considerably higher than those encountered in stationary boilers. Fig. 10a indicates the effect of excess air on furnace temperature.

The effectiveness of the water-cooled surface in the furnace is determined by applying the factors shown in Chapter 4 to the flat projected areas of the furnace walls and tube banks facing the furnace. Bare tangent tubes or membrane tubes are used wherever possible in furnace waterwalls. Where tubes must be spaced to facilitate replacement, it is preferable to limit the width of the exposed refractory areas between tubes to 1 in. (25.4 mm) or less to avoid wastage resulting from sodium compounds in the oil ash. The effect of wall tube spacing, or the ratio of water-cooled surface to refractory surface, on furnace heat absorption is shown in Fig. 10b. The heat absorption rate in the furnace increases with increased firing rate. However, furnace absorption as a percentage of the total boiler absorption decreases with increased firing rate as indicated in Fig. 10c.

Furnace tube temperatures

In all boiler tubes and particularly in tubes exposed to the high heat absorption rates of marine furnaces, adequate circulation must be provided to avoid critical heat flux (CHF) or departure from nucleate boiling (DNB) as discussed in Chapter 5. This is generally accomplished by empirical data and methods based on tests and operating experience. Tube wall thickness is usually set close to the minimum required for the design pressure, because weight is a primary consideration and excess thickness increases external tube temperature. The heat transfer coefficient across the boiling water film in the furnace steam generating tubes can be as high as 20,000 Btu/h ft² F (114 kW/m² K). However, in estimating tube temperature, a conservative value may be used, e.g., 2000 Btu/h ft² F (11.4 kW/m² K), to obtain a somewhat higher estimated tube temperature, resulting in lower allowable stress in the tube metal and therefore a somewhat more conservative tube thickness.

Fig. 9 B&W Progress-type oil burner with Racer® steam atomizer.

Fig. 10 General effect of excess air (a), ratio of heat-absorbing to refractory surface (b), and firing rate (c) on furnace heat absorption and temperature based on 18,500 Btu/lb (43 MJ/kg) fuel oil.

Scale deposits on the water side of boiler tubes are a long recognized cause of tube failure. These deposits can be particularly serious in the furnace tubes of marine units because of the high heat absorption rates. As an example, a calcium sulfate scale deposit on the inside of a tube with a thickness of only 0.024 in. (0.61 mm) and a thermal conductivity of 0.83 Btu/h ft F (1.44 W/m K) results in a 362F (201C) temperature differential across the scale. For a boiler operating at 665 psig (4.59 MPa), this scale would increase the tube outside metal temperature to 1004F (540C). This temperature exceeds the oxidation limit for steel, and oxidation and ultimate tube burnout will likely occur, even though boiler circulation may be adequate. Scale must be avoided by proper water conditioning. (See Chapter 42.)

Boiler tube banks

The boiler bank, composed of multiple rows of tubes where steam is generated, generally consists of a screen ahead of the superheater and a convection bank behind it. Both sections generate saturated steam but they are considered separately during the design stage. The screen tubes, by virtue of their location, absorb heat at a considerably higher rate than the main bank tubes. Consequently, to assure an adequate flow of water, the furnace screen tubes should be larger in diameter. For this reason, marine boilers are designed with two sizes of steam generating tubes. The diameters of screen tubes are generally 2 in. (50.8 mm) while those of the other generating tubes are 1, 1.25 or 2 in. (25.4, 31.8 or 50.8 mm), swaged to 1.5 in. (38.1 mm) at the drums. Circulation and the amount of heating surface required to obtain the desired gas temperature leaving the tube bank are the major factors in determining the tube size and the number of tube rows to be installed, although resistance to gas flow is also a factor.

In the design of the superheater screen, consideration must be given to the effect of tube spacing and the number of rows, the desired superheater outlet temperature and the maximum allowable superheater tube metal temperatures. The screen must be designed so that the gas temperature entering the superheater and the radiant heat penetration from the furnace will provide the desired steam temperature with a superheater of reasonable size and arrangement. Fig. 11 shows the effect of radiant heat penetration on the performance of the superheater over the designed load range of the boiler. The number of rows in the boiler bank is usually established by analyzing the economic advantages of economizers and air heaters as compared with boiler surface. The proper proportions of boiler surface and additional heat-absorbing surface beyond the boiler bank are based on the efficiency desired.

Superheaters

Superheaters of the convection type are generally used in marine boilers. While some radiant superheaters have been used, the difficulty of providing adequate cooling during fast startups and under maneuvering conditions has severely limited their application.

In the convection superheater, there is usually enough absorption by radiant heat penetration of the screen to give a flatter steam temperature characteristic than would be obtainable by convection alone. The characteristic steam temperature curves of radiant and convection superheaters are shown in Chapter 19.

With a properly designed screen between the convection superheater and the furnace, it is possible to maintain a high temperature differential between the gas and the steam. This minimizes the amount of heating surface necessary to obtain the desired steam temperature and reduces the size and weight of the superheater. Superheater heating surface usually consists of U-shaped tubes connected to headers at each

end, although continuous tube superheaters are used in special designs.

Either a vertical or a horizontal arrangement may be used in drum-type boilers. The horizontal arrangement can be vented, drained, and readily cleaned by mechanical or chemical means. However, complete draining and venting is possible only with the vessel on an even keel. Vertical superheaters have inverted loops and, although drainable at all times, they can not be vented. Typical superheater arrangements for a two-drum boiler are shown in Figs. 3 and 4.

Superheater surface is arranged in loops of in-line tubes (usually one to four loops), and the most commonly used tube size is 1.25 in. (31.8 mm) OD. Because the tubes are relatively short, adequate strength is available in the usual range of thicknesses to maintain proper alignment with a minimum of supports. The number of steam passes is selected to provide sufficient pressure drop to obtain proper steam distribution and to assure satisfactory tube metal temperatures.

Good practice requires that maldistribution of gas and steam be kept to a minimum to maintain proper superheater tube temperatures. However, with various fuels and operating demands it is not possible to maintain the conditions necessary for perfect distribution. To provide a satisfactory margin when calculating steam and tube temperatures, the average gas side heat transfer rate is increased and the steam side rate is reduced.

For steam temperatures below 850F (454C), tubes are usually expanded into headers to minimize leakage and to reduce maintenance costs. For temperatures above 850F (454C), rolled and seal welded joints, or joints of the stub welded type, are necessary for satisfactory service.

In addition to being supported by the headers, superheater tubes may also be supported at one or more

points by alloy castings dovetailed into brackets welded to water-cooled support tubes. With these designs, the superheater tubes can be replaced without removing the supports.

Superheater fouling and high temperature corrosion

The use of higher steam temperatures has resulted in rapid fouling of superheater surfaces and corrosion and wastage of superheater supports. The heavy ash deposits come from burning oils with 0.05 to 0.20% or more ash by weight. The most significant constituents of the ash are vanadium, sodium and sulfur. Experience indicates that heavy deposits occur with a combination of high gas and heat-receiving surface temperatures. The heaviest ash accumulations occur on the furnace side of a superheater, where the gas temperatures are relatively high, while less ash forms at the back side, where the gas temperatures are much lower. Because of the potential of high corrosion rates, superheater metal temperatures should not exceed 1100F (593C). For further discussion of high temperature corrosion in oil-fired boilers, see *Oil ash corrosion* in Chapter 21.

Steam temperature control

In the marine power plant, just as in the stationary power plant, accurate control of steam temperature is required. In most cases steam temperature controls are used to assure that the allowable metal temperatures of the main steam piping and the main turbine are not exceeded. Close control of the maximum steam temperature permits the use of less expensive alloys in the superheater and piping. Several methods are used for superheat control, as described in Chapter 19. One or more methods may be used to alter the characteristic steam temperature curve of a particular unit design.

One method used in marine boilers is the dual or two-furnace boiler design. As shown in Fig. 12, the furnace is divided into two sections separated by a superheater and screen tube section. The flue gas flows successively through the superheat furnace (left hand furnace), the superheater heat transfer surfaces, the second furnace (where fuel and air are burned) and, finally, the boiler bank before being exhausted to the stack. By varying the oil firing rate in the superheater furnace, the quantity and temperature of the gases flowing across the superheater are controlled to obtain the desired steam temperature. At the same time, the firing rate in the saturated furnace, which contains no superheater surface, is adjusted to hold the desired steam pressure.

In most modern two-drum boilers, steam temperature is controlled, where required, through the use of a drum-type surface attemperator. With this type of control, all of the flue gas passes over the superheater, but a portion of the steam is passed through the attemperator, which is a steam-to-water heat exchanger submerged in boiler water in the steam or water drum. Fig. 13 indicates two piping arrangements for control attemperators. In a submerged attemperator where the inlet steam temperature exceeds 850F (454C), 16Cr-1Ni alloy should be considered to protect against methane gas corrosion.

Fig. 11 Typical curves showing the effect of superheater location and firing rate on superheat.

Fig. 12 Twin furnace design used for marine boiler superheat temperature control.

Auxiliary desuperheaters

Steam for auxiliary use may be required at a lower temperature than that delivered by the superheater to the main engine. To satisfy these demands, auxiliary desuperheaters are used, often in conjunction with pressure reducing stations. These desuperheaters may be inside the drum as discussed above or separate external spray types.

Reheaters

The use of steam reheat in a marine plant is more attractive as the speed and power requirements of the ship increase. Although reheaters increase the complexity of the boiler design and the first cost of the plant, fuel savings in high horsepower, high utilization plants can be significant. Design considerations are similar to those for superheaters but must be augmented by the requirements to protect the reheater from overheating during periods when there is no steam flow during maneuvering, running astern or at a stop bell.

Economizer and air heater cycles

Economizers or air heaters, and in some instances both, are required if a high boiler efficiency is to be obtained. The temperature of flue gas leaving the boiler bank at full power (the design rate) is a function of the saturation temperature corresponding to the drum pressure at which the unit is operating. Space, weight and economic considerations usually result in a boiler bank sized to reduce the exit gas temperature to within 50 to 100F (28 to 56C) of the saturation temperature. Gas temperatures in the range of 550 to 650F (288 to 343C) leaving the boiler bank are typical of merchant ship boilers. To reduce this flue gas temperature sufficiently in order to obtain acceptable efficiency, economizers and/or air heaters may be

added. The choice of which to use depends on the design of the power plant and the desired performance characteristics of the unit.

Where the design includes a deaerating feedwater heater and a single stage of feedwater heating to supply water at 240 to 280F (116 to 138C), an economizer can be used to provide reasonably high boiler efficiency. The economizer can be used either alone or in conjunction with a steam air heater. In this range of feedwater temperature, an economizer can be economically designed to reduce the products of combustion to within 30F (17C) of the inlet water temperature at the normal rating. Therefore, with 280F (138C) feedwater, a boiler efficiency of 88.6% can be attained with an economizer alone and about 88.8% if a steam air heater is added.

When the feedwater temperature to the economizer is higher, the efficiency is limited, because the temperature of the gas leaving the economizer can not be lower than the inlet feedwater temperature. Consequently, when additional stages of regenerative feedwater heating are used, the inlet feedwater to the economizer may be at a temperature of 300 to 450F (149 to 232C), and it may not be economical to use an economizer unless it is followed by an air heater. Cycle efficiency is increased approximately 1% for each 100F (56C) rise in feedwater temperature through regenerative feedwater heating.

An air heater contributes additional efficiency even when the maximum practical amount of regenerative feedwater heating is used. At normal operating rates and an inlet air temperature of 100F (38C), exit gas temperatures of 300 to 320F (149 to 160C) are readily

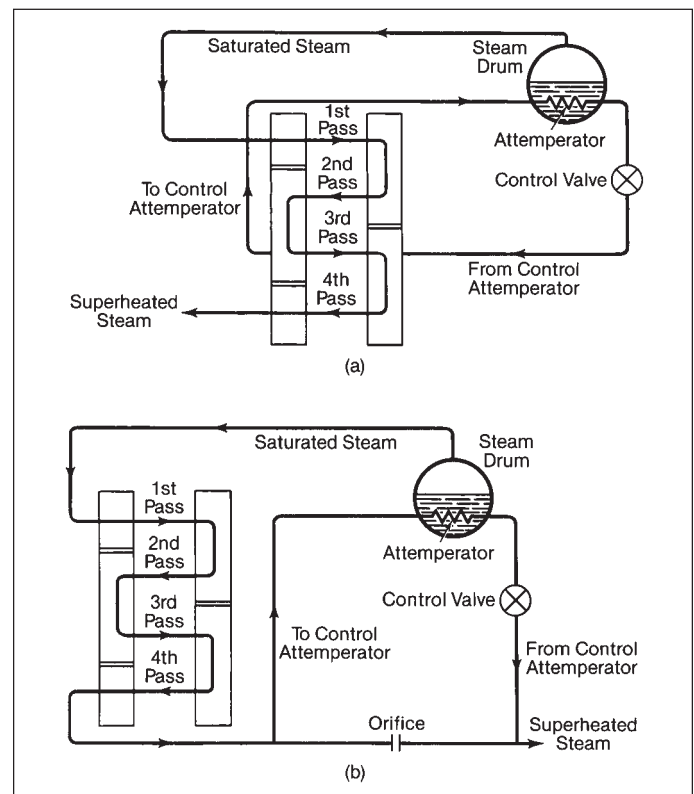

Fig. 13 Internal attemperators – (a) inter-pass, (b) after-pass.

obtained, corresponding to 88.5 to 88.0% efficiency. Air temperatures leaving air heaters are normally in the range of 300 to 450F (149 to 232C).

As an alternate to the standard economizer/air heater cycle, a dual economizer steam air heater cycle (DESAH), using a primary and secondary economizer, can be used. This arrangement will improve the cycle efficiency and reduce the fuel rate by utilizing turbine bleed steam to a high pressure feedwater heater. The actual cycle improvement will depend on the turbine characteristics with the additional bleed for the high pressure heater. The overall boiler efficiency will remain essentially unchanged over that with the regular economizer cycle; however, the fuel oil consumed will decrease because of additional heat added to the feedwater.

The cycle would use a feedwater temperature leaving the deaerator feedwater heater of about 285 to 300F (141 to 149C), presently being used on single economizer, steam air heater cycles. A feedwater temperature lower than this could result in economizer corrosion and plugging problems. If higher feedwater temperatures are desired in order to more efficiently use turbine bleeds, it should be pointed out that the boiler efficiency will correspondingly decrease. This is due to the higher gas temperatures occurring at the secondary economizer outlet because a terminal end temperature difference of 25F (14C) is required.

The feedwater would pass through the secondary economizer and be heated to about 335F (168C). It would then pass through a high pressure feedwater heater, that would raise the feedwater temperature about 50F (28C) before returning the water to the primary economizer and the steam drum (Fig. 14). This cycle shows a reduction in all purpose fuel use over that associated with the single economizer steam air heater cycle while being only slightly more complicated. Equipment costs rise somewhat due to the addition of a high pressure feedwater heater and its control. In addition, in order to realize the same exit gas temperature, the economizer heating surface would have to be increased 1.5 times the surface amount used with the single economizer cycle.

Economizers Two general types of economizers, the bare tube and extended surface types, are used in marine service. Both are nonsteaming and are almost always arranged for counterflow of water and flue gas to obtain the best possible heat transfer characteristics. (See Chapter 20.) The bare tube type is used where high feedwater temperature makes the application of both an economizer and air heater desirable. These economizers are designed to reduce the gas temperature about 100F (56C), with the remainder of the required temperature drop obtained with an air heater. All are drainable and ventable.

The second and more common type uses extended surface to reduce the size of the economizer. There are many types of extended surface, including cast iron or aluminum gill rings, spiral fins and small metal studs welded to the tubes. B&W has chosen the latter for its marine economizers due to the shape and size of the stud and because the method of attachment eliminates soot-collecting crevices where corrosion usually begins.

Extended surface economizers are usually con-

Fig. 14 Dual economizer steam air heater (DESAH) cycle schematic.

structed of 1.5 in. (38.1 mm) OD tubes formed into continuous loops. This construction requires only two headers. Tube-to-header joints are welded, or expanded and seal welded, to eliminate seat leakage. In the most recent designs, handhole fittings, except those required for inspection, are eliminated by externally welding the tubes in sockets or to stubs on the headers. A typical arrangement of an extended surface economizer with studded tubes is shown in Fig. 15.

When used alone, economizers are generally designed to reduce gas temperatures by 200 to 300F (111 to 167C), with a corresponding increase in the water temperature of 70 to 100F (39 to 56C). If the inlet water temperature is 280F (138C), the exit water temperature normally will range from 350 to 365F (177 to 185C), far enough below saturation temperature at a pressure of 600 psig (4.14 MPa) to prevent steaming.

In designing an economizer, the possibility of sulfuric acid corrosion of the economizer tubes must be considered. (See Chapter 20.) The tube metal temperature of bare tube economizers is essentially the same as that of the water within the tube. This is also true for the tube metal of extended surface elements, but the tip temperature of the studs is considerably higher.

In order to minimize gas side corrosion of carbon steel economizer tubes, B&W recommends that feed

Fig. 15 Extended surface stud tube economizer.

temperature be kept above 246F (119C) when burning Navy Special Fuel Oil (NSFO) and above 270F (132C) when burning Bunker C oil. Where these temperatures are not obtainable, the use of a corrosion resistant alloy tube is advised. The use of cast iron is not recommended as the corrosion resistance of cast iron is less than that of standard carbon steel, and any improvement in tube life with cast iron cladding is only due to its greater mass.

A bypass line is usually provided for operation of the boiler with the economizer out of service. During such operation, it is necessary to fire more fuel to maintain the required evaporative rating because of the decreased efficiency. This increases the steam temperature and requires either more attemperation or a reduction in rating to prevent overheating of superheater tubes or turbine. Normally there is no danger of metal oxidation in the economizer during bypass operation, because the gas temperatures entering the economizer are usually less than 850F (454C).

When economizers are included in the design, deaerating feedwater heaters should be installed to remove all traces of oxygen from the feedwater and to prevent internal corrosion of tubes and headers.

Air heaters (gas to air) Tubular and regenerative air heaters (see Chapter 20) have both been used for marine boiler applications. However, the tubular air heaters have become virtually obsolete due primarily to their extremely large space requirements and their relatively poor metal temperature characteristics.

Air heater corrosion can be reduced or practically eliminated by several means. For a given exit gas temperature, metal temperatures are somewhat higher with a regenerative air heater than with a recuperative type. Therefore, for a given satisfactory metal temperature, a lower exit gas temperature and a higher unit efficiency can be obtained with a tubular type air heater. With a regenerative air heater, air temperatures of 550F (288C) or higher can be produced with a resulting exit gas temperature of 235F (113C) or less. This in turn can result in a boiler efficiency of about 90.3% when using low excess air values.

As with the tubular air heater, corrosion can be a problem when the regenerative air heater is designed for low exit gas temperature and the corresponding high air temperature. This can result in an average cold-end metal temperature well below the acid dew point of the combustion gas. Corrosion can be reduced by the use of porcelain-enameled cold-end surface.

Another alternative available when using a rotary regenerative air heater is to place a small economizer in the gas stream and/or a steam air heater on the air side ahead of the regenerative air heater. Without the economizer, the regenerative air heater becomes large due to the relatively low heat transfer rates inherent in a gas-to-air heat exchanger. Often space and weight limitations, along with the increased cost associated with a large air preheater, dictate a reduction in its size. The addition of an economizer designed to reduce the gas temperature entering the air heater by 100 to 125F (56 to 69C) reduces the size of the air heater; the air temperature to the furnace is correspondingly reduced. This can frequently provide a better arrangement and at a lower overall cost.

Boiler casing

In marine service, the walls that form the boiler and furnace enclosure, together with those surrounding the economizer and air heater, are normally made gas-tight by using metal casing. Therefore, the term *casing* is generally used for the walls surrounding a marine unit.

To provide a comfortable fireroom, an outer casing temperature of 130F (54C) is usually specified. In the double case arrangement used for tangent tube boiler construction, the space between the inner and outer casing is pressurized with air at or near the forced draft fan discharge pressure to prevent leakage of combustion gases into the fireroom and to help maintain the desired outer casing temperature. With welded wall construction the boiler is, for the most part, single-cased and pressure-sealed to prevent leakage of combustion gases into the fireroom.

Circulation and steam separation

Satisfactory circulation characteristics and efficient steam separation are of prime importance in the successful operation of any boiler. These factors take on increased importance in a marine boiler that is rolling and pitching in a seaway or undergoing rapid load changes. In analyzing circulation, the procedures outlined in Chapter 5 are applied to the design at the maximum anticipated rate of evaporation.

Generally, steam drum diameters range from 54 to 72 in. (1.37 to 1.83 m) for merchant vessels and from 54 to 60 in. (1.37 to 1.52 m) for naval units. The drum must accommodate the desired number of tube rows and provide sufficient space for steam separation, feedwater introduction, distribution and treatment, and water level fluctuations caused by sudden load variations.

Marine steam drum baffling for lower rated boilers is usually simple in construction and arrangement. A V-type baffle using a triple layer of perforated steel plates is used in moderately-rated drum boilers. With relatively small clearances between the plates, it is installed (Fig. 15) just below the normal water level

to break up steam and water jets issuing from the riser circuits. The duplex compartment baffle is more effective in higher-rated two-drum boilers. In current B&W marine boiler designs, horizontal steam separators and scrubbers are used (Fig. 16). Cyclone separators and scrubbers are used to ensure that dry steam is sent to the superheater where moisture and dissolved boiler water containment carryover would not be acceptable. The principles of these cyclone separators are similar to those of the vertical cyclones used in stationary units. (See Chapter 5.)

Drum boilers are generally rated conservatively and do not require external downcomers. Adequate circulation can be maintained by the rear rows of boiler bank tubes as downcomers, where the gas temperature is 850F (454C) or less. At low loads, the first several rows of tubes act as risers, and the remaining tubes serve as downcomers. As the firing rate increases, the high temperature gas zone moves deeper into the tube bank, the number of tubes acting as risers increases, and the number of downcomers declines. Excessive firing rates and rates beyond those contemplated in the design can reduce the number of downcomers below the minimum requirements. For highly rated units, it is necessary to install unheated downcomers to supplement the number of boiler bank tubes acting as downcomers. Circulation is benefited by interposing a convection superheater in the boiler bank because the heat absorbed by the superheater reduces the temperature of the gas flowing over the boiler tubes beyond it. More boiler tubes consequently act as downcomers over a wide operating range. In vertical superheater units, external downcomers are also required because of physical arrangement constraints.

In most horizontal superheater drum boilers (Fig. 4), furnace waterwall supply headers receive water from the lower drum through supply tubes located below the furnace floor. These tubes are spaced along the length of the waterwall headers to assure even distribution of water to the high duty furnace tubes and provide cooling for the furnace floor refractory. Naval and other high-rated designs have external downcomer tubes from the steam drum to the lower wall header because the supply of water from the boiler

Fig. 16 Arrangement of horizontal cyclone separators in a marine boiler drum.

bank alone would be inadequate. In vertical superheater drum boilers (Fig. 3), furnace waterwall supply headers receive water from the steam or lower drum through external downcomers or feeder tubes.

Drum boilers should not be located with the drum longitudinal axis athwart ship. In such a design, rolling motion may stop circulation in some riser tubes located in the sides of the boiler. This can result in tube overheating and failures. While this difficulty is alleviated by locating the drums fore and aft, ship rolling can still affect boiler circulation. During rolling, some of the rear boiler tubes in the drum may become uncovered and the overall downcomer water flow to the lower drum reduced. However, marine boilers operating at conservative load ratings are usually able to accommodate such conditions.

Section IV

Environmental Protection

Environmental protection and the control of solid, liquid and gaseous effluents or emissions are key elements in the design of all steam generating systems. The emissions from combustion systems are tightly regulated by local and federal governments, and specific rules and requirements are constantly changing. At present, the most significant of these emissions are sulfur dioxide (SO₂), oxides of nitrogen (NO_x), and fine airborne particulate. All of these require specialized equipment for control.

Chapter 32 begins this section with an overview of current regulatory requirements and overall emission control technologies. The chapter concludes with a discussion of mercury emissions control which is expected to become an integral part of overall plant multi-pollutant control strategy. Following this overview, Chapters 33, 34 and 35 discuss specific equipment to control atmospheric emissions of particulate, NO_x and SO₂ respectively. The NO_x discussion focuses on post-combustion technologies; combustion-related control options are addressed in Chapter 11 and Chapters 14 through 18.

Finally, a key element in a successful emissions control program is measurement and monitoring. Chapter 36 addresses a variety of issues and outlines a number of technologies for flue gas monitoring.

Chapter 32

Environmental Considerations

Since the early 1960s, there has been an increasing worldwide awareness that industrial growth and energy production from fossil fuels are accompanied by the release of potentially harmful pollutants into the environment. Studies to characterize emissions, sources and effects of various pollutants on human health and the environment have led to increasingly stringent legislation to control air emissions, waterway discharges and solids disposal.

Comparable concern for environmental quality has been manifest worldwide. Since the 1970s, countries of the Organization for Economic Cooperation and Development have reduced sulfur dioxide (SO₂) and nitrogen oxides (NO_x) emissions from power plants in relation to energy consumption. In at least the foreseeable future, emission trends are expected to continue downward due to a combination of factors: change in fuel mix to less polluting fuels, use of advanced technologies, and new and more strict regulations. In Japan, the reductions in SO₂ emissions were particularly pronounced due to strong environmental measures taken in the 1970s. As an example, in the United States (U.S.) between 1980 and 2001, electricity generation increased by 56%, while SO₂ emissions declined 38%.

Environmental control is primarily driven by government legislation and the resulting regulations at the local, national and international levels. These have evolved out of a public consensus that the real costs of environmental protection are worth the tangible and intangible benefits now and in the future. To address this growing awareness, the design philosophy of energy conversion systems such as steam generators has evolved from providing the lowest cost energy to providing low cost energy with an acceptable impact on the environment. Air pollution control with emphasis on particulate, NO_x, SO₂, and mercury emissions is perhaps the most significant environmental concern for fired systems and is the subject of Chapters 33 through 36. However, minimizing aqueous discharges and safely disposing of solid byproducts are also key issues for modern power systems.

Sources of plant emissions and discharges

Fig. 1 identifies most of the significant waste streams from a modern coal-fired power plant. Typical discharge rates for the primary emissions from a new, modern 615 MW coal-fired supercritical pressure boiler are summarized in Table 1.

Atmospheric emissions arise primarily from the

byproducts of the combustion process (SO₂, NO_x, particulate flyash, and some trace quantities of other materials) and are exhausted from the stack. A second source of particulate is fugitive dust from coal piles and related fuel handling equipment. This is especially significant for highly dusting western U.S. subbituminous coals. Some low temperature devolatilization of the coal can also emit other organic compounds. A final source of air emissions is the cooling tower and the associated thermal rise plume which contains water vapor.

Solid wastes arise primarily from collection of the coal ash from the bottom of the boiler, economizer and air heater hoppers, as well as from the electrostatic precipitators and fabric filters. Pyrite collected in the pulverizers (see Chapter 13) is usually also included. Most of the ash is either transported wet to an ash settling pond where it settles out or is transported dry to silos from which it is taken by truck for beneficial use (e.g., cement additive). The chemical composition and characteristics of various ashes are discussed in Chapter 21.

The second major source of solids is the byproduct from the flue gas desulfurization (FGD) scrubbing process. Most frequently, this is a mixture containing primarily calcium sulfate for wet systems and calcium sulfite for dry systems. After dewatering, the wet system byproduct may be sold as gypsum or landfilled. Additional sources of solids include the sludge from cooling tower basins, wastes from the water treatment system and wastes from periodic boiler chemical cleaning.

Aqueous discharges arise from a number of sources. These include once-through cooling water (if used), cooling tower blowdown (if used), sluice water from the ash handling system (via the settling pond), FGD waste water (frequently minimal), coal pile runoff from rainfall, boiler chemical cleaning solutions, gas-side water washing waste solutions, as well as a variety of low volume wastes including ion exchange regeneration effluent, evaporator blowdown (if used), boiler blowdown and power plant floor drains. Many of these streams are chemically characterized in Chapter 42. Additional discussions of these systems as well as the controlling regulations are provided in References 1 and 2.

Air pollution control

U.S. legislation – Clean Air Act

The Federal Clean Air Act (CAA) is the core driving force for all air pollution control legislation in the United States (U.S.). The original CAA was first en-

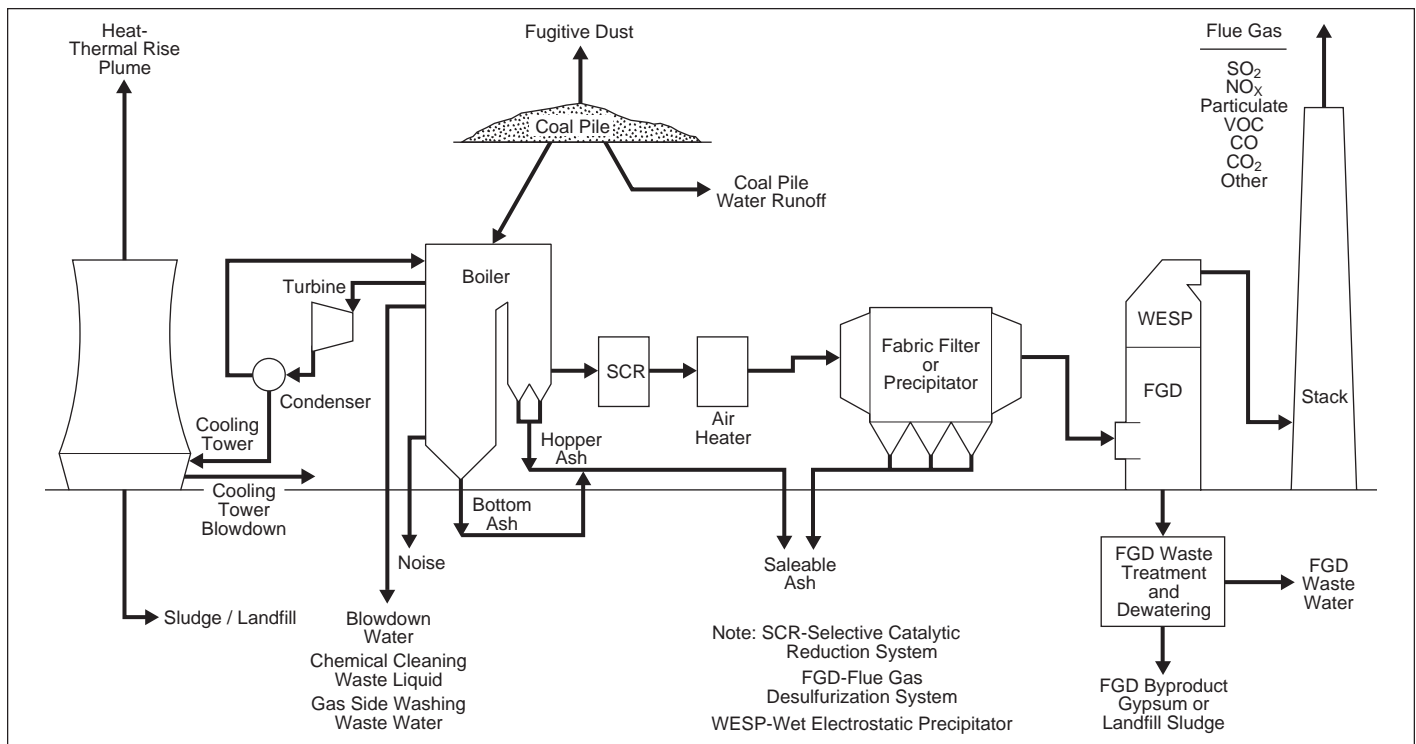

Fig. 1 Typical bituminous coal-fired power plant effluents and emissions.

acted in 1963, and since that time the Act has evolved through five significant amendment cycles in 1965, 1967, 1970, 1977, and 1990.

The primary objective of the CAA is to protect and enhance the quality of the nation's air resources to promote the public health and welfare and the productive capacity of its population.³ The legislation generally provides for the U.S. Environmental Protection Agency (EPA) to set national air quality standards and other minimum regulatory requirements through federal regulations and guidance to state and local regulatory agencies. The individual states are required to develop state implementation plans (SIPs) to define how they will meet the minimum federal requirements. However, state and local government agencies may also develop and implement more stringent air pollution control requirements. The CAA as amended prior to 1990 included the following regulatory elements of potential interest to boiler owners and operators.

National Ambient Air Quality Standards (NAAQS) Federal standards were developed to define acceptable air quality levels necessary to protect public health and welfare. The EPA promulgated National Ambient Air Quality Standards for six *Criteria Pollutants*: sulfur dioxide (SO₂), nitrogen dioxide (NO₂), carbon monoxide (CO), ozone (O₃), particulate matter and lead. Two levels of standards have been established: primary standards aimed at prevention of adverse impacts on human health and secondary standards to prevent damage to property and the environment. All geographic areas of the country are divided into a number of identifiable areas known as air quality control regions which are classified according to their air quality. Air quality control regions that meet or better the NAAQS for a designated pollutant are classified as

attainment areas for that pollutant, and regions that fail to meet the NAAQS are classified as nonattainment areas for that pollutant.

New Source Performance Standards (NSPS) Federal New Source Performance Standards were established for more than 70 categories of industrial processes and/or stationary sources. The NSPS rules set source-specific emission limitations and corresponding monitoring, recordkeeping and reporting requirements that must be met by new sources constructed on or after the effective date of an applicable standard. Sources constructed prior to the promulgation of an applicable NSPS are generally *grandfathered* and are not subject to the standards until such time that the source undergoes major modification or reconstruction. The EPA's NSPS regulations are published under Title 40, Part 60 of the Code of Federal Regulations.⁴ Table 2 provides reference to select Subparts of 40 CFR 60 applicable to a variety of industrial and utility boilers. The various NSPS rules governing fossil fuel-fired boilers include emission limitations for NO_x, SO₂, particulate and opacity. The NSPS emission limits are based on the EPA's evaluation of best demonstrated technology, and these limits are subject to periodic review and revision. Finally, the NSPS rules generally establish the least stringent emission limitation a new source would have to meet. Typically, more stringent emission limitations are necessary to meet other federal, state or local permitting requirements. For example, any significant new source or major modification to an existing source of emissions may be subject to the federal *New Source Review* rules discussed below.

New Source Review (NSR) New Source Review regulations were established to: 1) preserve existing air quality in areas of the U.S. that are in compliance with

Table 1
Modern 615 MW Supercritical Coal-Fired Steam Generator Emissions and Byproducts*
(2.3% Sulfur, 7.7% Ash, 13,100 Btu/lb Fuel)

Emission	Typical Control Equipment**	Discharge Rate — t/h (t _m /h)			
		Uncontrolled		Controlled	
SO ₂	WFGD	9.1	(8.3)	0.27	(0.25)
SO ₃	ESP or BH in conjunction with WFGD and WESP	0.2	(0.2)	0.03	(0.03)
NO _x as NO ₂	SCR (with LNB)	0.8	(0.7)	0.08	(0.07)
CO ₂	None (except cycle efficiency improvement)	536	(487)	—	—
Thermal discharge to water sources	Natural draft cooling tower	2.6 x 10 ⁹ Btu/h	(750 MW _t)	~0	(~0)
Flyash to air***	ESP or BH in conjunction with WFGD and WESP	13.0	(11.8)	0.03	(0.02)
Ash to landfill	Landfill or saleable product	2.6	(2.3)	16	(14)
WFGD gypsum byproduct	Landfill or saleable product	0.0	(0.00)	24	(22)

* See Table 1 in Chapter 1 for a typical 500 MW subcritical coal-fired steam generator.

** Definitions:

WFGD — Wet flue gas desulfurization (limestone reagent with forced oxidation)

ESP — Electrostatic precipitator

BH — Baghouse fabric filter

WESP — Wet electrostatic precipitator

SCR — Selective catalytic reduction

LNB — Low NO_x burners with overfire air

*** As flyash emissions to the air decline, ash shipped to landfills or alternate uses increases.

the NAAQS, and 2) avoid further degradation and improve air quality in those areas of the U.S. that do not meet the NAAQS. NSR as discussed herein refers to two separate and distinct regulatory programs: *Prevention of Significant Deterioration (PSD)* and *nonattainment NSR*. In general, the NSR process requires any major new source or major modification to an existing source, which exceeds certain specified emission thresholds defined in the regulations,⁵ to obtain permits and undertake other obligations prior to construction. A new or modified source subject to NSR generally must: 1) evaluate its potential impact on existing air quality, and 2) evaluate and utilize state-of-the-art air pollution control technologies. Under NSR, an affected project must conduct a pollutant-by-pollutant emissions evaluation. If a source is located in (or is impacting) an area which is in attainment with the NAAQS, the PSD rules apply. If the source is located in (or is impacting) a nonattainment area, the nonattainment NSR rules apply. Because a source may be located in an attainment area for one or more designated pollutants and in a nonattainment area for other designated pollutants, both the PSD and nonattainment NSR rules can apply simultaneously.

The PSD permitting process typically requires an air quality modeling analysis (which may require more than a year's worth of ambient air monitoring data) to demonstrate that new emissions will not cause a violation of the NAAQS or result in a significant deterioration of the existing air quality. Numerical limits (air quality increments) have been established by regulation for NO_x, SO₂ and fine particulate matter that restrict how much of the existing ambient air quality (µg/m³) can be consumed by a new or modified emission source. All areas in the U.S. that meet

the NAAQS are ranked into one of three classifications which determine the allowable increment consumption. Class I areas (national parks and designated wilderness areas) are to be kept in a pristine condition, whereas Class II or III areas allow for some further industrial growth. As might be expected, Class I areas allow almost no degradation of existing air quality. In addition to air quality impact analyses, the PSD process requires the use of *Best Available Control Technology (BACT)*. A permit applicant must conduct a thorough evaluation of available control technologies (considering energy, environmental and economic impacts) for each pollutant subject to PSD review. The permitting authority then evaluates, accepts or rejects the proposed control technology. Once the control technology is agreed upon, the applicant and permitting authority determine a final permit limit that represents BACT. As part of this process, BACT limits contained in other PSD permits issued to similar sources throughout the U.S. must be considered and final BACT limits can not be less stringent than any applicable NSPS limit.

Unlike the PSD permitting process, nonattainment NSR does not require ambient air modeling or monitoring; however, a new or modified source subject to nonattainment NSR must offset the impact of new emissions by securing emission reductions from other sources in the area. The amount of reduction (offset) must be as great as, or greater than, the new increase in emissions, and the required offset is based on the severity of the area's air quality issues. The more polluted the air, the greater the required emissions offset. Offsets must be real reductions in existing emission rates, not otherwise required by regulations under the Clean Air Act, must be enforceable by the EPA, and must result in a positive net air quality benefit.

Table 2
Selected Categories – New Source Performance Standards (40 CFR Part 60)⁴

40 CFR Part 60 Subpart	Title/Description
D	Performance Standards for Fossil Fuel Fired Steam Generators ($\geq 250 \times 10^6$ Btu/h) constructed after 08/17/71 (Note: generally superseded by Subparts Da or Db)
Da	Performance Standards for Electric Utility Steam Generating Units constructed after 09/18/78
Db	Performance Standards for Industrial, Commercial, Institutional Steam Generating Units ($\geq 100 \times 10^6$ Btu/h) constructed after 06/19/84
Dc	Performance Standards for Small ($< 100 \times 10^6$ Btu/h) Industrial, Commercial, Institutional Steam Generating Units constructed after 06/09/89
Cb	Emission Guidelines for Large Municipal Waste Combustors constructed on or before 09/26/94
Ea	Performance Standards for Municipal Waste Combustors constructed after 12/20/89 and on or before 09/20/94
Eb	Performance Standards for Large Municipal Waste Combustors constructed after 09/20/94 or modified after 06/19/96
Y	Performance Standards for Coal Preparation Plants
BB	Performance Standards for Kraft Pulp Mills (Note: includes kraft recovery boilers)
AAAA	Performance Standards for Small Municipal Waste Combustors constructed after 08/30/99 or modified after 06/06/01
BBBB	Emission Guidelines for Small Municipal Waste Combustion Units constructed on or before 08/30/99

In general, offsets must be secured for the life of the source. In addition to achieving a net improvement in air quality through offsets, an affected source must utilize state-of-the-art controls to achieve the *Lowest Achievable Emission Rate* (LAER). LAER is based on the most stringent emission limitation contained in any SIP, contained in an existing permit, or achieved in practice by a similar source, regardless of cost or other economic consideration. Final LAER emission limits are established as an integral part of the NSR permitting process.

For further details and current information regarding the NSR rules, including NSR reforms that may impact the utility industry, see the following EPA Web page: www.epa.gov/nsr/

The 1990 Clean Air Act Amendments

The 1990 Clean Air Act Amendments added many new provisions to the existing Act, several of which have significantly impacted the electric utility industry. Under Title I of the Act, areas of the country that do not meet the National Ambient Air Quality Standards (NAAQS) were given new classifications and deadlines to achieve compliance. This provision of the Act has forced a dramatic reduction in NO_x emissions from utility and large industrial boilers located in the eastern U.S. because large portions of the northeast are ozone nonattainment areas and NO_x is a primary precursor to the formation of ozone. Title III of the Act authorized a new regulatory scenario for controlling 188 *hazardous air pollutants* (HAPs) from a wide range of industrial and commercial sources. Title IV of the Act established a new *Acid Deposition Control* program principally aimed at reducing SO_2 and NO_x emissions from older electric utility plants.

SO_2 and NO_x control under the 1990 Clean Air Act Prior to the 1990 CAA, a large population of existing electric utility boilers, generally built before 1971, were grandfathered and did not have to meet NSPS emission limits or comply with NSR requirements unless they were significantly modified or upgraded. Coal-fired utility boilers built between 1971 and 1978 were required (by promulgation of New Source Performance Standards) to limit SO_2 emissions to 1.2 lb/ 10^6 Btu heat input and compliance could be achieved by utilizing low-sulfur coals. However, coal-fired utility boilers built after 1978 were further required (by promulgation of additional New Source Performance Standards) to install scrubbers to achieve between 70 and 90% SO_2 removal efficiency.

Under the 1990 Amendments, Title IV of the Act (Acid Deposition Control) established a new SO_2 control program aimed at reducing emissions from all existing electric utility boilers through an innovative cap-and-trade program. The Acid Deposition Control program (commonly referred to as the Acid Rain program) set a goal of reducing annual SO_2 emissions by 10 million tons in a two-phased process. Phase I of the SO_2 program began in 1995 and initially affected 263 units at 110 mostly coal-burning electric utility plants located in 21 eastern and mid-western states. Phase II, which began in 2000, tightened the annual emissions limits imposed on the Phase I units and set limitations on smaller, cleaner plants fired by coal, oil, and natural gas, ultimately impacting more than 2,000 total units.

Under the SO_2 cap-and-trade program, an affected unit must hold (own) one SO_2 Allowance to cover each ton of SO_2 emitted in a given year. Existing units were initially given a pre-determined allocation of yearly

allowances based on historical fuel consumption rates (heat input) and a mandated SO₂ emission rate (lb per million Btu heat input). A source owner has various options available to demonstrate compliance including: 1) reducing emissions through fuel switching, 2) adding more control equipment or improving the performance of existing control equipment, or 3) acquiring (purchasing) SO₂ allowances from other units. The bottom line compliance measure is straight forward; total SO₂ emissions from a unit in any given year must be covered by an equivalent number of SO₂ allowances. Once an allowance is used it is retired and any unused allowances may be sold or held (*banked*) with certain restrictions for future use. The total number of yearly SO₂ allowances allocated nationwide under Phase II of the program is fixed at 8.95 million tons and new power plants do not receive allowances. This effectively caps yearly SO₂ emissions from utility boilers at 8.95 million tons and ensures that the mandated reductions are maintained over time.

The Acid Rain program also mandated NO_x emission reductions from all existing utility boilers through a more traditional command-and-control approach where different types of boilers or combustion equipment were required to meet specified performance levels (i.e., a NO_x limit in pounds per million Btu of heat input). The NO_x command-and-control requirements were also implemented in a two-phased process with a goal of reducing utility boiler NO_x emissions by 2 million tons from 1980 levels.

The EPA's rules governing the Acid Rain program are published in the Code of Federal Regulations, under Title 40, Part(s) 72 through 78.

Further to the NO_x reductions mandated under the Acid Rain program, the EPA also implemented additional control measures (as authorized under Title I of the Act) to reduce interstate transport of NO_x emissions that contribute to ozone nonattainment problems in the eastern part of the U.S. These additional NO_x control measures (referred to herein as the *NO_x Budget programs*) are structured similarly to the SO₂ cap-and-trade program discussed above. However, unlike the SO₂ program which applies to all utility boilers year round, the NO_x Budget programs only apply to specified sources in the eastern part of the U.S. during the five month ozone season extending from May through September. As of this writing, the EPA has implemented the broadest of these NO_x Budget programs through a SIP Call (request for State Implementation Plans) mandating further NO_x reductions from electric utility boilers and other large industrial sources located in 21 eastern states and the District of Columbia (see Fig. 2).

For further details and current information regarding the SO₂ and NO_x trading programs see the following EPA Web page: www.epa.gov/airmarkets/

Control of air toxics under the 1990 Clean Air Act The 1990 CAA Amendments significantly changed the pre-existing regulatory structure for addressing air toxics. Prior to the 1990 amendments, the Act required the EPA to identify and regulate, on a pollutant-by-pollutant basis, each non-criteria air pollutant that in its judgment caused significant health risks. This regu-

latory approach was largely ineffective as the EPA became involved in many legal, scientific, and policy debates over which pollutants to regulate and how stringently to regulate them. As a result, only seven pollutants had been regulated by 1990.

The 1990 CAA redirected the EPA to impose tighter controls for a broad range of air toxics through a two-phase approach. The first phase requires the EPA to develop technology-based standards for categories of sources that have the potential to emit significant quantities of 188 (originally 189) HAPs which were specifically identified in the Act. The second phase requires the EPA to impose further controls, beyond the initial technology-based standards, as necessary to address any remaining health risk concerns. Under the first phase, the EPA must develop *Maximum Achievable Control Technology* (MACT) standards for different classes or categories of sources that could be considered *major* emitters of HAP as well as other smaller *area* HAP sources. A major HAP source is defined as any type of stationary source with the potential to emit 10 tons per year of a single HAP or 25 tons per year of a combination of HAPs. An area source is defined to include smaller source categories (such as dry cleaners, gas stations, etc.) that are not by themselves a major source, but may collectively emit HAPs in sufficient quantities to warrant regulation. The applicable MACT standard for a given type or category of source must reflect emission performance levels that are already being achieved in practice by the better controlled, lower emitting units within a common source category. As of this writing, the EPA has proposed or promulgated MACT standards for more than 80 different source categories including but not limited to industrial, commercial and institutional boilers and process heaters; combustion sources at kraft, soda, and sulfite pulp and paper mills; and fossil fuel-fired electric utility boilers. The EPA's final MACT rules

Fig. 2 Area covered by NO_x SIP Call is shown in gray.

for various categories of sources are published in the Code of Federal Regulations, under Title 40, Part 63.

The 1990 CAA specifically directed the EPA to study hazardous air emissions, including mercury, from electric utility plants and to regulate such emissions as necessary to protect public health. In December 2000, the EPA issued a formal determination that regulation of HAP emissions, principally mercury from coal-fired electric utility boilers and nickel from oil-fired utility boilers, was appropriate and necessary. As discussed later in this chapter in the mercury emissions and control technologies section, several regulatory options are being proposed to address mercury control as of the date of this publication.

For further details and current information regarding the HAP regulations, including source-specific MACT standards and proposed alternatives for regulating mercury from electric utility boilers, see the following EPA Web page(s): www.epa.gov/ttn/atw/index.html and www.epa.gov/mercury/

Pending legislation/regulation As of the date of this publication, a number of U.S. Federal and State legislative and regulatory initiatives are underway to further reduce air emissions from fossil fuel-fired power plants. The most significant of the near-term initiatives are addressed in an inter-related suite of proposed rules collectively known as the *Clean Air Rules*. This suite of rules includes the proposed mercury cap-and-trade program discussed later; proposed rules to achieve further reductions in emissions of SO₂ and NO_x from power plants; and additional measures to address ozone and fine particle pollution throughout the U.S. While the final form of these regulatory initiatives can not be determined at the time of this writing, the direction of future regulatory actions will no doubt focus on achieving further improvements in air quality in the most effective way possible. For further details and current information regarding these initiatives and others, see the following EPA Web page: www.epa.gov.

International regulations – air pollution control

The passage of the Clean Air Act in the U.S. in 1963, marked the first enactment of air pollution control legislation by a major industrial nation. Since that time, air pollution control regulations have become more widespread in industrial and developing nations, particularly in Japan, Canada, and the European Union.^{6,7} Many of the rapidly developing nations such as Korea, Taiwan, China, and the countries of former Eastern Europe are also aggressively controlling power plant emissions as their rapidly growing economies strain local ecosystems. As in the U.S., steam generating plants have been one focus of these regulatory measures, and the most common emissions of concern from combustion processes are SO₂, NO_x, particulates, and air toxics. The detailed regulations continue to evolve rapidly and are quite country specific. However, two trends are widespread:

1. Allowable emission limits for controlled pollutants will continue to decline with time.
2. A wider array of species will be considered for control.

Without attempting to be comprehensive, the following items provide a brief overview of worldwide SO₂ and NO_x regulatory efforts. These items provide a general indication of the range and application of control measures.

Control approaches One or more of the following measures have typically been adopted to control emissions:

1. *Emission standards* These limit the mass of SO₂, NO_x, or other pollutant emitted by volume, by heat input, by electric energy output, or by unit of time (hourly, daily, annually).
2. *Percent removal requirements* These specify the portion of the uncontrolled emissions that must be removed from the flue gas.
3. *Fuel requirements* Primarily aimed at SO₂ control, these either limit the type of fuel that can be burned or the fuel sulfur content.
4. *Technology requirements* These typically indicate the type of control technology specifically required or indicate the use of the best available control technology or reasonably available control technology at the time of installation. These requirements depend in many cases on some level of economic feasibility.

The most widely used control approach is emission standards, although this is usually combined with one or more of the other approaches. Emissions from new plants are usually more tightly controlled than emissions from existing capacity. Occasionally, older plants are not controlled, although this is changing, especially with the application of national cap-and-trade policies in the U.S. There have also been significant discussions on the applicability of international cap-and-trade programs that will link two or more national cap-and-trade programs together. The international cap-and-trade programs are proposed in the European Union (EU) Directive.

Emission control legislation and regulations throughout the world are currently in a state of flux as a variety of new and increasingly stringent regulations are phased in. Reference 6 provides a comprehensive and detailed summary of regulatory measures and current trends as of the end of 2003. The resulting compilation is quite complex as countries and areas consider the most effective alternatives. Reference 7 provides more detail for NO_x control.

Emissions standards worldwide are stated in a variety of units. See Appendix 1, Conversion Formulae for Emission Units.

Kinds of pollutants, sources and impacts

Air pollutants are contaminants in the atmosphere which, because of their quantity or characteristics, have deleterious effects on human health and/or the environment. The sources of these pollutants are classified as stationary, mobile or fugitive. Stationary sources generally include large individual point sources of emissions such as electric utility power plants and industrial furnaces where emissions are discharged through a stack. Mobile sources are those associated with transportation activities. Fugitive emissions generally include discharges to the atmosphere from conveyors, pumps, valves, seals and other

process points not vented through a stack. They also include emissions from area sources such as coal piles, landfills, ponds and lagoons. They most often consist of particulates and occur in industry-related activities in which the emissions are not collected.

The focus of this chapter is stationary emission sources, particularly fired utility and industrial boiler systems. Key pollutants from these sources are SO₂, SO₃, NO_x, CO and particulate matter. Another class of emissions is called air toxics. These are potentially hazardous pollutants that generally occur in only trace quantities in the effluents from fired processes. However, they are undergoing more intense examination because of their potential health effects.

Sulfur dioxide Most of the sulfur in fuel converts to SO₂ with small quantities of sulfur trioxide (SO₃). The main source of sulfur oxides is from the combustion of coal, with lesser amounts from other fuels such as residual fuel oil. Based upon the August 2003 revision of the U.S. EPA National Emissions Inventory (NEI) program, the utility and industrial sectors (smelters, iron and steel mills, refineries) remain the largest emitters of sulfur oxides (see Table 3).⁸ Sulfur oxides have been related to irritation of the human respiratory system, reduced visibility, materials corrosion and varying effects on vegetation. The reaction of sulfur oxides with moisture in the atmosphere has been identified as contributing to acid rain.

Sulfur trioxide Some of the sulfur dioxide that forms converts to sulfur trioxide (SO₃). The typical conversion rate is 1% or less in the boiler. However, the catalytic process that is frequently used to control NO_x levels has the undesirable side effect of converting additional SO₂ to SO₃, which can range from 0.5 to 2% additional conversion. The SO₃ readily combines with water to form sulfuric acid (H₂SO₄) at flue gas temperatures less than 500F (260C). This acid can create extremely corrosive conditions. The sulfuric acid condenses to form a fine mist when the flue gas passes through a wet flue gas desulfurization system that is used to remove sulfur dioxide (SO₂). This sulfuric acid mist contributes to the total stack particulate loading. Such mist is extremely fine, less than 0.5 micron, and very small amounts of this mist (5 ppm or less) can cause visible, bluish stack plumes, even in the absence of solid particulate.

Nitrogen oxides (NO_x) This category includes numerous species comprised of nitrogen and oxygen, although nitric oxide (NO) and nitrogen dioxide (NO₂) are the most significant in terms of quantity released to the atmosphere. NO is the primary nitrogen compound formed in high temperature combustion processes where nitrogen present in the fuel and/or combustion air combines with oxygen. The quantity of NO_x formed during combustion depends on the quantity of nitrogen and oxygen available, the temperature, the intensity of mixing and the time for reaction. Control of these parameters has formed the basis for a number of control strategies involving combustion process control and burner design. Based on the most recent EPA emissions inventory, utilities account for 22% of NO_x emitted in the U.S., with the transportation sector emitting 56%. Of the total utility NO_x emis-

sions, approximately 90% comes from coal-fired boilers. The most deleterious effects come from NO₂ which forms from the reaction of NO and oxygen. NO₂ also absorbs the full visible spectrum and can reduce visibility. NO_x has been associated with respiratory disorders, corrosion and degradation of materials, and damage to vegetation. NO_x has also been identified as a precursor to ozone and smog formation.

Carbon monoxide This colorless, odorless gas is formed from incomplete combustion of carbonaceous fuels. CO emissions from properly designed and operated utility boilers are a relatively small percentage of total U.S. combustion source CO emissions, most of which come from the internal combustion engine in the transportation sector. The primary environmental significance of CO is its effect on human and animal health. It is absorbed by the lungs and reduces the oxygen carrying capacity of the blood. Depending on the concentration and exposure time, it can cause impaired motor skills and physiological stress.

Particulate matter Solid and liquid matter of organic or inorganic composition which is suspended in flue gas or the atmosphere is generally referred to as particulate. Particle sizes from combustion sources are in the 1 to 100 µm range, although particles smaller than 1 µm can occur through condensation processes. Among the effects of particulate emissions are impaired visibility, soiling of surrounding areas, aggravation of adverse effects of SO₂, and human respiratory problems.

PM₁₀ and PM_{2.5} Subsets of particulate matter, PM₁₀ is particulate matter 10 µm and finer and PM_{2.5} is particulate matter 2.5 µm and finer. Fine particles are emitted from industrial and residential oil combustion and from vehicle exhaust. Fine particles are also formed in the atmosphere when gases such as SO₂, NO_x and VOCs, emitted by combustion processes, are transformed into fine particulate by chemical reactions in the air (i.e., sulfuric acid, nitric acid, and photochemical smog). PM_{2.5} is considered to have more deleterious health affects than coarser particulate.

VOC Volatile organic compounds represent a wide range of organic substances. These compounds con-

Table 3
2002 U.S. Emissions
U.S. EPA National Emission Inventory⁸

Category	Emissions (10 ³ short tons)			
	SO ₂	NO _x	VOC	TSP
Utility combustion	10,293	4,699	52	695
Industrial combustion	2,299	2,870	170	269
Other combustion	575	725	790	405
Industrial process	1,399	1,000	7,418	1,127
Transportation	696	11,452	7,231	515
Other	91	356	883	19,142
Total	15,353	21,102	16,544	22,153

Notes: SO₂ — Sulfur dioxide
NO_x — Nitrogen oxides as NO₂
VOC — Volatile organic compounds
TSP — Total solid particulate (PM-10)

sist of molecules containing carbon and hydrogen, and include aromatics, olefins and paraffins. A major source is the refining and use of petroleum products. Also included among VOCs are compounds derived from primary hydrocarbons including aldehydes, ketones and halogenated hydrocarbons. The major source of these compounds is the transportation and the commercial/residential combustion sectors. VOCs are environmentally significant because of their role in the formation of photochemical smog through photochemical reactions with NO_x . Control of VOCs has been a primary means of addressing areas of ozone nonattainment. Smog arising from VOC emissions can cause respiratory problems, eye irritation, damage to vegetation and reduced visibility.

Toxic air pollutants This is a large category of air pollutants that could have hazardous effects.⁹ The EPA had only promulgated standards for arsenic, asbestos, benzene, beryllium, mercury, radionuclides and vinyl chlorides for certain defined industries before the passage of the 1990 Amendments to the Clean Air Act. The 1990 Act first identified 189 toxic pollutants for which emissions are to be regulated. The list includes a wide range of simple and complex industrial organic chemicals and a small number of inorganics, particularly heavy metals. The EPA has identified hundreds of categories of air toxics sources, among which are municipal solid waste combustors, industrial boilers, and electric utility boilers. For these combustion sources, mercury has been the primary focus.

Mercury Present in only trace amounts in coal, mercury is released during the combustion process as elemental mercury, and is predominantly in the vapor phase at the exit of the furnace. Emissions from utility plants are extremely low. While other pollutants are recorded in pounds per million Btu (mg/Nm^3), mercury emissions are typically six orders of magnitude less and are frequently expressed in units of pounds per trillion Btu or $\mu\text{g}/\text{Nm}$. Fig. 3 indicates that the utility emissions account for approximately one-third of the U.S. manmade emissions of mercury or 48 tons/year ($43.5\text{t}_m/\text{year}$). (See Reference 10.)

Mercury in some chemical forms is very toxic. From whatever source, mercury can find its way into water sources where it can be converted into water soluble species such as methyl-mercury by microorganisms and accumulate in the fatty tissues of fish. Consumption of contaminated fish is the main identified risk to humans.

Carbon dioxide During the 1980s, concern increased about the potential impact of carbon dioxide (CO_2) emissions from manmade sources. CO_2 is one of several so-called *greenhouse* gases which may impact the climate and contribute to global warming. CO_2 is emitted from a variety of naturally occurring and manmade sources including the combustion of all fossil and hydrocarbon based fuels.

Greenhouse gas emissions in the U.S. totaled 1906 million metric tons in 2000, of which 83% or 1583 million metric tons was CO_2 . CO_2 from the electric power sector totaled 642 million metric tons or 33.6% of total greenhouse gas emissions.¹¹

Improving the power cycle efficiency (more power from less fuel) and the use of fuels with less carbon

content are potential methods to address CO_2 emissions from any combustion source. Another option is separation and capture followed by sequestration. However, technology similar to SO_2 scrubbers or particulate collectors does not exist for carbon dioxide. Although CO_2 separation technologies exist, they are at present not economically viable for the large volumes of flue gas produced by electric power generation. Geologic, terrestrial, or ocean sequestration have their own technical and political challenges. Geologic sequestration holds considerable potential, as the storage capacity is estimated to be centuries of emissions, and this route may be the most environmentally acceptable.

Air pollution control technologies

The strategies for control of all emissions from a utility or industrial boiler are formulated by considering design fuels, kind and extent of emission reduction mandated, and economic factors such as boiler design, location, new or existing equipment, age and remaining life.

SO_2 control strategies and technologies SO_2 emissions from coal-fired boilers can be reduced using pre-combustion techniques, combustion modifications and post-combustion methods.

Pre-combustion These techniques include the use of natural gas or low sulfur oil in new units or the use of cleaned (beneficiated) coal or fuel switching in existing units. By using natural gas, sulfur emissions can be reduced to almost zero while the use of low sulfur oil will minimize SO_2 emissions. While the low sulfur content of oil and gas is advantageous, the price volatility and availability of these fuels make them less attractive. Switching to oil and gas in existing boilers requires attention be given to receiving equipment, storage facilities, combustion equipment including safety systems and boiler design. In the case of new systems, oil or gas firing can significantly reduce steam system capital costs. Even switching from one coal to another lower sulfur coal can have a dramatic impact on fuel handling, combustion and particulate collection equipment. These effects are explored in more detail in Chapters 21 and 44.

Fig. 3 Anthropogenic (manmade) emissions of mercury in the U.S.

Combustion modifications These techniques are primarily used to reduce NO_x emissions but can also be used to control SO_2 emissions in fluidized-bed combustion where limestone is used as the bed material. The limestone can absorb up to 90% of the sulfur released during the combustion process. (See Chapter 17.)

Sorbent injection technologies Sorbent injection, while not involving modification of the combustion process, is applied in temperature regions ranging from those just outside the combustion zone in the upper furnace to those at the economizer and flue work following the air heater. Sorbent injection involves adding an alkali compound to the coal combustion gases for reaction with the SO_2 . Typical calcium sorbents include limestone [calcium carbonate (CaCO_3)], lime (CaO), hydrated lime [$\text{Ca}(\text{OH})_2$] and modifications of these compounds with special additives. Sodium or magnesium based compounds are also used.

Wet and dry scrubbing technology Worldwide, wet and dry scrubbing or flue gas desulfurization (FGD) systems are the most commonly used technologies in the coal-fired electric utility industry. 2003 data indicate that in the U.S. more than 30% of the coal-fired utility capacity have SO_2 emission control. In contrast, more than 90% of coal-fired utility boilers in Germany and Japan have SO_2 control. Both wet and dry scrubbing use slurries of sorbent and water to react with SO_2 in flue gas, producing wet and dry waste products. (See Chapter 35.)

In the wet scrubbing process, a sorbent slurry consisting of water mixed with limestone, lime, magnesium promoted lime or sodium carbonate (Na_2CO_3) is contacted with flue gas in a reactor vessel. Wet scrubbing is a highly efficient (> 97% removal at calcium/sulfur molar ratios close to 1.0), well established technology which can produce usable byproducts.

Dry scrubbing involves spraying an aqueous sorbent slurry into a reactor vessel so that the slurry droplets dry as they contact the hot flue gas [$\sim 300^\circ\text{F}$ ($\sim 149^\circ\text{C}$)]. The SO_2 reaction occurs during the drying process and results in a dry particulate containing reaction products and unreacted sorbent entrained in the flue gas along with flyash. These materials are captured downstream in the particulate control equipment. Dry scrubbing is a well established technology with considerable operational flexibility. The waste residue is dry.

NO_x control technologies NO_x emissions from fossil fuel-fired industrial and utility boilers arise from the nitrogen compounds in the fuel and molecular nitrogen in the air supplied for combustion. Conversion of molecular and fuel nitrogen into NO_x is promoted by high temperatures and high volumetric heat release rates found in boilers. The main strategies for reducing NO_x emissions take two forms: 1) modification of the combustion process to control fuel and air mixing, and reduce flame temperatures, and 2) post-combustion treatment of the flue gas to remove NO_x . (See Chapters 11, 14, 16, and 34.)

Combustion modification This approach to NO_x reduction can include the use of low NO_x burners, combustion staging, gas recirculation or reburn technology.

Low NO_x burners slow and control the rate of fuel and

air mixing, thereby reducing oxygen availability in the ignition and main combustion zones. Low NO_x burners can reduce NO_x emissions by 50% or more, depending upon the initial conditions, are relatively low cost, and are applicable to new plants as well as retrofits.

Staged combustion uses low excess air levels in the primary combustion zone with the remaining (overfire) air added higher in the furnace to complete combustion. In some cases, the primary combustion zone may be operated substoichiometrically. Significant NO_x reductions are possible with staged combustion, although reducing zones and potential for corrosion and slagging exist.

Flue gas recirculation reduces oxygen concentration and combustion temperatures by recirculating some of the flue gas to the furnace without increasing total net gas mass flow. Large NO_x reductions are possible with oil and gas firing while only small reductions at best are possible with coal firing. Modifications to the boiler in the form of ducting and an efficiency penalty due to power requirements of the recirculation fans can make the cost of this option higher than some of the other in-furnace NO_x control methods.

Reburning is a technology used to reduce NO_x emissions in selected applications. In reburning, 75 to 80% of the furnace fuel input is burned in the primary combustion zone with minimum excess air. The remaining fuel (gas, oil or coal) is added to the furnace above the primary combustion zone. This secondary combustion zone is operated substoichiometrically to generate hydrocarbon radicals which reduce NO formed in the initial combustion to N_2 . The combustion process is then completed by adding the balance of the combustion air through overfire air ports in a final burn-out zone further up the furnace.

Post-combustion The two main post-combustion techniques for NO_x control are selective noncatalytic reduction (SNCR) and selective catalytic reduction (SCR). In SNCR, ammonia or other compounds such as urea (which thermally decomposes to produce ammonia) are injected downstream of the combustion zone in a temperature region of 1400 to 2000°F (760 to 1093°C). SCR systems remove NO_x from flue gases by reaction with ammonia in the presence of a catalyst (see Chapter 34). SCR is being used worldwide where high NO_x removal efficiencies are required in gas-, oil- or coal-fired industrial and utility boilers.

Particulate control technologies Particulate emissions from boilers arise from the noncombustible, ash forming mineral matter in the fuel that is released during the combustion process and is carried by the flue gas. Another source of particulate is the incomplete combustion of the fuel which results in unburned carbon particles. A brief description of the principal options for particulate emissions control in industrial and utility boilers follows while Chapter 33 provides an in-depth discussion.

Coal cleaning Historically, physical coal cleaning has been applied to reduce mineral matter, increase energy content and provide a more uniform boiler feed. Although reduction in flue gas particulate loading is one of the potential benefits, coal cleaning has been driven by the many other boiler performance benefits

related to improved boiler maintenance and availability and, more recently, the reduction in SO₂ emissions.

Mechanical collectors These are generally cyclone collectors and have been widely used on small boilers when less stringent particulate emission limits apply. Cyclones are low-cost, simple, compact and rugged devices. However, conventional cyclones are limited to collection efficiencies of about 90% and are poor at collecting the smallest particles. Improvements in small particle collection are accompanied by high pressure drops.

Fabric filters These filters, also commonly referred to as baghouses, are available in a number of designs (reverse air, pulse jet, and shake/deflate), each having advantages and disadvantages in various applications. Applications include industrial and utility power plants firing coal or solid wastes, plants using sorbent injection and spray dryer FGD, and fluidized-bed combustors. Collection efficiency can be expected to be at least 99.9% or greater. Fabric filters have the potential for enhancing SO₂ capture in installations downstream of sorbent injection and dry scrubbing systems as discussed in Chapter 35.

Electrostatic precipitators (ESP) ESPs are available in a broad range of sizes for utility and industrial applications. Collecting efficiency can be expected to be 99.8% or greater of the inlet dust loading. ESPs are considered to be less sensitive to plant upsets than fabric filters because their materials are not as sensitive to maximum temperatures. They also have a very low pressure drop. ESP performance is sensitive to flyash loading, ash resistivity and coal sulfur content. Lower sulfur concentrations in the flue gas can lead to lower ESP collection efficiency. ESPs tend to collect coarser particulate more easily, whereas a fabric filter tends to have a more uniform collection efficiency across the particle size range. Therefore, a fabric filter has higher collection efficiency of fine particulate than an ESP. The desire to further control sulfuric acid mist emissions and very fine flyash has led to the utilization of wet ESPs downstream of wet flue gas desulfurization systems.

Mercury emissions and control technologies

Regulatory considerations

As discussed earlier in this chapter, mercury emissions are regulated under the hazardous air pollutants (HAPs) sector of the Clean Air Act. Mercury emission regulations are already in place for municipal solid waste (MSW) combustors, medical waste incinerators, and cement plants with the following levels as of this writing:

Source	Regulation
MSW combustion	0.08 mg/DSCM or 85% reduction
Medical waste incinerators	0.55 mg/DSCM or 85% reduction
Cement plants	0.12 mg/DSCM (existing plants), 0.056 mg/DSCM (new plants)

Note: DSCM = dry standard cubic meter (at 32F/0C)

The EPA has also determined that it is both appropriate and necessary to regulate utility units for emissions of mercury. As of this writing, the EPA has proposed several regulatory alternatives for controlling mercury emissions from new and existing electric utility boilers which generally fall into two categories: 1) MACT standards as discussed above, or 2) alternate performance standards coupled with a market based cap-and-trade program. EPA has promulgated rules for a cap-and-trade program where mercury reductions would occur over a two-phase process. When fully implemented by 2018, this would result in estimated mercury emission reductions of 33 tons (30.0 t_m) per year or approximately 70%. As of this writing, the pros and cons associated with the regulatory alternatives are the subject of extensive debate and the final outcome and timing are uncertain. However, mercury will be controlled and emissions reduced over time.

Mercury in U.S. coals

Coals vary in mercury content by rank, seam, mine, and mine internal location. Table 4 summarizes the mercury content data obtained for U.S. bituminous, subbituminous and lignite coals fired at U.S. utilities as part of an EPA study (see Reference 12). There are only modest differences between the average mercury contents of the three ranks of coal. However, the variation in mercury content among coals within a given rank is much larger.

Mercury in coal combustion flue gas

Mercury appears in coal combustion flue gas in both the solid and gas phases (*particulate-bound* mercury and *vapor-phase* mercury, respectively). Due to the high volatility of mercury and many of its compounds, most of the mercury found in flue gas is vapor-phase. Vapor-phase mercury, in turn, can appear as *elemental* mercury (elemental, metallic mercury vapor) or as *oxidized* mercury (vapor-phase species of various compounds of mercury). The form of mercury present, commonly referred to as *speciation*, is a key factor in the development of emissions control strategies.

Mercury speciation and emissions data have been gathered under an EPA study, wherein a subset of the U.S. boiler population was selected for flue gas emissions sampling on the basis of fuel type, boiler configuration, particulate control device, and SO₂ control technology (see Reference 12). This EPA study is known as the Information Collection Request (ICR). Flue gas sampling, in triplicate, was performed at approximately 84 U.S. plants to quantify total mercury and mercury speciation at the inlet and outlet of the last emission control device. The EPA Preliminary Test Method 003 [PRE-003: Standard Test Method for Elemental, Oxidized, Particle-Bound, and Total Mercury in Flue Gas Generated from Coal-Fired Stationary Sources (Ontario Hydro Method)] was used to determine the particulate-bound and vapor-phase mercury emissions. In the Ontario Hydro Method, flue gas samples are withdrawn isokinetically from the flue. The mercury species are collected on a quartz fiber filter, in potassium chloride (KCl) solutions, and in acidic peroxide and acidic potassium permanganate.

Table 4
Mercury in Selected U.S. Coals¹²

Coal Type	Number of Analyses	lb Hg/trillion Btu (HHV)		
		Low	High	Median
Bituminous	27,884	0.04	103.81	8.59
Subbituminous	8,193	0.39	71.08	5.74
Lignite	1,047	0.93	75.06	10.54

ate (KMnO₄) solutions. Mercury speciation is reported on the basis that the oxidized form of mercury is collected in the KCl impingers, and the elemental form of mercury is collected in the peroxide and potassium permanganate impingers.

Results of these extensive studies indicated that the speciation of vapor-phase mercury depends on coal type and other factors. Eastern U.S. bituminous coals tend to produce a higher percentage of oxidized mercury than do western subbituminous and lignite coals. Western coals have low chloride content compared to typical eastern bituminous coals. It has been recognized for several years that an empirical relationship holds between the chloride content of coal and the extent to which mercury appears in the oxidized form. Fig. 4 illustrates the relationship between coal chlorine content and vapor-phase mercury speciation for the plants and coals tested in the EPA study. An important reason for the significant uncertainty (scatter) is that mercury oxidation proceeds by both homogeneous (gas-to-gas) and heterogeneous (gas-to-solid) reaction mechanisms. Boiler convection pass and air heater temperature profiles, flue gas composition, flyash characteristics, and the presence of unburned carbon have all been shown to affect the conversion of elemental mercury to oxidized mercury species. Table 5 provides a summary of general mercury speciation by coal type.

Mercury control technologies

For industrial sources, such as MSW combustors, the typical mercury control technology is activated carbon injection in conjunction with a spray dryer FGD system and fabric filter. Activated carbon injection is used to reduce both mercury and dioxin emissions. The system is comprised of a series of injection nozzles located in the flue gas stream between the last boiler heat trap (economizer or air heater) and the entrance to the spray dryer absorber (SDA). At this location, the injected carbon particles adsorb both mercury and dioxin onto their surfaces by direct contact. When the carbon particles become trapped in the downstream fabric filter, additional adsorption takes place. A typical carbon injection rate is 0.2 lb (0.09 kg) of carbon per ton of MSW combusted. Thus, for a 750 t/d (680 t_m/d) refuse boiler, approximately 150 lb (68 kg)/day of activated carbon would be used. Long-term experience reveals that mercury reduction without carbon injection averages around 70% for a system with only a spray

dryer FGD with fabric filter and about 90% with carbon injection added. Most of the mercury produced by these MSW combustors is oxidized mercury.

For utility coal-fired boilers, the development of mercury emissions control technology in the U.S. over the past decade has progressed from a very limited database to one in which utilities, various government agencies, and system suppliers have increasingly quantified various parameters that influence mercury emissions control. This work is ongoing and reflects the complexity of the measurement and control issues. There are three basic methodologies for controlling mercury stack emissions from coal-fired power plants:

1. Choice of a coal with as low a mercury concentration as possible. The degree to which the coal has been characterized and represents the inlet conditions for the emissions control devices is the first step in setting the expectations for equipment performance. The potential effectiveness of emission control devices is influenced most directly by the form of the mercury, either solid or vapor phase, and the vapor phase mercury speciation, elemental mercury versus oxidized mercury. The presence of a selective catalytic reduction system (SCR) for NO_x emission control upstream of the particulate control device tends to increase the oxidized mercury present, which is subsequently easier to control in a downstream FGD system.
2. Use of a suitably injected sorbent for mercury capture, such that the sorbent particulate matter is captured with the flyash. Powdered activated carbon is the most likely sorbent and can be effective for both elemental and oxidized mercury capture, though the costs can be significant. Typically, the amount of activated carbon needed with downstream fabric filtration is less than that required when using electrostatic precipitation. Flyash from coal-fired utility boilers frequently is sold for byproduct uses such as cement manufacturing. However, flyash contaminated with activated carbon is generally not marketable. One solution is to inject the powder activated carbon downstream of the primary dust collector and add a separate dust collector to trap the injected activated carbon.

Fig. 4 Relationship between coal mercury content and mercury speciation for U.S. EPA Information Collection Request.

Table 5
Typical Mercury Speciation by Coal Type

Coal Type	Relative Content		Primary Mercury Form in Flue Gas
	Mercury	Chlorine	
Bituminous (Eastern U.S.)	Intermediate	High	Oxidized
Bituminous (Western U.S.)	Low	Intermediate	Mixture
Subbituminous (Powder River Basin)	Low	Low	Mixture, more elemental
Lignite	High	Low	Primarily elemental

- Use of the dry or wet FGD system to provide substantial mercury removal from the gas stream. This approach is particularly suitable if the vapor phase mercury contains a relatively high proportion of oxidized mercury species.

Mercury capture in conventional coal-fired systems

Mercury removal efficiency across air pollution control devices at existing U.S. coal-fired plants was also quantified under EPA's ICR study.¹² Average mercury removal for bituminous coals was higher than that achieved for the subbituminous coals and lignites. This is due to the higher percentage of oxidized mercury produced by eastern coals, but also may result, in part, from differences in flyash properties and the tendency of bituminous coals to produce higher levels of unburned carbon.

FGD systems Both wet and spray dryer FGD systems perform better at removing mercury with bituminous coal than with the low rank fuels. The difference is due almost entirely to the higher percentage of oxidized mercury produced by the bituminous coals. Oxidized mercury, typically mercuric chloride, is soluble in water, making it amenable to removal in SO₂ scrubbers. Elemental mercury, insoluble in water, passes through most scrubbers. In the scrubber, the soluble mercury species react with the slurry to produce insoluble mercuric sulfide that is collected as a solid waste byproduct. There is a growing body of evidence that a phenomenon known as mercury re-emission can exist in a wet FGD system. Some of the captured oxidized mercury is actually reduced back to elemental mercury and released into the outlet flue gas. The Babcock & Wilcox Company (B&W) has developed a patented additive for wet FGD systems to minimize re-emission.

SCR systems The same catalysts that reduce NO_x to N₂ in SCR systems also help oxidize elemental mercury. As the flue gas passes through the SCR reactor and over the catalyst, a portion of the elemental mercury is converted to mercury oxidized species, for example mercuric chloride and mercury oxides, which can then be more readily removed in the FGD system. The current data suggests that the presence of HCl in the flue gas is needed for mercury oxidation to occur across the SCR.

Fabric filter systems Fabric filters tend to remove significantly more mercury than do ESPs. Both systems are capable of high-efficiency removal of particu-

late-bound mercury. Fabric filters may perform better on the same flue gas by providing more intimate contact between the flue gases and flyash as the flue gases pass through the filter cake on the filter bags. This intimate contact may promote the adsorption of mercury species onto the flyash or unburned carbon particles in the filter cake. While providing many insights into the behavior of mercury species in coal-fired systems, it should be noted that the EPA ICR data are subject to a variety of limitations. The individual plant data represent a brief period in time and give little insight into the variability of mercury emissions due to variability in coal properties, impacts of plant operating conditions, or mercury sampling uncertainties.

Enhanced mercury capture

Numerous other studies have been and continue to be conducted by B&W and others to shed additional light on the behavior of mercury in coal-fired systems, and to develop cost-effective approaches to its control.

Powdered activated carbon (PAC) Many studies have focused on the injection of some form of PAC. Adsorption is a technique that has often been successfully applied for the separation and removal of trace quantities of undesirable components. PAC injection is used to remove mercury in municipal waste combustor exhaust gases, as discussed above. Although this approach appeared attractive for coal-fired boilers in early work, the economics of high injection rates can be prohibitive when applied to these plants. More refined studies are now in progress to define more precisely what can and can not be achieved with PAC. Other studies seek to enhance PAC technology by impregnation with additives such as halides to yield improved chemisorption of the mercury species that may be present.

Enhanced scrubbing As noted above, conventional emissions control system components are capable of removing oxidized mercury due to its water solubility. A variety of advanced technologies are currently under development to enhance the performance of these systems. Some of these increase the effectiveness of the wet scrubbing systems in capturing the mercury once it is in the soluble state. Others introduce oxidizing agents to the flue gas to increase the conversion of elemental mercury to soluble oxidized species.

Commercial demonstration Efforts to develop mercury emission control technology have progressed to full-scale limited-term demonstration tests. During 2001, full-scale PAC injection tests were run at Alabama Power's Plant Gaston and at We Energies' Pleas-

ant Prairie Power Plant. At about the same time, B&W conducted full-scale tests of its enhanced wet FGD process at both Michigan South Central Power Agency's Endicott Station and at Cinergy's Zimmer Station. Such demonstrations are an important step in gaining commercial acceptance of the technologies. As of this writing, additional testing is ongoing.

Water pollution control

U.S. legislation – Clean Water Act

In 1972, the U.S. Congress enacted landmark legislation that greatly expanded existing laws designed to control water pollution. Commonly referred to as the Clean Water Act (CWA),¹³ the Federal Water Pollution Control Act of 1972 and successive amendments, the Clean Water Act of 1977, and the Water Quality Act of 1987 provide the basic framework for protecting the quality of surface waters in the United States. The stated objective of the CWA is to restore and maintain the chemical, physical and biological integrity of the nation's waters.

Two significant elements of the 1972 Act were the creation of the National Pollution Discharge Elimination System (NPDES), a permitting program to regulate pollutant discharges from industrial and municipal sources, and the establishment of technology-based *end of pipe* effluent standards for specified industries and processes.

Requirements under the Act The NPDES permit program requires that every industrial or municipal facility or other *point source* discharging into public waters obtain a NPDES permit. The NPDES program also regulates wet weather discharges including storm water runoff associated with many industrial activities.

NPDES permits include specific numerical limits for a wide range of conventional, toxic and other non-conventional pollutants to ensure that discharges to receiving waters are protective of human health and the environment. NPDES permits may contain technology-based effluent limits (generally industry/process specific standards), water quality-based effluent limits (as may be necessary to protect the quality of the receiving waters according to designated use classifications), or a combination of both.

The intent of technology-based effluent limits is to establish a minimum level of treatment or control of pollutants in point source discharges using available treatment technologies. In 1982, the EPA promulgated technology-based effluent limits and pretreatment standards for 21 major industrial categories including new and existing steam power facilities [Note: pretreatment standards apply to any indirect discharges to publicly owned treatment works (POTWs) that are not otherwise covered under a facility's NPDES discharge permit]. The key effluent limits applicable to steam power plants are summarized in Table 6. The detailed requirements are set forth in the Code of Federal Regulations – 40 CFR Part 423.

Another provision of the CWA, initially focused on large steam electric facilities, required the EPA to develop regulations governing the capacity, location,

design and construction of water intake structures used to draw large volumes of cooling water from lakes, rivers, estuaries and oceans. This CWA requirement is unique in that it applies to the intake and not the discharge of water. The major goal of the requirement is to protect aquatic life by minimizing the impingement and entrainment of fish and other organisms into cooling water systems. Phase I rules, applicable to new utility facilities with a water intake flow of greater than two million gallons per day and using 25% or more for cooling purposes, were promulgated in December 2001 (Re: 40 CFR Part 125). Phase II rules governing cooling water intake structures at existing electric utility plants withdrawing 50 million gallons or more of water per day were promulgated in July of 2004. Phase III rules governing water intake structures at certain other existing utility and industrial facilities (not covered under the Phase II rules) were proposed in November of 2004 and are due to be finalized by June of 2006.

Visit the EPA's home page on the World Wide Web at www.epa.gov for further information regarding the CWA and related regulatory programs.

Power plant discharge sources

The following describes the principal aqueous discharge streams from utility power plants.

Once-through cooling water Water from rivers, lakes or oceans is used to absorb heat from the steam condenser. The cooling water exiting the steam condenser is at an elevated temperature and can be returned to the source or pumped to a cooling tower for evaporative cooling before being returned to the steam condenser. In the former case, the cooling water contains significant concentrations of only one principal regulated pollutant, total residual chlorine (TRC), which arises out of chlorine addition for condenser fouling control. The duration of each chlorination event is limited. The concerns over TRC discharge include toxicity to living organisms and the generation of halogenated hydrocarbons.

Cooling tower blowdown When the heated cooling water from the steam condenser is cooled in an evaporative cooling tower, a buildup of dissolved solids and suspended matter occurs. Most of this buildup is removed from the system by cooling tower blowdown. Some of the suspended matter can settle out in the cooling tower basin and is removed at infrequent intervals. All of the dissolved solids and the remaining suspended solids are removed largely by cooling tower blowdown. Blowdown flow is adjusted to keep the concentration of dissolved and suspended solids below the limits required to control condenser tube fouling and corrosion. Other sources of chemical pollutants in blowdown include chlorine and organic chemicals for control of biofouling, corrosion inhibitors (consisting of chromate, zinc, polyphosphates, etc.), chemicals for scale control and products of corrosion. Some of these maintenance chemicals appear on the EPA's regulated toxic pollutants list and none are permitted to be present in detectable levels in cooling tower blowdown after treatment (except for chromium and zinc, which are separately regulated).

Table 6
Aqueous Discharge Limits for
New Steam Power Generating Systems (Note 4)

Source and Pollutant (Note 1)	NSPS Effluent Limits, mg/l (Notes 2 and 3)	
	Maximum	Average
All discharges		
pH (unitless)	6 to 9	—
PCBs	No discharge	—
Low volume waste (Note 5):		
TSS	100	30
OG	20	15
Chemical metal cleaning wastes:		
TSS	100	30
OG	20	15
Copper	1.0	1.0
Iron	1.0	1.0
Bottom ash transport water:		
TSS	100.0	30.0
OG	20.0	15.0
Once-through cooling water:		
Total residual chlorine (TRC)	0.2	—
Free available chlorine	0.5	0.2
Cooling tower blowdown:		
Free available chlorine	0.5	0.2
Zinc	1.0	1.0
Chromium	0.2	0.2
Other 126 priority pollutants	No detectable amount	
Coal pile runoff:		
TSS (1980)	50	—

Notes:

1. Nomenclature: TSS – total suspended solids; OG – oil and grease.
2. New Source Performance Standards.
3. 30 day rolling daily average (Average); maximum any one day (Maximum).
4. Adapted from Reference 1.
5. Low volume wastes include ion exchange, water treatment, evaporator blowdown, boiler blowdown, lab and floor drains, plus FGD waste water.

Ash handling water waste Ash produced from the combustion of fuel, whether oil or coal, is collected at different points in the combustion process. Flyash is the finer size ash collected by particulate collection systems and bottom ash is removed from hoppers at the furnace bottom. Additional hoppers at intermediate points also accumulate ash. In many cases, ash is moved from these points with sluice water, which then goes to a settling pond and can typically contain 5% suspended solids by weight.

The ash settling pond overflow contains dissolved and suspended solids, the quantities of which will depend on the source of the ash, the type of combustion process and the point from which it is extracted from the combustion process. Coal ash contains, in addition to the eight or nine major elemental constituents,

a number of trace elements that can appear in pond overflow and which may need to be treated.

Coal pile runoff Open storage of large quantities of coal is required for an uninterrupted fuel supply to utility plants [on the average, 800 to 2400 yd³ (611 to 1834 m³) per megawatt of rated capacity is kept on hand]. The water and oxygen from the air react with the minerals in bituminous coal to produce a leachate contaminated with ferrous sulfate and sulfuric acid. The low pH from the acid accelerates dissolution of many of the metals present in the coal minerals.

FGD blowdown In wet FGD systems, a portion of the absorber slurry that is sprayed into the flue gas stream to remove SO₂ is removed from the absorber tank for dewatering. In the dewatering process, the solid reaction products are separated from the liquor. The liquor is recycled to the absorber tank where additional sorbent is added. Recycling of the liquor can result in chloride buildup which, in turn, can cause increased corrosion to the alloys in the system. This buildup can be controlled by the loss of liquor retained in the dewatered sludge or by a blowdown. An aqueous blowdown discharge would typically contain calcium sulfate, calcium sulfite and calcium chloride. Also, depending on flyash carryover, traces of metal ions could also be present. In setting effluent limitations in 1982, the EPA reserved regulating FGD aqueous discharge to a future date.

Metal cleaning wastes These aqueous wastes can arise from either *chemical* or *nonchemical* cleaning of metal heat transfer surfaces in the boiler.

Chemical metal cleaning uses chemical solvents for water-side cleaning of boiler system components to remove corrosion products. Cleaning intervals are measured in years for large utility boilers, and produce three to four boiler water volumes [20,000 to 100,000 gal (75,707 to 378,533 l)] of waste water per cleaning. The composition of the waste solvents depends on the construction material of the boiler system, but largely consists of iron with lesser amounts of copper, nickel, zinc, chromium, calcium and magnesium. The disposal method for the spent solvent depends on the type of chemical cleaning solvents used. When hydrochloric acid based solvents are used, spent solvent is treated on-site by neutralization and is discharged subject to the effluent limits in Table 6 or more stringent water quality standards. With approval from appropriate regulating bodies, organic-based solvent wastes are often incinerated in other operating boilers at the site. The metals in the chemical cleaning wastes are retained with the normal boiler ash.

Nonchemical water cleaning is used to remove fire-side deposits by means of high pressure jets of water. The waste water can contain the same metals and pollutants contained in the ash deposits being removed. Because the deposit composition varies with location in the boiler, the wash water composition will depend on the location of the area being cleaned. These waste waters may be classified as either low volume wastes or metal cleaning wastes and are treated according to the corresponding effluent limits.

Low volume wastes These include discharges from ion exchange water treatment, evaporator blowdown,

boiler blowdown, cooling tower basin cleaning, laboratory and floor drains, and drains and losses from house service water systems. FGD blowdown is also included until the EPA develops specific regulations for this stream. By EPA definition, low volume wastes are those from all sources taken collectively as if they were from one source. Excluded are those wastes for which specific effluent limits are established.

Water pollution control technologies

The technologies for waste water treatment used to meet limits for discharge include clarification and filtration.

Clarification This process is used to settle out larger suspended particles and condition smaller colloidal particles to make them settle and allow filtration for removal. A pond, reservoir or tank is used to allow larger particles to settle in a matter of hours. The finer particles overflow and are made to settle more quickly by the addition of chemical agents, coagulants and polymers that cause agglomeration to sizes large enough to settle out of suspension.

Filtration This uses a porous barrier across flowing liquid to remove suspended materials. Filtration can be used to supplement clarification and permits reducing suspended solids to the parts per million level. Filter types include sand filters that are generally slow and do not handle fine clay well. Preconditioning with coagulants can improve filtration rates. Dual media filters improve on sand filters by superimposing a coarse, granular material over the fine bed. This allows more of the filter bed to be used, reduces head loss, and provides higher flow rates and longer operating cycles before cleaning.

As required, and with approvals from appropriate regulating bodies, final waste stream pH is controlled by combining various plant streams to provide a neutral pH product. Where needed, acid or alkali addition can be used to achieve the final pH. Other treatments are also available to address other criteria pollutants where concentration warrants.

In selected cases, zero discharge water management is provided which does not return any waste water to water sources. Effectively all water brought into the plant is evaporated through cooling towers, ponds, evaporators, or the stack. Residual solids are then sent to disposal.

Solid waste disposal

The Resource Conservation and Recovery Act

The rapid growth of industrial activity and use of consumer goods by society have resulted in an explosive growth in the generation of solid wastes. The EPA has estimated that over 100 million tons of fossil fuel combustion wastes are generated annually in the U.S., principally from coal ash residues generated at utility power plants.

In 1976, the U.S. Congress passed the Resource Conservation and Recovery Act (RCRA)¹⁴ as an amendment to the Solid Waste Disposal act of 1965. The RCRA establishes the regulatory framework to en-

sure that solid and hazardous wastes are properly managed to protect human health and the environment. Subtitle C of the Act establishes a comprehensive management system to regulate hazardous waste from the time it is generated until its final disposal, commonly referred to as a *cradle to grave* approach. Subtitle D of the Act directs states to develop and implement solid waste management plans and regulations to promote environmentally sound management practices for non-hazardous wastes which address landfill performance standards and recycling/beneficial use programs. Subtitle I of the Act regulates petroleum products and other hazardous substances that are stored in underground tanks.

As originally drafted, RCRA did not clearly address how fossil fuel combustion wastes should be regulated and in 1980, the U.S. Congress passed the Solid Waste Disposal Act Amendments which included what is commonly referred to as the *Bevill Exemption*. The Bevill Exemption excluded, among other things, fossil fuel combustion wastes from being regulated as hazardous waste under RCRA Subtitle C, pending completion of a report to Congress and a formal determination by the EPA as to whether regulation under Subtitle C is warranted.

In August 1993, the EPA published the first of two regulatory determinations concerning fossil fuel combustion wastes. This first determination applied only to separately managed, *large volume* wastes including flyash, bottom ash, boiler slag and flue gas emission control waste generated at coal-fired electric utilities and independent power facilities. The EPA determined that if managed properly, these materials would remain exempt from regulation as a hazardous waste under Subtitle C of the RCRA. The EPA's second ruling, published in May 2000, generally extended the hazardous waste exemption to other defined categories of *low volume* wastes generated at electric utilities and industrial facilities that combust coal, oil, natural gas, petroleum coke or mixtures of coal and other fuels. These low volume wastes, when properly co-managed with large volume combustion wastes, would typically include (but are not limited to) coal pile runoff, coal mill rejects/pyrite, water treatment sludge, and boiler chemical cleaning waste. However, if certain wastes are managed independently and exhibit the characteristics of a hazardous waste, they are subject to the hazardous waste regulations. For more detailed information refer to the EPA's final regulatory determination published in the Federal Register on May 22, 2000 (65 FR 32213).

While the EPA has concluded that fossil fuel combustion wastes do not warrant regulation as hazardous waste, the agency further determined that national non-hazardous waste standards under RCRA Subtitle D are needed for coal combustion wastes disposed in landfills and surface impoundments, or used in minefill applications. However, national regulations have yet to be developed under Subtitle D; therefore, the management and regulation of combustion waste products are currently handled by the individual states.

Finally, the EPA has concluded that beneficial uses of coal combustion waste (other than for minefill) pose

no significant risk and no additional national regulations are needed. The EPA has stated they do not want to add any unnecessary barriers to the beneficial uses of combustion waste products because such uses conserve natural resources, reduce disposal costs and reduce the total amount of waste ultimately destined for disposal.

Solid combustion wastes

The principal solid waste streams in coal- and oil-fired utility boilers include the following:

1. *Bottom ash* is the portion of fuel ash that falls to the bottom of the furnace or from the stoker discharge. In coal-fired Cyclone furnace boilers, the bottom ash consists of slag that drops from the bottom of the furnace into a slag tank for solidification.
2. *Flyash* is the finer ash material that is borne by the flue gas from the furnace to the back end of the boiler; it drops out in the economizer and air heater hoppers or is collected by particulate control equipment.
3. *Pyrite* is iron sulfide, an impurity which is separated from coal in the pulverizer and which is combined with bottom ash for disposal.

FGD waste characteristics depend on the particular technology used:

1. *Wet scrubbing (calcium-based system)* A natural oxidation system produces a wet sludge containing a mixture of calcium sulfite and calcium sulfate reaction products, trace amounts of flyash and unreacted limestone. In a forced oxidation system, the principal difference is that the reaction product is almost totally in the form of calcium sulfate or gypsum, which is more easily dewatered to a filter cake for wallboard, landfill or other use.
2. *Dry scrubbing* Waste is dry and contains calcium sulfite, calcium sulfate, flyash and unreacted sorbent (hydrated lime). The potential uses for this material are more limited.
3. *Dry lime injection* Waste is dry and contains calcium sulfite, calcium sulfate, flyash and a large proportion of calcium oxide (CaO).

Solid waste treatment methods

To dispose of waste materials from wet FGD systems, treatment methods are applied to ultimately produce a solid. These methods include dewatering, stabilization and fixation, and are designed to achieve waste volume reduction, stability and better handling, and liquid recovery for reuse.

Dewatering This process is used to physically separate water from solids to increase the solids content of the product and recover water for reuse and further treatment.

A settling pond is the simplest method for dewatering, is not sensitive to inlet solids content, requires low maintenance and is highly reliable. Ponds are often used for ash or wet FGD scrubber slurries. Sizing provides low flow velocity so that solids can settle undisturbed by gravity. Settling ponds are unpopular with regulatory agencies, require substantial acreage and must be shut down for solids removal.

Thickeners are large cylindrical tanks with radial rakes at the bottom. The rakes carry plows to push material on the bottom that slopes toward the center. The plows push settled material toward the underflow discharge. Thickeners rely on gravity to separate high specific gravity solids. Although thickeners are complicated and have high capital and maintenance costs, they have high throughput rates and require less land area than settling ponds.

Liquid cyclones or hydroclones are now commonly used in place of thickeners to remove solids from slurries by centrifugal and liquid shear effects. Hydroclones separate and collect particles down to a particular size, with finer particles staying with the liquid overflow. Hydroclones do not separate material less than 5 μm effectively and are not efficient with slurries containing more than 20% solids. They are low in cost, have low space requirements, and produce low solids content in the overflow and a high solids fraction in the underflow.

Vacuum filters, either of the drum or belt type, are generally used for second stage dewatering of wet scrubber slurries. They take little space and produce a high solids content product, up to 95% for FGD slurry. Centrifuges are also an option for second stage dewatering.

Stabilization This process increases the solids content of scrubber waste by adding dry solids such as flyash. Stabilization is applied to impart greater physical stability to the waste, making it easier to place in the landfill and making it less susceptible to future problems. Stabilization and fixation are generally applied to scrubber wastes as the final treatment step after dewatering. Bottom ash and flyash, because of their more granular nature, generally dewater easily and do not require stabilization for disposal. For stabilization, a dry solid such as soil or flyash is mixed with the waste slurry, spreading the water in the waste over a larger mass of solids. Also, there is improvement in particle size distribution that leads to closer packing, lower permeability and lower combined volume. Stabilization can be reversible and if the waste is rewetted, it may fluidize and fail structurally.

Fixation This process involves the addition of an agent such as lime to produce a chemical reaction to bind free water and produce a dry product. Fixation includes a number of processes. Mixing suitable proportions of scrubber slurry with alkaline flyash containing sufficient CaO produces chemical reactions that result in a material with compressive strength comparable to low-strength concrete and with very low permeability. Both characteristics contribute to ease of placement and minimal leaching problems.

When the flyash does not have sufficient alkalinity, lime may be added to the flyash and scrubber slurry mixture to produce the cementitious reaction. Four percent addition of lime has produced material with the necessary physical properties for disposal or use. The cured material is suitable for structural fill, providing a site that can be used for building construction after completion of the landfill. Comparable fixation reactions with scrubber sludge have been obtained with additions of 5 to 10% blast furnace slag.

Disposal and utilization methods and requirements

Ultimate disposition of utility plant wastes (ashes and FGD residues) is by disposal (in landfills or impoundments) or by utilization. Where disposal is used, the waste stream is analyzed, and the site is permitted and approved by the appropriate regulatory agencies.

Disposal methods These can be either wet or dry, depending on the physical condition of the material. Wet disposal requires construction of a pond which may be below or above grade with impermeable barriers or dikes. Below grade construction may be considered and depends on suitable geology and hydrology at the site. With wet disposal, the waste is placed in slurry or liquid form. After settling, the liquid that has separated is collected, treated and either released or recycled. Dry disposal can use a simple method of landfill construction in which the waste is placed and compacted to form an artificial hill. The trend is toward dry disposal because of smaller volumes and more options for site or material reclamation.

Utilization methods These become more attractive as waste management costs increase. Bottom ash, flyash and boiler slag are used in applications where they can be substituted for sand or gravel. The characteristics of boiler slag and bottom ash also make these materials useful for blasting grit, roofing gran-

ules and controlled fills. Flyash, because of its chemistry and physical properties, is applicable in the manufacture of Portland cement and concrete mixes. The value of these materials is so low that the cost of transportation severely limits their use to applications close to the producing power plant.

With the increased use of ammonia reagents for NO_x emissions control, flyash (particularly from bituminous coal) can adsorb excess ammonia present in the flue gas and this adsorption may hinder the beneficial use or end disposal of flyash or FGD byproduct streams. Ammonia absorbed by flyash can be released (off-gassed) when coming in contact with water. Currently, there are various processes in development to remove residual ammonia from flyash.

FGD byproduct use is potentially in the areas of agriculture, sulfur recovery and gypsum. Agricultural use is limited. Trace elements from flyash contamination could have an unacceptable impact and make wide use doubtful. Use for sulfur recovery is limited by incomplete technology development, high capital cost, and the low market price of sulfur.

FGD byproduct from forced oxidation wet scrubbing systems, primarily gypsum, has seen extensive commercial use in wallboard production. However, gypsum byproduct specifications may vary significantly by end user and must be established and confirmed prior to FGD system design.

Chapter 33

Particulate Control

As steam is widely generated by the combustion of most fossil fuels, the flue gas carries particulate matter, principally ash, from the furnace. Except for natural gas, all other fossil fuels contain some quantity of non-combustibles which form the majority of the particulate. Unburned carbon also appears as particulate. Particulate control is needed to collect this material and to limit its release to the atmosphere.

All coals contain some amount of ash. The amount of ash varies depending on the type of coal, location, depth of mine and mining method. In the United States (U.S.), eastern bituminous coals typically contain 5 to 15% ash while the western subbituminous coal ash content may range from 5 to 30% ash by weight. Texas lignites also contain up to 30% ash. Mining methods on thin seams of coal may also contribute to higher ash quantities (see Chapter 9).

When coal is burned in conventional boilers, a portion of the ash drops out of the bottom of the furnace (*bottom ash*) while the remainder of the ash is carried out of the furnace in the flue gas. It is this remaining ash (*flyash*) that must be collected after the furnace and before exhausting the flue gas to the atmosphere.

Different combustion methods contribute different proportions of the total coal ash content to the flue gas. With pulverized coal firing, 70 to 90% of the ash is carried out of the boiler with the flue gas. A stoker-fired unit will emit about 40% of its ash in the flue gas along with some amount of unburned carbon. With Cyclone firing, only 15 to 40% of the ash is normally carried by the flue gas. On circulating fluidized-bed boilers, all of the ash, along with the fluidized-bed material, is carried by the flue gas. Therefore, the selection and design of particulate control equipment are closely tied to the type of firing system.

An American Society for Testing and Materials (ASTM) ash composition analysis test (ASTM D-3682-01) of a coal ash sample reveals the major ash components. Proximate and ultimate coal analyses commonly offer additional insight and also provide total ash content. Ash components are typically reported in the oxide form and include silicon dioxide, titanium dioxide, iron oxide, aluminum dioxide, calcium oxide, magnesium oxide, sodium oxide, potassium oxide, sulfur trioxide and diphosphorous pentoxide. Trace quantities

of many more elements are also found in ash. The proportion of the major constituents varies significantly between coal type and mine location. The analysis and composition of flyash are discussed in greater detail in Chapters 9 and 21.

Other significant coal ash properties are particle size distribution and shape, both of which are dependent on the type of firing method. Stoker-fired units generally produce the largest particles. Pulverized coal-fired boilers produce smaller, spherical shaped particles of 7 to 12 microns (Fig. 1). Particles from Cyclone-fired units, also mostly spherical, are among the smallest. Fluidized-bed units produce a wide range of particles that are generally less spherical and are shaped more like crystals. Knowledge of ash properties is important in the selection of the correct particulate control equipment.

Regulation of particulate emissions

Particulate control equipment was first used by utilities in the 1920s and before that time in some industrial applications.¹ Prior to 1971, however, controls were installed largely on a best effort basis. In 1971, the first Environmental Protection Agency (EPA) performance standard limited outlet particulate emissions to 0.1 lb/10⁶ Btu (123 mg/Nm³ at 6% O₂) heat input

Fig. 1 Flyash from pulverized coal (magnified X 1000).

and stack opacity to 20% for those units larger than 250×10^6 Btu/h (73.3 MW_t) heat input. *Opacity*, measured by an instrument called a transmissometer, is the portion of light which is scattered or absorbed by particulate as the source of light passes across a flue gas stream. Therefore, both the amount and appearance of the stack emissions are regulated. Since 1979, the EPA New Source Performance Standards (NSPS) for particulate control permit a maximum of 0.03 lb/10⁶ Btu (36.9 mg/Nm³ at 6% O₂) heat input for these units. A 20% opacity is still permissible.

Federal and state EPA regulations set the primary guidelines for particulate emissions. In addition, many local regulatory bodies have generally stricter regulations than those set by the federal EPA. There are separate emissions standards for a variety of combustion processes including steam generators firing coal, oil, refuse and biomass. Currently there are three major classification levels for steam generating units: one for units greater than 250×10^6 Btu/h (73.3 MW_t), one for the 100 to 250×10^6 Btu/h (29.3 to 73.3 MW_t) units, and a third for those units less than 100×10^6 Btu/h (29.3 MW_t) heat input.^{2,3} Finally, if a new plant is in a nonattainment area, the permissible particulate emissions and opacity may be significantly reduced from nominal control levels.

Particulate control technologies

Particulate emissions from the combustion process are collected by particulate control equipment (Fig. 2). This equipment must remove the particulate from the flue gas, keep the particulate from re-entering the gas, and discharge the collected material. There are several major types of equipment available including electrostatic precipitators, fabric filters (baghouses), mechanical collectors and venturi scrubbers. Each of these uses a different collection process with different

factors affecting the collection performance. Prior to the 1990s, the technology of choice for large coal-fired utility plants was the dry electrostatic precipitator, with fabric filters a distant second. Today, preference is given to the fabric filter (pulse jet type) for reasons described below.

Dry electrostatic precipitators

A dry electrostatic precipitator (ESP) electrically charges the ash particles in the flue gas to collect and remove them. The unit is normally comprised of a series of parallel, vertical metallic plates (collecting electrodes or CEs) forming ducts or lanes through which the flue gas passes. Centered between the CEs are discharge electrodes (DEs) which provide the particle charging and electric field. Fig. 3 is a plan view of a typical ESP section which indicates the process arrangement.

Charging The CEs are typically electrically grounded and connected to the positive polarity of the high voltage power supply. The DEs are suspended off of electrical insulators in the flue gas stream and are connected to the output (negative polarity) of a high voltage power source, typically 55 to 85 average kV DC. An electric field is established between the DEs and the CEs, and the DEs will exhibit an active glow, or *corona*. As the flue gas passes through the electric field, the particulate takes on a negative charge which, depending on particle size, is accomplished by field charging or diffusion.

Collection The negatively charged particles are attracted toward the grounded CEs and migrate across the gas flow. Some particles are difficult to charge, requiring a strong electric field. Other particles are charged easily and driven toward the plates, but also may lose the charge easily, requiring recharging and recollection. Gas velocity between the plates is also an important factor in the collection process since lower velocities permit more time for the charged particles to move to the CEs and reduce the likelihood of loss back into the gas stream (re-entrainment). In addition,

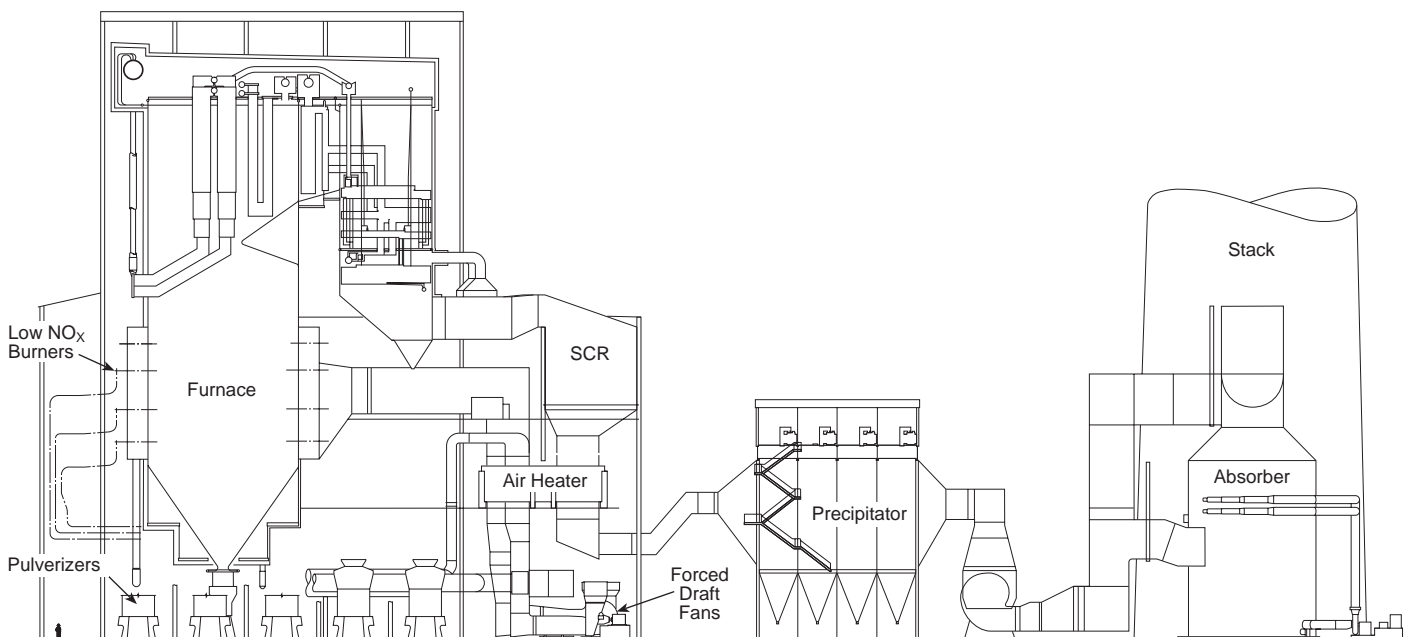

Fig. 2 Particulate control equipment – plant side view.

Fig. 3 Particle charging and collection within an ESP.

tion, a series of CE and DE sections is generally necessary to achieve overall particulate collection requirements. In modern ESPs designed for utility flyash, four or more sections in series are required to achieve design collection levels.

The ash particles form an ash layer as they accumulate on the collection plates. The particles remain on the collection surface due to the forces from the electric field as well as the molecular and mechanical cohesive forces between particles. These forces also tend to make the individual particles agglomerate, or cling together.

Rapping The ash layer must be periodically removed. The most common removal method is rapping which consists of mechanically striking the collection surface; this rapping force dislodges the ash. Because particulate tends to agglomerate, the ash layer is removed in sheets. This sheeting is important to prevent the re-entrainment of individual particles into the flue gas stream, requiring recharging and recollection downstream.

While most of the particles are driven to the CEs, some positively charged particles attach to the DEs. A separate rapping system is therefore used to remove deposits from these electrodes and maintain proper operation.

Ash removal The dislodged particulate falls from the collection surface into hoppers. Once the particulate has reached the hopper it is important to ensure, by proper design, that it remains there in bulk form with minimal re-entrainment until the hopper is emptied. (See Chapter 24 for hopper ash removal methods and equipment.)

Dry ESP applications

Utility Because coal is the most common fuel for steam generation, collection of the coal ash particles is the greatest use of a particulate collector. The electrostatic precipitator has been the most commonly used collector. To meet the particulate control regulations for utility units and considering the resulting high collection efficiency, special attention must be given to details of precipitator sizing, rapping, flow distribution and gas bypass around the collector plates. The result will then be a collector that can be confidently and consistently designed and operated to meet the outlet emissions requirements. Operating collection efficiencies which exceed 99.9% are common on the me-

dium and higher ash coals with outlet emissions levels of 0.01 to 0.03 lb/10⁶ Btu (12.3 to 36.9 mg/Nm³ at 6% O₂) heat input common on all coals. ESPs are also widely installed on utility boilers that fire oil as their principal fuel.

Industrial Other common noncoal-fired industrial units where ESPs are successfully being applied include municipal refuse incinerators and wood, bark, and oil-fired boilers. For these, the ash in the flue gas is typically more easily collected than coal flyash so an ESP of modest size will easily collect the particulate. The moisture content in the refuse, wood and bark is the major contributor to the low resistivity. The carbon content of the residue, ash and unburned combustibles also contributes to low resistivity. (See note below.)

Pulp and paper In the pulp and paper industry, precipitators are used on power boilers and chemical recovery boilers. The power boiler particulate emissions requirements are the same as those for the industrial units using the same fuels. For the recovery boilers, precipitators are used to collect the residual salt cake in the flue gas. Chapter 28 contains further information on the recovery boiler processes and the reuse of the collected material.

A recovery boiler is a unique application for a precipitator due to the small particulate size and the tendency for the cohesive ash particles to stick together. The resistivity of the particulate is low so it is collected easily in the ESP. However, the fine particulate can also cause problems with the generation of effective corona by the DEs due to an effect called space charge. Because the particulate is so small, gas bypass around collector plates and re-entrainment of rapped particulates in the flue gas are more of a design concern. Re-entrainment is minimized by proper gas flow control and by lower gas velocities. Precipitator collection efficiencies are 99.7 to 99.8% to meet the 20% opacity and the local emissions requirements. Due to the characteristics of the salt cake particulates, a drag chain conveyor across a precipitator floor, rather than a

Note: Resistivity is an inverse measure of a particle's ability to accept and hold a charge. Lower resistivity indicates improved ability to accept a charge and be collected in an ESP.

normal hopper, is used for salt cake removal. In addition, casing corrosion is a more significant concern and as a result more insulation is required to reduce casing heat loss. Finally, in order to improve system reliability, two precipitator chambers are commonly used, each capable of handling 70% of the gas flow and each equipped with separate isolation capabilities.

Precipitators have also been applied in the steel industry to collect and recover the fine dust given off by some processes.

Dry precipitator components

All ESPs have several components in common (Fig. 4) although there is some shape and size variation between units.

Casing As shown in Fig. 4, the structure forming the sides and roof of an ESP is a gas-tight metal cased enclosure. The structure rests on a lower grid, which serves as a base and is free to move as needed to accommodate thermal expansion. All of the collecting

plates and the discharge electrode system are top supported from the plate girder assemblies. The entire enclosure is covered with insulation and lagging. Access doors in the casing and adequately sized walkways between the fields assist in maintenance access for the internals.

Materials for the precipitator enclosure and internals are normally carbon steel, ASTM A-36 or equivalent, because gas constituents are noncorrosive at normal operating gas and casing temperatures. Projects with special conditions may warrant an upgrade in some component materials.

Hoppers For utility flyash applications, metal inverted pyramid-shaped hoppers are supported from the lower grid and are made of externally stiffened casing. The hoppers provide the lower portion of the overall enclosure and complete the gas seal. Their sides are designed with an inclination angle of at least 60 deg from horizontal. Hoppers are generally designed as particulate collection devices that can store

Fig. 4 B&W rigid frame electrostatic precipitator.

ash for short periods of time when the ash removal system is out of service.

Because many ash removal systems are noncontinuous, the following items are normally supplied with the precipitator hoppers to ensure good particulate removal: hopper heaters, electromagnetic vibrators, poke holes, anvil bars and level detectors. Hot air fluidizing systems are also sometimes supplied to assist in ash removal.

For non-utility flyash applications, the use of alternative ash holding/removal designs are common. These include flat-bottom with drag scrapers, wet-bottom, and trough-type hoppers.

Collecting electrodes As shown in Fig. 4, the CE surface typically consists of a series of roll-formed collector plates assembled into a CE and supported from the top. CEs are also widely referred to as plates or curtains. The CEs are spaced in rows across the width of the precipitator, typically on 12 or 16 in. (305 or 406 mm) centers in modern designs that also use rigid DEs. In older designs, CE spacings of 9 or 10 in. (229 or 254 mm) were generally seen when used with wire (0.109 in./2.8 mm diameter typical) DEs. In the direction of gas flow, the CE sections are arranged into fields which are normally powered by separate and dedicated power supplies. The collection surface area in the Deutsch-Anderson equation (see Equation 1) is the total CE plate area required for particulate collection. For calculating surface area, the CE assembly is treated as a plane and includes both sides of the CE where exposed to gas flow. The rolled plates can be up to 50 ft (15.2 m) in length with a shop straightness tolerance of 0.5 in. (12.7 mm). CEs may also be large flat plates with stiffener bars added to maintain straightness. For optimum performance with a uniform electric field and with minimal inter-electrode spark-over or electrical arcing (high current spark), the alignment of collection surface and electrodes must be maintained within tight tolerances.

Discharge electrodes and insulators As described in the section on charging, the DEs, connected to the high voltage power source, are located in the gas stream and serve as the source of the corona discharge. These electrodes are the central components of the discharge system which is electrically isolated from the grounded portions of the ESP. An electrical clearance gap of 6 to 8 in. (152 to 203 mm), depending on CE spacing, must be maintained throughout the ESP between the DE system and any grounded components.

Discharge electrodes are found in several shapes. Common types include the rigid frame, rigid electrode and weighted wire. The rigid frame, shown in Fig. 5, consists of strips of electrode supported between sections of frame tubing. Each frame is attached to a structural carrier, both front and rear. This assembly is supported by insulators forming a four point suspension system. The rigid electrode consists of a member with proprietary shape that is top supported and hangs the full height of the precipitator. The typical rigid electrode top support is also a frame hanging from insulators. The lower ends of the rigid electrode have a guide bar and side to side spacers. The third type of discharge electrode, weighted wire, consists of a round or barbed wire supported at the top and held

straight and in tension with a weight at the bottom. The upper frame is supported from insulators and there is a lower steadying frame to guide and space the electrodes.

For highest equipment reliability, either the rigid frame or rigid electrode is the most common configuration. Discharge electrode failure in the form of broken wires has been a recurring problem with the weighted wire electrodes, particularly with lengths of 30 ft (9.1 m) or more, resulting in performance deterioration.

Gas flow control devices ESPs operate most efficiently when the gas flow is distributed evenly across the ESP cross section. Flow control devices such as turning vanes, flow straighteners and perforated plates are frequently installed in the inlet and outlet flues, and flow transition pieces, to provide the desired degree of flow uniformity while optimizing resultant pressure drop.

Rapping systems As shown in Fig. 4, the most effective method of cleaning the collector curtains is to rap each one separately and in the direction of gas flow. This method assures that each curtain receives a rapping force. The rapping system shown is a tumbling hammer type, where the hammer assemblies are mounted on a shaft extending across the ESP in a staggered arrangement. The shaft is turned slowly by an external drive controlled by timers for rapping fre-

Fig. 5 Rigid frame discharge electrode and rapping system for an ESP.

quency and optimum cleaning. Hammer size is selected to match the application and size of the collector curtain. External, top-mounted rapping technology has also been widely used, principally in the U.S. Typically, more than one collector curtain is rapped at a time with this method, and the rapping force is in the downward direction on the top edge of the curtains. Both a drop rod and magnetic impulse are the drive mechanisms used.

Due to the difficulty of cleaning high resistivity flyash from the collection surface, considerable tests have been performed to ensure that adequate rapping forces are transmitted across the entire collection surface. A minimum acceleration of 100 g applied at the farthest point from impact has been established as an industry standard.

Typically, rapping of the rigid frame discharge electrodes is accomplished using a tumbling hammer system as shown in Fig. 5. The hammer assemblies are mounted in a staggered arrangement on a shaft across the width of an electrical section. Note that a smaller hammer than that used for the collector system is required for proper cleaning of the discharge electrodes. An external drive unit mounted on the precipitator roof is used to slowly turn the rapper shaft and, because it is attached directly to the carrier frame, the drive shaft must also be electrically isolated with an insulator. As with the collector system, top rapping of the discharge electrodes is another method of cleaning that is typically used with the rigid electrode designs.

A rapping system is sometimes used on the flow distribution devices at the precipitator inlet.

Power supplies and controls A transformer rectifier (TR) set along with a controller supply the high voltage power to the discharge electrode system. Several TR sets are normally needed to power a precipitator. With this combination of electrical components, the single-phase 480 V AC line voltage is regulated in the controller and then transformed into a nominal 55,000 to 75,000 V before being rectified to a negative DC output for the discharge system. Electrically, a precipitator most closely resembles a capacitive load. Due to the capacitive load and the nature of the precipitator internals, the TR set must be designed to handle the current surges caused by arcs between the discharge electrodes and the grounded collection surface. A current-limiting reactor in series with the TR set primary also helps to temporarily limit the current surges.

Traditionally, a voltage controller tries to maximize the voltage input to the precipitator. To achieve this input and when operating as designed, the controller must periodically raise the voltage to the point of sparking between the discharge electrode and the collection surface. The controller must then also detect the sparks and reduce the voltage to avoid an arc.

Today's microprocessor TR controls with quick response times, interface advantages and programming capabilities provide many functions to optimize particulate collection.

Dry precipitator sizing factors

An ESP is sized to meet a required performance or particulate collection efficiency. The sizing procedure determines the amount of collection surface to meet

the specified performance. An equation which relates the collection efficiency (E) to the unit size, the particle charging and the collection surface is the Deutsch-Anderson equation:¹

$$E = 100\% \times \left(\frac{\text{Inlet dust loading} - \text{Outlet dust loading}}{\text{Inlet dust loading}} \right) \quad (1)$$

$$1 - \frac{E}{100} = e^{-\frac{wA}{V}} \quad (2)$$

or

$$A = \left[\ln \left(\frac{1}{1 - (E/100)} \right) \right] \frac{V}{w} \quad (3)$$

where

E = ESP removal efficiency, % of inlet particulate removed

w = migration velocity, ft/min (m/s)

A = collection surface area, ft² (m²)

V = gas flow, ft³/min (m³/s)

Migration velocity is the theoretical average velocity at which the charged particles travel toward the collection surface. This velocity is dependent upon how easily the particulate is charged, and the value is normally selected by empirical means based on experience. The factors which affect migration velocity are the fuel and ash characteristics, the operating conditions, and the effects of gas flow distribution.

These factors also have an effect on the ability of the particulate to accept a charge. A commonly used indication of this effect is resistivity, measured in ohm-cm. Fig. 6 illustrates typical resistivity curves for two fuel ashes. High resistivity ashes result in low migration velocities and large collection surface areas while average resistivity ashes result in moderately sized surface areas, i.e., lower resistivity indicates improved collection.

As previously discussed, the flue gas will pass through a series of collection fields. ESPs collect particulate in geometric fashion meaning each field will tend to collect very roughly 80% of the particulate entering that particular field. Therefore, the inlet field will collect the vast majority of the total mass particulate with each successive field collecting geometrically less of the total. For example, the first field could collect 80% of the total particulate loading while the second field would collect 80% of the remaining 20% or 16% of the total particulate loading, etc.

Fuel and ash characteristics The fuel and ash constituents which reduce resistivity or that are favorable to ash collection in an ESP include moisture, sulfur, sodium and potassium. Applications with sufficient quantities of these components usually result in moderately sized precipitators. Constituents which hamper ash collection and increase outlet emissions include calcium and magnesium. High percentage concentrations of these items without offsetting quantities of the favorable constituents result in poorer collection and larger precipitators. The fuel and ash constituents and their relative quantities must be reviewed in the siz-

ing process to determine the overall effect on migration velocity. The migration velocity/resistivity can then be altered to some extent by controlling the content of the critical constituents.

Gas temperature, volume and distribution As indicated in Fig. 6, gas temperature has a direct effect on resistivity and on the gas volume passing through the ESP. Gas flow from the boiler also has an effect on sizing as indicated by the Deutsch-Anderson equation. There is an optimum gas velocity range within an ESP for maximum performance which must be considered as part of the design selection. Maximum ESP efficiency is achieved when the gas flow is distributed evenly across the unit cross section. Uniform flow is assumed in the ESP sizing calculations and should be verified during the design stage by using a flow model. These models should include the precipitator as well as the inlet and outlet flues. Flow uniformity is typically achieved by installing distribution devices in the flue transition sections immediately upstream and downstream of the ESP. Hopper design must also prevent high velocity areas to avoid flyash re-entrainment. The industry standard for flow distribution and modeling is the Institute of Clean Air Companies EP-7.⁵

Particle size distribution Particle size also affects ESP design and performance. A particle size distribution versus collection efficiency curve (Fig. 7) indicates that an ESP is less efficient for smaller particles (less than 2 microns) than for larger ones. Therefore, ESP applications with a high percentage of particles less than 2 microns will require more collection surface and/or lower gas velocities.

Sectionalization Sectionalization refers to how many or how few independent high voltage power supplies are installed on an ESP. ESP performance improves with additional, independently energized sections, but improving performance must be weighed against additional capital and operating costs. Proper sectionalization can overcome the effects of a poorly operating section(s) due to adverse process or mechanical/electrical conditions.

Fig. 6 Typical ash resistivity.

Fig. 7 Summary of fine particulate collection (adapted from Reference 4).

Rapping effects Rapping causes some amount of particulate re-entrainment in the flue gas flow. Given the nature of the precipitation process, adjustment of rapping (how often and how intense) can greatly impact outlet emissions, either positively or negatively. Proper rapping adjustment in the outlet sections is especially important because there are no downstream sections to handle re-entrainment due to over-rapping. There are no set industry standards for rapping adjustments although many suppliers begin with proprietary guidelines. Effective fine-tuning is usually based upon the supplier's field experience or plant personnel familiar with the specific ESP.

Ash removal Proper ESP design will prevent operational issues associated with re-entrainment from the hoppers. However, a malfunctioning ash removal system can also cause problems. High ash levels can permit excessive re-entrainment, and can cause electrical malfunction if the ash pile contacts the discharge electrode system (high resistance grounding). If not corrected, ash removal malfunction can also cause the ash pile to float upward and distort the DEs.

Performance enhancements

A change in fuel, a boiler upgrade, a change in regulation, or performance deterioration may call for a precipitator performance enhancement. Enhancement techniques include additional collection surface, flue gas conditioning, improved/modified gas flow distribution, additional sectionalization, additional rapping, control upgrades and internals replacement. Gas conditioning alters resistivity by adding sulfur trioxide (SO_3), ammonia, moisture, or sodium compounds while the other modifications involve only mechanical and/or electrical hardware changes.

After identifying the causes of current or anticipated performance deterioration, the equipment is surveyed to determine the need for replacement or upgrade. Additional collection surface, in series or in parallel with existing surface, may be needed to meet improved particulate collection needs. Gas condition-

ing may be used to offset some collection surface deficiency or to enhance the performance of a marginal precipitator. Large dust accumulations near the precipitator entrance, flow patterns on the collection surface, and a velocity traverse across the precipitator face indicate possible flow maldistribution. In addition, TR set controllers made before the mid-1980s can potentially benefit from an upgrade to improve performance. Finally, a detailed internal inspection will determine a possible need for replacement of collection surface and discharge electrodes and the need to upgrade the rapping system. A combination of enhancement techniques may be needed.

Wet electrostatic precipitators⁶

The collection of acid mists consisting of fine particulate has been accomplished with wet electrostatic precipitators (WESPs) for nearly 100 years, principally on industrial processes. These WESPs differ from the dry ESPs in both materials and configuration; however, the collection mechanism is basically the same. Typical operation is at or below the flue gas acid moisture dew point temperature for the gas being filtered, and particulate loading is low compared to normal coal-fired dry ESP applications. Collection efficiencies of 99% have been reported with wet ESPs when precipitator sections or modules are placed in series. (See Chapter 35, Fig. 15.)

Boiler applications Wet ESPs have not historically been used for utility or industrial boiler emissions control when firing coal, oil or gas. However, with the emergence of expanded emission control requirements, reduced emission limits, use of non-traditional fuels and the interactions of other emissions control equipment, there has been renewed interest in the use of WESPs to control selected emissions, especially of sulfuric acid mist and fine dry particulates. Firing of petroleum coke and Orimulsion[®] fuel can result in elevated levels of SO₃ in the flue gas. In addition, as noted in Chapter 34, SCRs on coal-fired systems have a tendency to increase the concentration of SO₃ in the flue gas due to the oxidation action of the catalyst. Depending upon the catalyst selection, this oxidation can increase the SO₃ significantly on the higher sulfur fuels. As the SO₃ is carried through the cooler backend equipment, it condenses and becomes an acid mist (H₂SO₄). When wet flue gas desulfurization systems are used for sulfur control, significant levels of SO₃/acid mist tend to pass through the system and result in opacity/visibility problems at the stack. (See Chapter 35.) Acid mist has also been noted on some units without the wet FGD systems. WESPs have demonstrated the ability to effectively collect the H₂SO₄ and other aerosols in such environments.

Wet precipitator design The WESP design generally follows that of dry ESPs. However, WESPs differ from dry ESPs in three key areas. First, the physical arrangement of WESPs can be non-standard compared to dry ESPs. The WESP configuration and shapes of the key components can be adapted to integrate the WESP with other system equipment, such as the case of the integration of a WESP in a wet flue gas desulfurization system discussed in Chapter 35.

The components can also be configured in a more conventional stand-alone arrangement. Second, the moist corrosive atmosphere present requires careful selection of material in critical areas. Third, instead of a rapping system to remove the collected particulate, water spray or a water film removes the material deposited on the collection surfaces and discharge system. The physical arrangement of the bottom of the WESP is then adapted to collect the water film discharge.

Fabric filters

A fabric filter, or baghouse, collects the dry particulate matter as the cooled flue gas passes through the filter material. The fabric filter is comprised of a multiple compartment enclosure (see Fig. 8 and chapter frontispiece) with each compartment containing up to several thousand long, vertically supported, small diameter fabric bags. The gas passes through the porous bag material which separates the particulate from the flue gas.

Operating fundamentals

With the typical coal-fired boiler, the particle laden flue gas leaves the boiler and air heater and enters the filter inlet plenum which in turn distributes the gas to each of the compartments for cleaning. An outlet plenum collects the cleaned flue gas from each compartment and directs it toward the induced draft fan and the stack. Inlet and outlet dampers then allow isolation of each compartment for bag cleaning and maintenance. Each compartment has a hopper for inlet gas flow as well as for particulate collection and removal by conventional equipment, as discussed further in Chapter 24. The individual bags are closed at one end and connected to a tubesheet at the other end to permit the gas to pass through the bag assembly. The layer of dust accumulating on the bag is usually referred to as the *dustcake*.

Collection of the particulate on the bag fabric is the heart of the filtering process. The major forces causing this collection include impingement by either direct contact or impaction and dustcake sieving. Minor forces which assist in the collection are diffusion, electrostatic forces, London-Van der Waal's forces and gravity.⁷ The dustcake is formed by the accumulation of particulate on the bags over an operating period. Once formed, the dustcake, and not the filter bag material, provides most of the filtration. Some filter media such as membrane and tight needle felts provide higher removal efficiency than normally achieved by filter cake alone. Although impingement collection is most effective on the larger particles and the sieving process collects all particle sizes, a dustcake must form to maximize overall collection.

As the dustcake builds and the flue gas pressure drop across the fabric filter increases, the bags must be cleaned. This occurs after a predetermined operating period or when the pressure drop reaches a set point. Each compartment is then sequentially cleaned to remove the excess dustcake and to reduce the pressure drop. A residual dust coating is preferred to enhance further collection. In pulse jet fabric filters (discussed below), it is common to perform cleaning online which maintains all compartments in operation.

Fig. 8 Pulse jet fabric filter.

Initial filter bags have a pre-coat filter media. The pre-coat is an optimum particle size mixture which aids in developing the first filter cake and tends to stay within the outer surface of the filter media.

Types of fabric filters

Bag cleaning methods distinguish the types of fabric filters, with the three most common types being reverse air, shake deflate and pulse jet. The cleaning method also determines the relative size by the air/cloth (A/C) ratio and the filtering side of the bag. Both the reverse air and the shake deflate are inside-the-bag filters with gas flow from inside the bag to outside; the pulse jet is an outside-the-bag filter with the flow from outside to inside (Fig. 9). Note that the tubesheet on the inside-bag filtering is located below the bags; for the pulse jet the tubesheet is above the bags.

A reverse air, more correctly termed *reverse gas*, filter reverses the flow of clean gas from the outlet plenum back into the bag compartment to collapse the bags in an isolated compartment and dislodge the dustcake. This is a gentle cleaning motion. Once the dislodged particulate falls to the hopper, the bags are gently reinflated before full gas flow is allowed for filtering. This system requires a reverse gas fan to supply the cleaning gas flow along with additional dampers for flow control. This type of filter system has been used in most large utility power plant fabric filters in the U.S. to date. Experience with this type of fabric filter on some coal flyash applications has demonstrated that reverse gas cleaning alone does not provide an acceptable operating pressure drop. Therefore, some units have added sonic air horns to each compartment to assist in the cleaning.

Shake deflate (*shaker*) filters are similar to reverse air units in that the cleaning occurs in an isolated compartment and a small amount of cleaned flue gas is used to slightly deflate the bags. In addition, a mechanical motion is used to shake the bags and dislodge the accumulated dustcake.

Pulse jet technology is a more rigorous cleaning method and can be used when the compartment is either isolated or in service. A pulse of compressed air is directed into the bag from the open top which causes a shock wave to travel down its length, dislodging the dustcake from the outside surface of the bag. A unique aspect of the pulse jet system is the use of a wire cage in each bag to keep it from collapsing during normal filtration. The bag hangs from the tubesheet. A series of parallel pulse jet pipes are located above the bags with each pipe row having a solenoid valve. This permits the bags to be pulsed clean one row at a time. Use of pulse jet units with utility boilers is increasing and they are expected to be the major contributor for retrofit or new units.

A variant of the pulse jet fabric filter called COHPAC® (compact hybrid particulate collector) is the unique use of a high velocity fabric filter commonly installed after a malperforming electrostatic precipitator. This arrangement reduces particulate emissions and may prove to be a good solution in special applications.

Design parameters

Three key fabric filter design parameters are air/cloth (A/C) ratio, emission rate and drag. A/C ratio is the gas volumetric flow rate divided by the exposed bag surface area and is commonly referred to as the filtration velocity. Industry standards, along with operating experience, establish the design A/C ratios. The A/C has a significant impact on useful bag life. Lowering the A/C ratio for a specific fabric filter design tends to increase bag life and conversely increasing A/C ratio decreases bag life. A/C ratios are typically stated with one compartment out of service for cleaning (net condition).

A/C ratios commonly applied to coal-fired boilers may range from 1.5 to 2.3 ft/min (0.45 to 0.7 m/min) with reverse air fabric filters and 3.0 to 4.0 ft/min (0.9 to 1.2 m/min) for pulse jet fabric filters. The type of firing and ranges in fuel significantly affect the appropriate filtration velocity.

The emission rates are generally established based upon historical data. Several prediction models have been developed but they are of limited use. Bench tests using collected particulate samples have proven beneficial as an indicator for media selection.

The pressure drop includes the drop across the bags, the dustcake and the attachment of the bag to the tubesheet. The calculation of drag is useful in evaluating performance.

The general equation for drag can be expressed as follows:

$$\Delta P = a \times V + b \times c \times t \times V^2 \quad (4)$$

where

ΔP = pressure drop, in. wg (kPa)

a = constant with units of in. wg-min/ft (kPa-min/

m) (This value is determined based upon actual operating data. This constant increases as the fabric filter media ages. The product of $a \times V$ is referred to as the effective residual pressure drop.)

V = the filtration velocity, ft/min (m/min)

b = the cake coefficient with units of in. wg-min-ft/lb. Values range significantly from 0.1 to 700. Flyash from coal ranges from 5 to 20. (kPa-min-m/kg)

c = the inlet dust concentration with units of lb/ft³ (kg/m³)

t = time, min.

Applications

The Babcock & Wilcox Company (B&W) participated in the first U.S. utility fabric filter installation in the 1960s, on an oil-fired boiler in southern California.⁸ Several utilities followed by the late 1970s. Interest in these systems continues to grow due to the high particu-

Fig. 9 Fabric filter types.

late removal efficiency. Well designed filters routinely achieve greater than 99.9% particulate removal, meeting all current U.S. EPA and local regulations.

Besides standard utility coal-fired applications, fabric filters are used on circulating fluidized-bed boilers, industrial pulverized and stoker coal units, refuse-fired units in combination with a dry flue gas scrubber, and in the cement and steel industries. Fabric filters are not currently used on oil-fired units due to the sticky nature of the ash.

A unique advantage with fabric filters is that all of the flue gas passes through the dustcake as it is cleaned. When the dustcake has high alkalinity, it can be used to remove other flue gas constituents and acid gases, such as sulfur dioxide (SO₂). (See Chapter 35.) Addition of activated carbon into the flue gas has been used to control mercury emissions. Fabric filters generally are better collectors of the carbon and mercury components than are electrostatic precipitators.

Fabric filter components

Configurations Pulse jet fabric filters have two general arrangements. The first is called *hatch style*, that has large horizontal covers used to access the area above the tubesheet for bag replacement. The most common arrangement includes a penthouse above the hatch covers. The second type, called *walk-in*, has a gas-tight compartment above the tubesheet with vertical doors to access the area above the tubesheet for bag replacement. Walk-in arrangements are more common for industrial sized units with shorter bags.

Reverse air and shaker units generally have access through vertical doors located at the tubesheet level and also located at a level near the top of the bags.

All styles of fabric filters can be provided with integral compartments sharing common division walls or with separate walls forming the compartments. The latter style is commonly referred to as modular and generally used on small industrial units.

The gas conveying flues of all styles of fabric filters can be of a design integral to the compartment casing walls or totally separated. Most utility size fabric filters utilize common wall construction.

Casing, hoppers and dampers

Enclosure or casing The fabric filter is a metal encased structure with individual bag compartments. The inlet and outlet plenums are typically located between two rows of compartments to provide short inlet and outlet flue connections (see Fig. 8). This enclosure rests on a support steel structure. For reverse air units, interior access is required at both the lower tubesheet and bag support elevations. In a pulse jet filter, access is required above the tubesheet for bag cage removal. This is provided by large roof access doors or by a top plenum and a side manway. Typical enclosure materials are carbon steel ASTM A-36 or equivalent under normal coal-fired boiler conditions. The entire enclosure is covered with insulation and lagging to keep metal temperatures high and to minimize corrosion potential.

Hoppers Each filter compartment has a hopper to collect the dislodged particulate and to channel its flow

to the ash removal system. Most filters also use the hopper as part of the flue gas inlet to each compartment. Therefore, the hopper is designed with steep sides for ash removal along with considerations for proper gas flow distribution. Hopper heaters, level detectors, poke holes and an access door are common hopper features.

Dampers Each filter compartment may be provided with both inlet, outlet and on reverse air filters, deflation dampers. These dampers may be manual or automated. Louver and poppet dampers are normally used. Dampers allow isolation of compartments for offline cleaning and online service entry. Some units include bypass dampers.

Bag materials and supports

Substantial research and development on bags and their materials have taken place to lengthen their life and to select bags for various applications. (See Table 1.) The flexing action during cleaning is the major factor affecting bag life. Bag blinding, which occurs when small particulate becomes trapped in the fabric interstices, limits bag life by causing excessive pressure drop in the flue gas. Finishes on the bag surface are also used to make some bags more acid resistant and to enhance cleaning.

The most common bag material in coal-fired utility units with reverse fabric filters is woven fiberglass. Typical bag size is 12 in. (305 mm) diameter with a length of 30 to 36 ft (9.1 to 11.0 m). Bag life of three to five years is common. The shake deflate filters also use mostly fiberglass bags. On both of these units, the fiberglass bag is fastened at the bottom to a thimble in the tubesheet. At the top, a metal cap is fitted into the bag and the bag has a spring loaded support for the reverse air filters. The bags are attached to the tubesheet commonly using a thimble and clampless designed bag. The upper operating temperature limit is 500F (260C) for most fiberglass bags.

The most common bag material in coal-fired utility units with pulse jet fabric filters is polyphenylene sulfide (PPS) needled felt. In addition to polyphenylene sulfide, fiberglass, acrylic, polyester, polypropylene, Nomex®, P84®, special high temperature fiberglass media, membrane covered media, and ceramic are used in various applications. For the pulse jet filters, the typical bag size is 5 or 6 in. (127 or 152 mm) diameter round or oval with a length of 10 to 26 ft (3 to 8 m). Advances in cleaning technology are increasing the ability to provide longer bags. Pulse jet bags are commonly sealed to the tubesheet using a snap-band seal. The bag is supported internally from a metal wire cage to prevent bag collapse during operation. Cages are normally carbon steel and may include a variety of coatings from pre-galvanized to coated wire. Some applications use a stainless steel cage.

Filter media cleaning

Reverse air fabric filters employ the most gentle form of cleaning. The method dislodges collected particulate by closing compartment dampers and, with the use of a reverse air fan, reversing the direction of gas flow. During reverse flow, gas passes from the outside of the bag to the inside, dislodging the collected ash from the in-

side surface of the bag. Sonic horns have proven successful in certain applications to assist in reverse air cleaning.

The shaker style of cleaning begins with the isolation of a compartment. Next, mechanical energy in the form of sinusoidal acceleration is applied to the top of the bag and travels along the bag to dislodge the material caked on the filter.

Pulse jet cleaning can be accomplished with all compartments operating, which is more normal, or by removing a compartment from service. Pulse air varies from low pressure, high volume to high pressure, low volume. The components of most pulse cleaning systems are similar. Blowers or air compressors are used to supply the cleaning air. Pulse valves are rapid opening and closing valves. Air is discharged from the outlet of the pulse valve along a supply pipe to nozzles or holes for discharge into the top of the bag. This air inflates the bag, dislodging collected filter cake from the outside surface of the bag. The more common style of pulse system has fixed supply pipes called blowpipes. An alternate type of pulse system has a rotating blowpipe.

Mechanical collectors

Mechanical dust collectors, often called cyclones or multiclones, have been used extensively to separate large particles from a flue gas stream. The cyclonic flow of gas within the collector and the centrifugal force on the particulate drive the particulate out of the flue gas (Fig. 10). Hoppers below the cyclones collect the particulate and feed an ash removal system. The mechanical collector is most effective on particles larger than 10 microns. For smaller particles, the collection efficiency drops considerably below 90%.

Mechanical collectors were adequate when the emissions regulations were less stringent and when popular firing techniques produced larger particles. These collectors were frequently used for reinjection to improve unit efficiency on stoker firing of coal and biomass. With stricter emissions regulations, mechanical collectors can no longer be used as the primary control device. However, with the onset of fluidized-bed boilers, there has been a resurgence of mechanical collectors for recirculating the bed material. A high efficiency collector is then used in series with the mechanical one to meet particulate emissions requirements. (See Chapter 17 for more information on fluidized-bed combustion.)

Wet particulate scrubbers

A wet scrubber can be used to collect particulate from a flue gas stream with the intimate contact between a gas stream and the scrubber liquid. The venturi-type wet scrubber (Fig. 11) is used to transfer the suspended particulate from the gas to the liquid. Collection efficiency, dust particle size and gas pressure drop are closely related in the operation of a wet scrubber. The required operating pressure drop varies inversely with the dust particle size for a given collection efficiency; or, for a given dust particle size, collection efficiency increases as operating pressure drop increases.

Due to the excessive pressure drop and the stringent particulate regulations, wet particulate scrubbers are now infrequently used as a primary collection device. However, on most coal-fired applications where wet FGD scrubbers are required in series with a high efficiency collector for control of acid gas emissions, the extra particulate removal of the FGD scrubber is an added benefit.

Equipment selection

Major evaluation factors to consider when selecting particulate control equipment include emissions requirements, boiler operating conditions with resulting particulate quantity and sizing, allowable pressure drop/power consumption, combined pollution control requirements, capital cost, operating cost, and maintenance cost. For new units that must meet the stringent federal, state and local regulations, the selection is reduced to a comparison of electrostatic precipitators and fabric filters because these are the only high efficiency, high reliability choices. For retrofits on operating units, the performance of existing control equipment as well as unique flue gas conditions may require specialized equipment.

The advantages of a well designed ESP are high total collection efficiency, high reliability, low flue gas pressure loss, resistance to moisture and temperature upsets, and low maintenance. Advantages of a fabric filter include high collection efficiency throughout the particle size range, high reliability, resistance to flow upsets, little impact of ash chemical constituents on performance, and good dustcake characteristics for combination with dry acid gas removal equipment.

Table 1
Fabric Filter Typical Media Applications

Fabric Filter Type	Construction	Materials	Typical Maximum Operating Temperature	Chemical Resistance
Reverse gas Shake deflate	Woven	Treated fiberglass	500F (260C) ±	Acid resistant coatings available
Pulse jet	Felted	PPS Nomex® P84® Acrylic Polyester	Ambient to 350F (177C) ± depending on specific media selected	Highly variable — consult manufacturer

Fig. 10 Mechanical collector.

Plants equipped with dry scrubbing systems will typically require a fabric filter if high SO₂ collection efficiencies (greater than 90%) are required due to the secondary scrubbing effect of the fabric filter. A comparison of overall and particle size collection efficiencies for precipitators and fabric filters is shown in Fig. 7. An application where small particulate dominates would favor a fabric filter for maximum control as long as bag blinding does not occur.

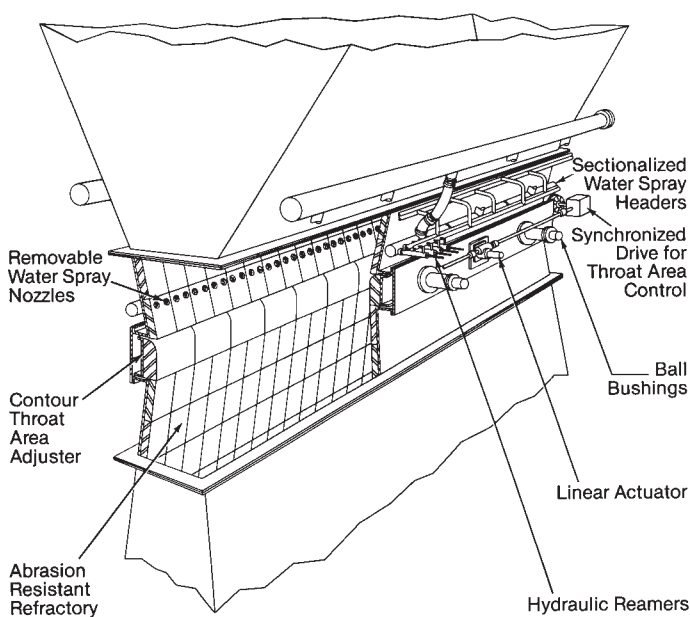

Fig. 11 Venturi-type wet scrubber.

For those applications where an ESP or fabric filter is technically acceptable and high collection efficiencies are required, some general guidelines on initial capital costs are: 1) on small units, a pulse jet fabric filter is generally more economical, 2) on units with medium or high sulfur coal, an ESP is economical, and 3) on low sulfur coal-fired large units, a pulse-jet fabric filter may again be more economical. However, when operating and maintenance costs are also considered, the lowest capital cost may not provide the lowest overall cost. Therefore, it is important to perform a detailed engineering study to quantify all of the variables for a specific site to obtain a true assessment of the real cost.

Chapter 34

Nitrogen Oxides Control

Nitrogen oxides (NO_x) are one of the primary pollutants emitted during combustion processes. Along with sulfur oxides (SO_x) and particulate matter, NO_x emissions contribute to acid rain and ozone formation, visibility degradation, and human health concerns. As a result, NO_x emissions from most combustion sources are regulated, monitored, and require some level of control. This control is closely tied to the combustion process and to various boiler system components.

NO_x formation mechanisms

NO_x refers to the cumulative emissions of nitric oxide (NO), nitrogen dioxide (NO_2), and trace quantities of other nitrogen-bearing species generated during combustion. Combustion of any fossil fuel generates some level of NO_x due to high temperatures and the availability of oxygen and nitrogen from both air and fuel.

NO_x emissions from fired processes are typically 90 to 95% NO with the balance NO_2 . However, once the flue gas leaves the stack, most of the NO is eventually oxidized in the atmosphere to NO_2 . It is the NO_2 in the flue gas which contributes to the brownish plume sometimes seen in a power plant stack discharge.

There are two principal mechanisms of NO_x formation in steam generation: *thermal* NO_x and *fuel* NO_x which are explored more in depth below. An additional source is *prompt* NO_x . Prompt NO_x is produced in fuel-rich conditions by a complex series of reactions between hydrocarbon radicals and molecular nitrogen in the flame zone, resulting in the formation of amines and cyano compounds and their subsequent oxidation to NO.¹ It is a relatively small contributor to total NO_x formation, especially in the combustion of coal and other nitrogen-containing fuels.

Thermal NO_x

Thermal NO_x refers to the NO_x formed through high temperature oxidation of the nitrogen found in the combustion air. The formation rate is a function of temperature as well as residence time at temperature. Significant levels of NO_x are usually formed above 2200F (1204C) under oxidizing conditions, with exponential increases as the temperature is increased. At these high temperatures, molecular nitrogen (N_2)

and oxygen (O_2) dissociate into their atomic states and participate in a series of reactions.^{2,3} One product of these reactions is NO. Since the traditional factors leading to complete combustion (high temperatures, long residence time, and high turbulence or mixing) all tend to increase the rate of thermal NO_x formation, some compromise between effective combustion and controlled NO_x formation is needed.

Thermal NO_x formation is typically controlled by reducing peak and average flame temperatures. Controlled mixing burners can be used to slow the combustion process. A second approach is staged combustion, where only part of the combustion air is initially added to burn the fuel; the remaining air is added separately to complete the combustion process. A third method is to mix some of the flue gas with the combustion air at the burner, referred to as flue gas recirculation (FGR). This increases the gas weight which must be heated by the chemical energy in the fuel, thereby reducing the flame temperature. Refer to Chapters 10 through 17 for more detail on the combustion processes and the fuel effects on NO_x formation.

Fuel NO_x

The major source of NO_x emissions from nitrogen-bearing fuels such as coal and oil is the conversion of fuel-bound nitrogen to NO_x during combustion. Laboratory studies indicate that fuel NO_x contributes approximately 50% of the total uncontrolled emissions when firing residual oil and more than 80% when firing coal. Nitrogen found in these fuels is typically bound to the fuel as part of organic compounds. During combustion, the nitrogen is released as a free radical to ultimately form NO or N_2 . Although it is a major factor in NO_x emissions, only 20 to 30% of the fuel-bound nitrogen is converted to NO.

The majority of NO_x formation from fuel-bound nitrogen occurs through a series of reactions that are not fully understood. However, it appears that this conversion occurs by two separate paths (see Fig. 1).

The first path involves the oxidation of volatile nitrogen species during the initial phase of combustion. During the release and prior to the oxidation of the volatile compounds, nitrogen reacts to form several intermediate compounds in the fuel-rich flame re-

Fig. 1 NO_x formation from nitrogen contained in coal during combustion.

gions. These intermediate compounds are then oxidized to NO or reduced to N₂ in the post-combustion zone. The formation of either NO or N₂ is strongly dependent on the local fuel/air stoichiometric ratio. It is estimated that this volatile release mechanism accounts for 60 to 90% of the fuel NO_x contribution.

The second path involves the release of nitrogen radicals during combustion of the char fraction of the fuel. These reactions occur much more slowly than the reactions involving the volatile species.

Conversion of fuel-bound nitrogen to NO_x is strongly dependent on the fuel/air stoichiometry but is relatively independent of variations in combustion zone temperature. Therefore, this conversion can be controlled by reducing oxygen availability during the initial stages of combustion. Techniques such as controlled fuel-air mixing and staged combustion provide a significant reduction in NO_x emissions by controlling stoichiometry in the initial devolatilization zone.

Global effects of NO_x in atmosphere

Once in the atmosphere, the NO₂ is involved in a series of reactions that form secondary pollutants. The NO₂ can react with sunlight and hydrocarbon radicals to produce ground level ozone/photochemical (urban) smog, acid rain constituents, and particulate matter.⁴ Each of these formations can have a significant effect on human health and on the environment. Automobiles and other vehicles are the major source of NO_x emissions with greater emissions concentration in the large metropolitan areas (see Fig. 2). Utility power plants and other fossil fuel burning steam generation sources also contribute to global NO_x emissions.

Acid rain

NO_x and sulfur dioxide (SO₂) contribute to the formation of *acid rain*, which includes a dilute solution of sulfuric and nitric acids with small amounts of carbonic and other organic acids. The NO_x and SO₂ react with water vapor to form acidic compounds; these acids account for more than 90% of acid rain. Nitric acid is formed through the reaction:

Most acid rain control has concentrated on SO₂ contributions instead of those due to NO_x because it is

estimated that NO_x contributes less than one-third of the acid rain generated.

Particulate matter

NO_x emissions can also contribute to fine, ambient particulate matter. In the atmosphere, NO_x reacts with other airborne chemicals to form nitrates, which contribute to the less than 2.5 micron particulate (inhalable portion of the ambient pollutants). NO_x also promotes the transformation of SO₂ into sulfate particulate compounds that can also be less than 2.5 microns in size.

NO_x control technologies in steam generation

Combustion technology-based NO_x control (see Chapters 11 through 16) is typically the lowest cost solution, provided it meets local and federal emissions requirements. Where further control is needed, fuel switching is used and/or post-combustion control is added.

Pre-combustion fuel switching

Unlike sulfur and particulate constituents in coal, nitrogen species contained in the fuel can not be easily reduced or removed. Therefore, the most common pre-combustion option for reducing NO_x levels is to switch to a fuel with inherently lower nitrogen content. For boilers capable of firing multiple fuels with minimal impact on the steam cycle, this may be the most cost-effective solution.

Coal combustion generally produces the highest NO_x emissions. Oil combustion generates less NO_x while gas firing produces even less. When firing oil fuels, a reduction in fuel nitrogen content results in reduced NO_x emissions. However, there does not appear to be a similar correlation between coal nitrogen content and NO_x formation. Other factors in coal chemistry, including volatile species, oxygen, and moisture content, appear to dominate the formation of NO_x during coal combustion. Therefore, reducing coal nitrogen content may not provide a corresponding NO_x reduction.

Fig. 2 Sources of United States NO_x emissions – 2001.

Combustion control

NO_x formation is promoted by rapid fuel-air mixing. This produces high peak flame temperatures and excess available oxygen which, in turn, promotes NO_x emissions. Combustion system developments responsible for reducing NO_x formation include low NO_x burners (see Fig. 3), staged burning techniques, and FGR. The specific NO_x reduction mechanisms include controlling the rate of fuel-air mixing, reducing oxygen availability in the initial combustion zone, and reducing peak flame temperatures. These are explored further in Chapters 11 through 16.

Post-combustion reduction

With current and proposed regulations, it is economically logical to consider NO_x controls that achieve the lowest emission levels possible. Additional NO_x control techniques can be applied downstream of the combustion zone to achieve the further reductions. These post-combustion control systems are referred to as selective catalytic reduction (SCR) and selective noncatalytic reduction (SNCR). In either technology, NO_x is reduced to nitrogen (N_2) and water (H_2O) through a series of reactions with a reagent (or reagents) injected into the flue gas. The most common reagents used in commercial applications are ammonia and urea for both SCR and SNCR systems.

SCR can effectively reduce NO_x levels leaving the boiler by 90% or greater depending on the specific project and space availability. SNCR typically is limited to lower NO_x reduction levels but may be the more economical choice depending on the required NO_x reduction or the unique project requirements. Both technologies have been successfully applied for NO_x reduction on multiple fuels and boiler types.

A combination of combustion and post-combustion NO_x control is frequently the most economical approach for existing installations and is the favored approach for installations that can not achieve emissions by combustion alone.

Selective catalytic reduction

Selective catalytic reduction technology is currently the most effective method of post-combustion NO_x reduction. SCR technology has been applied to a variety of fuels including natural gas, refinery gas, coals (bituminous, subbituminous, and lignite), fuel oils, petroleum coke, Orimulsion®, biomass, and refuse. It has been applied with conventional boilers as well as fluidized-bed boilers, process heaters, steel mill furnaces, and combined cycle gas turbines. SCRs have also been successfully installed on gas turbine based systems, reciprocating engines, and nitric acid plants. The technology and performance are sensitive to temperature and flue gas constituents and therefore are more closely related to boiler operation than are other types of environmental control equipment.

Initial development of SCR technology began in Japan around 1963. Early laboratory tests included the evaluation of many catalyst formulations and their life expectancies, as well as process design optimizations.

Fig. 3 DRB-4Z® low NO_x burner for coal firing.

Development tests were followed by several catalytic pilot plant installations during the early 1970s; the first commercial installations occurred in 1978.

NO_x reduction process

In the SCR process, a catalyst facilitates a chemical reaction between NO_x and a reagent (usually ammonia) to produce nitrogen and water vapor. The most common and predominant reactions are represented by the following equations. While the reactions are exothermic, the temperature rise across the catalyst is typically negligible due to the low NO_x concentrations.

As shown in Fig. 4, the ammonia (NH_3) is injected into the hot flue gas through an injection grid, the flue gas with the ammonia passes across the catalyst surface, and the NO_x reactions occur within the micropores of the catalyst. Nitrogen oxides are present in flue gas in the form of both NO and NO_2 with NO being the greater; however, NO_2 is preferentially reduced in this process.

SCR system description

While the main component of the SCR process is the catalyst, the full system contains a variety of components and subsystems. The catalyst is housed in a

Fig. 4 Principles of NO_x removal process for SCR.

large reactor. Flue gas is directed to and from the reactor by large flues that may contain control and shut-off dampers as well as flow distribution devices and static mixers, depending upon project-specific requirements. The reactor is a gas-tight steel enclosure that permits the flue gas and reagent to contact the catalyst for the required residence time to achieve design performance. The reactor structure includes internal stiffeners and a catalyst support system that also permits rapid loading and unloading of catalyst materials. The design includes a sealing system to avoid flue gas bypass, and may include catalyst cleaning devices (sootblowers and/or sonic horns). The reactor can be configured for vertical or horizontal flue gas flow depending upon the fuel, space availability, and upstream and downstream equipment. Separate economizer and SCR flue gas bypass flues are frequently included.

The reagent (usually ammonia) subsystems include truck or rail unloading, storage, vaporization or hydrolysis equipment, flow control, dilution air supply and mixing, and reagent distribution and injection components. Each subsystem contains piping valves, instrumentation, controls and safety equipment for appropriate ammonia handling and material compatibility. Further details are provided in subsequent sections of this chapter.

A critical part of SCR system design is integration into the overall boiler system. This is particularly important because the SCR system is normally integrated into the heat recovery portion of the boiler system between the close-coupled economizer and air heater. As a result, SCR system design must accommodate swings in flue gas temperature while maintaining the desired performance, without affecting boiler operation.

Hot side/high dust The ideal gas temperature for NO_x reduction ranges from 700 to 750F (371 to 399C). In utility boilers, this places the typical SCR system at the economizer outlet, preceding the air heater. (See Fig. 5.) This is the hot side location for all fuel types and the high dust location for ash-laden fuels. Units with hot side electrostatic precipitators (ESPs) can locate the SCR between the ESP and air heater to take advantage of the ideal temperature and to avoid ash effects on the catalyst. This has been labeled hot side/low dust. For some boiler applications, the ideal temperature range does not occur at a convenient location, and system design therefore requires special accommodations, such as a split economizer.

Cold side/low dust An alternative SCR location is after the air heater and particulate collection or flue gas desulfurization (FGD) systems, as shown in Fig. 6. SCRs installed in these arrangements are designated as cold side/low dust. These systems include all of the components referenced previously, but must also include a method to increase the flue gas temperature. On utility boiler applications, the cold side location has been reserved for retrofit installations where lack of space and outage duration have driven the decision. The additional equipment required for this design may include gas-to-gas air heaters, high pressure steam heat exchangers, duct burners, or a combination of

Fig. 5 New utility boiler with SCR.

these components. When installed after an FGD system or on a low sulfur fuel and after the particulate collector, this typically results in a design gas temperature of 600 to 650F (316 to 343C). This arrangement also allows a constant operating gas temperature throughout the boiler load range.

Industrial boiler applications may have a greater need for this arrangement. Package boilers may require a duct burner to achieve the required gas temperature. Boiler systems for biomass or refuse/waste fuels that contain rapid catalyst deactivation components should also consider the cold side/low dust arrangement.

Fig. 6 SCR located after air heater.

Catalyst

Catalyst formulation, pitch and sizing are the keys to successful SCR system application and performance. Although catalyst formulations are proprietary, the most common components in steam generation applications use titanium dioxide with small amounts of vanadium, molybdenum, tungsten, or a combination of other active reagents. Formulation is matched to the flue gas conditions based on ash-free flue gas, low-ash flue gas, high-dust flue gas and the ash constituents.

Catalyst types Catalyst types and materials typically fall into one of three categories: base metal, zeolite, and precious metal.

Most steam generation experience has been with base metal catalysts. These are typically described as titania-vanadia and can be provided as plate type, honeycomb type, or corrugated fiber type (see below). All three are similar in performance characteristics and can be supplied in a homogeneous construction or as a coated active layer on a base material.

The plate type catalyst (Fig. 7) is manufactured from a roll of stainless steel expanded metal substrate. The homogeneous catalyst is paste-pressed into and around the substrate to form a catalyst plate of 0.9 to 1.0 mm thickness. After cutting to length, correctly sized undulations, to set the catalyst pitch, are formed onto each plate prior to final processing and drying. The completed plates are then assembled into encased blocks; multiple blocks are packaged into a metal-frame shipping module. (See Fig. 8.)

Homogeneous honeycomb catalyst (see Fig. 9) is formed in an extrusion process that produces a catalyst log approximately 6 in. \times 6 in. (152 \times 152 mm) in cross section with the selected honeycomb cell pitch, and cut to proper length. After final processing and drying, the logs are assembled and packaged into metal-frame shipping modules.

Corrugated catalyst (Fig. 10) consists of a corrugated glass fiber substrate coated with titanium dioxide. After further processing, the base is impregnated with the active components. This catalyst is more porous and lighter than either the honeycomb or plate type. The resulting catalyst is cut to size and assembled into encased blocks and metal-frame shipping modules.

Fig. 8 Installation of catalyst blocks.

Zeolite catalysts are less common than the base metal catalysts but are effective in certain applications. These are aluminosilicate materials which function similarly to base metal catalysts. One advantage is the higher allowable operating temperature of greater than 1000F (538C). This catalyst will also oxidize SO_2 to SO_3 , is more sensitive to ash-laden flue gas, and is best applied to clean flue gas projects. Zeolite catalysts offer advantages for simple cycle gas turbines.

Most precious metal catalysts are manufactured from platinum and rhodium. There is little operating experience with these catalysts in steam generation systems. They also require careful consideration of flue gas constituents and operating temperatures. While effective in reducing NO_x at gas temperatures below

Fig. 7 Plate-type catalyst block.

Fig. 9 Honeycomb catalyst geometry.

Fig. 10 Corrugated catalyst geometry (courtesy of Haldor Topsoe, Inc.).

550F (288C) without reagent, these catalysts can also be used as oxidizing catalysts, converting CO to CO₂ under proper temperature conditions. However, SO₂ oxidation to SO₃ and high material costs often make these catalysts less attractive and limit the application to clean flue gas. Some catalyst manufacturers have combined the precious metal and base metal catalysts to allow both NO_x reduction and CO oxidation within one catalyst chamber.

Sizing criteria Catalyst performance depends on the surface area velocity, enabling the NO_x reduction reactions to occur. A common term that relates catalyst volume with a specific surface area is space velocity (S_v), expressed as Equation 4.

$$S_v = \frac{\text{flue gas flow (Nm}^3/\text{hr)}}{\text{catalyst volume (m}^3\text{)}} \quad (4)$$

Thus, the greater the space velocity the less catalyst required. Each catalyst configuration and formulation has a unique base space velocity. Catalyst pitch (plate centerline or cell spacing dimension) and catalyst type contribute to this space velocity.

A project's design space velocity is dependent on many factors. Primary factors include required NO_x reduction, flue gas flow, ammonia slip, gas velocity, flue gas constituents, required catalyst life, and distribution profiles (gas temperature, velocity, NO_x and NH₃/NO_x). An iterative process optimizes the selected catalyst volume and arrangement, accounting for gas velocity, pressure drop and fan adequacy. Typical performance guarantees include NO_x reduction/NO_x emissions, ammonia slip, catalyst life, pressure drop, ammonia consumption and SO₂ oxidation.

Operating issues Catalyst is not consumed during operation but does deteriorate. Deterioration is typically caused by poisoning, masking or blinding, and is most pronounced in the high dust arrangement. Deterioration occurs when the active sites within the catalyst micro-pore structure become contaminated and inactive. Moisture in liquid form can accelerate the deterioration. Operation at gas temperatures greater than 800F (427C) can also accelerate deterioration due to sintering of the pore structure. In some cases, poisoning from coal constituents like arsenic can

be eliminated with limestone addition to the coal. Catalyst management recommendations to address the deterioration issues are provided in a later section.

Catalyst protection is needed for extended boiler outage periods and when the catalyst is isolated during the periods when high NO_x control is not required. Humidity control and ash removal are necessary.

On projects with SO₃ in the flue gas, ammonium sulfates can deposit on the catalyst surface when gas temperature is below the precipitation temperature, as determined by capillary condensation at the ammonia concentration entering the catalyst. Therefore, a minimum continuous operating temperature is required. At the catalyst outlet there is a concern for deposits formed by the combination of ammonia slip and available SO₃ in the flue gas. This precipitation temperature typically occurs within the air heater. Remedies are provided later in this chapter. SO₂ oxidation to SO₃ across the catalyst may also increase the possibility of ammonia bisulfate formation and can affect downstream corrosion concerns; however, the amount of deposit is ammonia-limited.

Ammonia reagents and control

Reagents most commonly used today are anhydrous ammonia, aqueous ammonia, and urea. When urea is used, it is typically decomposed on site to ammonia, CO₂ and water. Regardless of the source, once the ammonia is in vapor form, it is common to dilute the ammonia stream with air to assist with transport, flow control and injection functions.

A typical ammonia control and supply system is shown in Fig. 11.

Anhydrous ammonia reagent systems Various grades of anhydrous ammonia are available. Commercial grade ammonia is the most common grade used for SCR systems. It is approximately 99.5 to 99.7% pure NH₃. The remaining fraction is water with a small amount of oil. The water component helps combat stress corrosion cracking, which is more likely to occur when the highest metallurgical grade ammonia at 99.995% pure NH₃ is used with standard carbon steel storage tanks.

Anhydrous ammonia is the purest form of ammonia available and allows the greatest storage volume efficiency. The storage tanks are typically horizontal, consisting of a cylindrical section with elliptical ends. These tanks are designed for the high pressures exhibited by the ammonia vapor at normal ambient conditions. Tank design pressure ratings are usually in the range of 250 to 265 psi (1724 to 1827 kPa) while normal operating pressures are generally between 80 and 120 psi (552 to 827 kPa). Storage and use of anhydrous ammonia are considered more hazardous compared to other reagent systems. This is primarily due to high concentrations, pressures, volatility, and explosiveness once it is evaporated to gaseous form. The typical tank capacity ranges from 10,000 to 100,000 gallons. In the United States (U.S.), federal and potentially state and local regulations may affect storage system design. To supply ammonia from the storage tank to the ammonia injection grid (AIG), the ammonia is typically vaporized and diluted with the

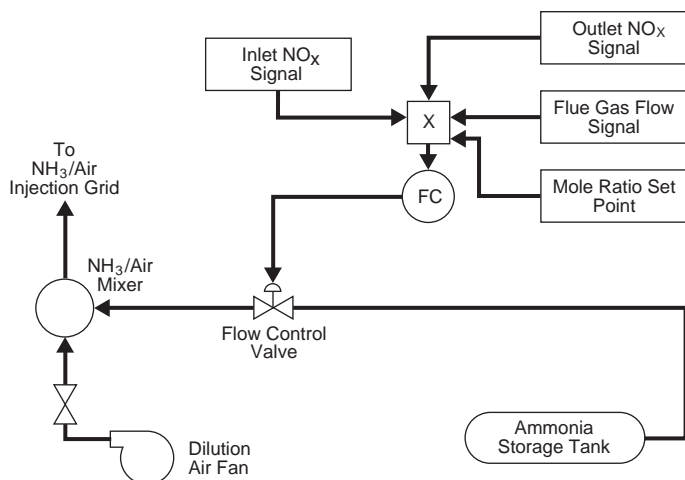

Fig. 11 NH₃/dilution air supply and control system.

air transport media. Vaporization can be integral to the storage tank or separate and closer to the SCR system. Sufficient dilution air is added to produce an ammonia-air mixture that is not within the combustible limits of approximately 15 to 30% NH₃ in air and to provide sufficient transport media volume for the injection process. The typical dilution air quantity will yield an approximate concentration of 5% NH₃ in air by volume.

In most cases, the dilution air flow is constant and the ammonia flow is adjusted to satisfy SCR system demand based on operating load, flue gas flow, inlet NO_x concentration, and the design or set point NO_x removal or SCR outlet concentration. An in-line static mixer is typically provided immediately downstream of the point where ammonia and dilution air combine. This ensures the mixture is adequately blended prior to its arrival at the manifold valve station. The manifold valve station controls the flow of this uniform ammonia-air mixture to individual ammonia injection locations within the SCR system inlet flue.

Aqueous ammonia reagent systems Aqueous ammonia is a diluted form of ammonia with NH₃ dissolved in water to form NH₄OH. Aqueous ammonia is typically available at concentrations up to a maximum of 29.4% [solubility limit at ambient conditions of 86F (30C) and 1 atm] by weight of NH₃ equivalent. This concentration is also frequently described as 26°Bé, where degrees baumé is an alternate measurement of density.

In the past, the 29.4% solution was typically preferred to minimize storage volume, cost associated with transportation weight of water, and cost of water vaporization. However, a legal classification change in the U.S. now lists ammonia-water solution concentrations below 20% as non-hazardous. This has encouraged the industry to consider a 19% concentration. This, however, increases storage tank volume and vaporization energy requirements due to the increased water content.

The storage tanks are typically horizontal, similar to those for anhydrous ammonia. Where anhydrous ammonia vessels are typically designed for approximately 250 psi (1724 kPa), aqueous tanks are normally rated at 20 to 50 psi (138 to 345 kPa). Tank material is typically carbon steel. Some installations utilize stainless steel to avoid startup problems asso-

ciated with rust. Most storage system designs will also incorporate a containment basin in case of a ruptured line or vessel.

The delivery method and unloading equipment are typically the same as for anhydrous systems. However, while the vapor pressure of ammonia in the water solution can present similar vapor lock or cavitation problems when using pumps, the problem potential is less severe. Therefore, pumped delivery is more common.

Various vaporization methods exist for aqueous ammonia. Many utilize a spray nozzle to atomize the aqueous ammonia into a hot dilution air stream in an evaporation chamber. The vaporized mixture is then transported to the manifold valve station which in turn supplies the AIG. Kettle-type systems that utilize an alternate heat source independent of the dilution air have also been used. These systems essentially boil off the ammonia, which is subsequently mixed with hot dilution air at a downstream location. The dilution air is hot in all cases, as it is important to maintain a stream temperature above the water saturation point during transport to the AIG. Transport lines are often heat traced and/or heavily insulated to prevent heat loss along the travel length. When the dilution air is the source of the heat of vaporization, the supply temperature must be even higher to account for vaporization and heat loss along the travel distance. Hot combustion air or flue gas is often used as the source of dilution medium on clean-fuel applications. Even so, it is sometimes necessary to incorporate electric or steam heaters to maintain minimum temperature requirements. When dilution air is pulled from ambient, heater cost and power consumption can become significant.

Similar to anhydrous systems, the dilution air quantity is typically that sufficient to provide an approximate 5% by volume NH₃ in air. If the design air temperature is lower than desired and/or the design ammonia flow demand is high, it can become necessary to dilute to lower NH₃ concentrations to maintain minimum transport temperatures. As with anhydrous systems, the dilution air flow is typically constant and the ammonia flow is modulated to satisfy the SCR system ammonia demand.

Ammonia from urea reagent systems Due to reduced handling concerns, urea has gained popularity. These systems utilize the relatively benign urea as the source of ammonia. Urea is commonly available in either liquid solution or solid form. The systems attempt to produce ammonia at a rate as close to demand as possible to essentially eliminate storage issues associated with large quantities of ammonia.

Most of these systems are designed to produce a gaseous mixture of ammonia, carbon dioxide and water by the hydrolysis of a urea-in-water solution. Often, the urea solution is produced at the site by blending deionized water and solid urea. Solutions are typically maintained in the 40 to 50% by weight range to avoid crystallization. Urea has an ammonia equivalence of approximately 53% by weight. The hydrolysis reaction is also endothermic and thus requires heat input to maintain the reaction. The basic hydrolysis reaction is as follows:

Other processes utilizing either variations on the hydrolysis process, high temperature flash vaporization, or catalysts are in initial commercial use. The primary goal among all of these systems is improved safety in transportation, storage, and handling of the required bulk reagent.

While solid urea is less costly to transport, it does present material handling challenges. The material tends to melt and break, leading to compaction and cohesive/adhesive handling and storage problems. These processes typically produce a moist gaseous product of approximately 20 to 30% ammonia. Similar to aqueous systems, the presence of water vapor requires a hot dilution air stream to prevent water condensation during transport to the AIG. Depending on system design, the dilution air may also be used to maintain line temperatures above those of undesirable corrosive substances. System capabilities to produce ammonia at changing demand rates can impact plant operation. The ramp rates of ammonia production may not closely follow the plant boiler load and subsequent ammonia demand. Due to these variations in system designs, operation and production capabilities, a thorough review is typically needed on a case-by-case basis.

Ammonia flow controls

As indicated in the equations for the ammonia reaction with the NO_x , one mole of ammonia is required to reduce one mole of NO_x and thus the required injection mole ratio of ammonia to NO_x is equal to the required NO_x reduction plus the ammonia slip value (ppm) divided by the inlet NO_x concentration (ppm). The control system logic uses a feed forward and feed back input with this equation, along with a flue gas flow input, to provide the ammonia flow control demand. The feed forward input is determined by either an inlet NO_x analyzer or a curve-generated value for repeatable boiler conditions. The feed back input can use the output of an SCR outlet analyzer or in some cases the stack continuous emissions monitor (CEM). Because of the hazardous nature of the ammonia, typically there are several interlocks that will interrupt ammonia flow upon upset conditions.

Distribution requirements

SCR reactor performance is influenced by the distribution of velocity, temperature and reacting gas components through the catalyst bed (see Fig. 12). The degree of a given profile uniformity can be generally described by the coefficient of variation (Cv), commonly reported as the percentage of the profile standard deviation from the arithmetic mean value.

$$Cv = \frac{\sigma}{\bar{x}} 100\% \quad (6)$$

$$\sigma = \sqrt{\frac{1}{(n-1)} \sum_{i=1}^n (x_i - \bar{x})^2} \quad (7)$$

Fig. 12 Typical downflow SCR reactor module.

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \quad (8)$$

where

σ = standard deviation
 \bar{x} = arithmetic mean

SCR reactor distribution goals for flow and molar ratio are commonly stipulated in this coefficient of variation format. Temperature distribution criteria is the exception by typically being expressed as a minimum and maximum (\pm) deviation about the arithmetic mean. The goal is to achieve the most uniform profile possible at the SCR catalyst inlet for NO_x concentration, ammonia to NO_x molar ratio, velocity and temperature. The degree of uniformity required for each parameter, coupled with the physical space and arrangement limitations presented, drives the level of complexity and intricacy of a successful design. Numerical or physical flow model studies are almost always used to determine the necessary distribution devices to achieve the desired uniformities.

Velocity distributions Velocity distributions are typically reviewed at two primary locations, at the inlet to the AIG and at the inlet to the catalyst. The velocity distribution at the AIG can impact the injection and subsequent or dosing concentration profile of ammo-

nia into the flue gas. This is where the initial NH_3/NO_x molar ratio variance is produced. Independently controllable AIG injection zones are often incorporated to allow some compensation for imperfect flow profiles. These designs offer the ability to improve the ammonia concentration profile by reducing flow to low gas velocity areas and increasing flow to high velocity regions.

Variations in flow across the reactor cross section produce variations in local space velocities. The effect of this on the overall NO_x removal and NH_3 slip is negligible if the C_v is less than 15%.

The high flow zones increase the localized catalyst operating space velocity. This reduces the residence time in that region of the catalyst bed. The result is a localized reduction in reagent utilization and efficiency while producing a corresponding increase in the local ammonia slip concentration. The low velocity areas exhibit the opposite. These areas allow excess ammonia to be more effectively utilized. The result is increased local efficiency and reduced local ammonia slip. The ultimate amount of excess ammonia in any zone is, however, limited to that of the local NO_x concentration.

When systems process dust-laden gases, the concern for velocity maldistribution extends to the potential for particulate deposition and particle impact induced erosion. The pressure drop across the catalyst bed can act to rebalance the flow distribution approaching the catalyst bed inlet. Thus, the actual flow through the catalyst may improve from that measured upstream. However, when gas approaches with a poor velocity distribution, the redistribution effect can aggravate erosion and deposition potential. The typical value for the catalyst inlet velocity coefficient of variation is 15% or less.

Temperature distributions Temperature distribution concerns are usually associated with the extremes in the profile. Concerns for reduced catalyst activity and/or ammonium bisulfate precipitation are associated with the low temperature zones, while catalyst degradation is a concern in the high temperature areas. Due to this interest in the extremes, the temperature distribution requirements are typically expressed as an allowable range and are often specified as a specific minimum and maximum (\pm) deviation about the arithmetic mean.

A commonly specified limit for profile extremes is $\pm 20\text{F}$ (11C). This range is fairly strict when compared to typical mean values of 550 to 750F (288 to 399C) and at times can be difficult to satisfy. This is especially true for sulfur-laden gases, which during low-load conditions require a portion of the flue gas to bypass the economizer to maintain a minimum operating reactor temperature. A review of the specific catalyst temperature requirements against the expected mean operating temperature can potentially allow for an increased deviation range.

Ammonia-to- NO_x molar ratio distribution Multiple factors determine the allowable NH_3/NO_x variation at the catalyst. These factors include the design NO_x removal efficiency, allowable ammonia slip, inlet NO_x concentration, and amount of excess catalyst.

NO_x removal efficiency is a significant factor. The

ability to satisfy low average and peak ammonia slip concentrations by the addition of extra catalyst volume becomes exceedingly difficult at high removal efficiencies. As 100% NO_x removal is approached, the problem is exemplified by the potential for a given deviation in the mole ratio distribution to produce localized zones in the reactor where the ammonia concentration exceeds that of the NO_x concentration. At these locations, once all of the NO_x is removed, no further ammonia can be utilized; the overall average removal efficiency becomes limited and average slip is increased. This is particularly problematic for coal or other sulfur-containing fuel systems where the average slip is more limited.

While there are no specific break points, systems designed for NO_x removal efficiencies below 80% can often allow a molar ratio coefficient of variation of 10% for both coal- and gas-fired projects. In the range of approximately 80 to 90% NO_x removal, the assessment becomes more complex. Coal or sulfur-laden gas projects typically require a molar ratio C_v of 5%, where gas-fired projects may still allow a C_v of 10%. The difference is due to the level of average excess ammonia reagent. Gas-fired designs usually have higher allowable ammonia slip values, typically on the order of 10 ppm. The resulting increase in excess reagent makes operation at higher inlet molar ratio maldistributions more practical. Above 90% removal, the performance becomes very sensitive to the precise design efficiency, design slip and inlet NO_x level, and a molar ratio C_v of 5% is typically required. For lower ammonia slip designs and/or when approaching 95% removal, the molar ratio C_v may need to move toward values of 3% or better. Such uniformity levels can require significant mixing and/or flue length.

Injection design and mixing

Two principal factors affect ammonia distributions prior to the catalyst. One is the degree with which ammonia disperses or merges from one injection point to another. The other is the dispersed, but locally imbalanced, concentrations produced by the imperfect injection of local ammonia flux to local NO_x flux within the duct. An additional factor, to be discussed later, is the degree of turbulent mixing occurring in the downstream flue, either naturally or by a forced action (i.e., mixing devices). (See Fig. 13.)

The first factor of dispersing ammonia from point-to-point can be improved by increasing the injection point area concentration or the number of injection points per square foot (meter). The quantity of injection points required considers the distance from grid to catalyst and the degree of mixing along that path. Obviously, there is a point of diminishing returns. The second factor can be improved by locally adjusting the ammonia flow to more uniformly inject ammonia flow into the local NO_x mass flux across the injection plane. Local NO_x mass flux is determined by the local volumetric gas flow times the local NO_x concentration. Designing the injection grid with independently controllable zones allows adjustment of the ammonia flow based on the gas flow variance and NO_x concentration variance across this injection plane. This can lead

Fig. 13 Turbulent flow model.

to improved final mixtures through better injection, and a reduced initial molar ratio variance.

Imbalances due to flow and NO_x concentration variations across the plane of ammonia injection are best addressed by upstream flue gas flow correction, independently controllable injection zones, and/or downstream mixing.

Static mixing (blending of multiple fluids across fixed vanes and/or obstructions) is often incorporated for high uniformity levels. Static mixing devices (see Fig. 14) vary in shape, size and functionality. In many cases, a coordinated approach between the ammonia injection grid design and the static mixers is required. The use of static mixers is not without consequences. The general pros and cons are:

Pros:

1. higher level of achievable uniformity in temperature and/or chemical component distributions,
2. increased stability in the degree of uniformity achieved, and
3. simpler ammonia injection grid design and/or operation.

Cons:

1. a need for sufficient downstream flue length to ensure mixer performance,
2. additional pressure drop attributed to the mixer(s),
3. reduced traceability of the injected ammonia path from a particular injection grid zone to the catalyst, and
4. production of velocity disturbances downstream of the mixer(s).

Operating issues

In addition to the catalyst operating issues discussed previously, general operating issues and system effects must also be considered.

Ash accumulation in horizontal flues during periods of reduced gas flow can cause buildup to form, move, and accumulate above the catalyst. Larger ash

agglomerate particles, often referred to as *popcorn ash* or *large particle ash* (LPA), can rapidly cover and block the inlet catalyst surface if allowed to reach the reactor. Flow model studies and arrangement design reviews are required to address these issues.

Sulfur-containing gases will experience a partial oxidation of SO_2 to SO_3 across the catalyst surface. While typically low, this oxidation level can influence air heater plugging when ammonium bisulfate is formed. It is also important when downstream scrubber systems are used and acid mist plume generation is of concern. Accurate ammonia flow control is required to minimize ammonia slip, and air heater design should consider the recommended features for reducing sulfate compound deposits.

Retrofit and general equipment issues

When an SCR system is retrofit on an existing plant, boiler modifications may be necessary for optimum performance. (See Figs. 15, 16 and 17.) Burner alterations/replacements to reduce furnace outlet NO_x can reduce reactor requirements. However, these same burner changes may increase furnace outlet NO_x maldistribution, and thus impact ammonia injection and/or mixing.

Physical space requirements of the reactor are often significant, and can require relocation of existing plant equipment. Air heaters are sometimes moved to allow proper flues between the upstream economizer outlets, the reactor, and the downstream air heaters. Arrangements become further complicated if economizer flue gas bypass is needed to sustain low load temperatures.

Air heater cold end surfaces can be enameled for ease of cleaning and to reduce corrosion. Changes in air heater surface design, as well as sootblower design and application, are often considered. These changes relate to ammonium bisulfate deposition and clean-

Fig. 14 Static mixing device for utility boiler SCR.

ing concerns when handling sulfur-laden gases and increased SO_3 concentrations.

The source of ammonia dilution air will vary depending on the ammonia system chosen and the nature of the boiler fuel being fired. Gas-fired systems produce a hot secondary air source that is essentially free of particulate. The coal-fired systems can exhibit sufficient entrainment of ash and traces of SO_3 into the secondary air stream of regenerative type air heaters; ammonia vaporization and injection system fouling can preclude using this source of heated air. Ambient air can be used in combination with steam or electric heaters. Designing for SCR reactor bypass can present additional arrangement challenges and costs. A catalyst protection system is also required to maintain dry catalyst conditions.

Pressure drop increase associated with the addition of flues, ammonia injection systems, mixers and catalyst can exceed existing fan limitations. Higher upstream static pressures in the boiler may also require costly furnace modifications to raise the design pressure. When new induced draft (ID) fans are added, other equipment such as precipitators may require a design pressure review.

The existing sale and/or disposal of flyash can be influenced by the retrofit. Flyash can absorb a portion of the ammonia, influencing its value as a saleable byproduct. Ammonia off-gassing can also occur when ammoniated high alkaline ash is wetted, as in the cement industry.

Whether a retrofit or a new system installation, structural design costs can be considerable. Catalyst weights and reactor spans are significant and the re-use and attachment to existing steel can complicate the analysis and the final design.

Operating system service needs

Due to the effects of flue gas (especially ash-laden), changes in control valve settings, or subtle changes in distribution, performance will change with operation. An increase in ammonia slip is the major indicator of this change. Therefore, catalyst activity, AIG valve settings, ash accumulation, and reactor pressure loss must be closely monitored.

The catalyst bed will typically contain samples which can be removed and tested during a short unit outage. Yearly sample analysis will establish an activity deterioration curve to establish a catalyst man-

Fig. 15 SCR retrofit on a 655 MW coal-fired boiler.

Fig. 16 SCR retrofit on two 600 MW coal-fired boilers.

agement plan. Frequent measurement and tracking of ammonia in most fly ashes can also be used to monitor reactor and catalyst performance.

Catalyst management activities include catalyst addition or replacement, depending on reactor design, and catalyst regeneration. Regeneration techniques include in-situ washing and catalyst layer removal for washing by specialists. Regeneration involves the re-

moval of ash from the catalyst surface and, in some cases, addition of active catalyst components. Some management plans will require a combination of methods. The cost of regeneration is generally less than the cost of new catalyst.

Eventually, the catalyst or a portion of the modules will require disposal due to erosion or unrecoverable poisoning. Since the catalyst is contaminated with the

Fig. 17 Oil- and gas-fired utility boiler SCR retrofit.

constituents from some fuels, the spent catalyst may require special landfill disposal procedures. Crushing of the honeycomb modules to reduce volume, sale of plate catalyst to steel mills, or negotiating disposal as a condition of new catalyst purchase are common solutions.

Re-optimization of the AIG control valve settings may also be required. A potential cause is a change in flow characteristics throughout the dilution medium and ammonia systems. Changes in the uniformity of gas flow, NO_x and gas temperature may also lead to re-optimization.

On high dust applications, cleaning during outage periods is recommended. Other periodic checks include removal of water accumulations from anhydrous ammonia systems, instrument and NO_x analyzer maintenance, and cleaning of impurities from aqueous ammonia and urea systems.

Technology enhancements

SCR advancements have centered on catalyst development for improved erosion resistance, resistance to chemical deactivation, lower SO₂ to SO₃ conversion, greater activity configurations, and an expanded temperature performance range. Catalyst materials such as zeolite and precious metals are more recent innovations.

Application of neural network control technology offers the potential to further optimize NO_x reduction for load-following operation.

Selective noncatalytic reduction technology

There are currently two basic selective noncatalytic reduction (SNCR) processes available. An ammonia-based system and a urea-based technology have been developed and commercially operated for many years. Although there are distinct differences to each technology, the overall processes are similar and will be presented as the same in the following sections. While the current emphasis in NO_x control has centered on the SCR technology, SNCR is an effective control technology for certain applications or in combination with combustion and control system techniques.

NO_x reduction reaction

SNCR technologies inject a reducing agent into NO_x-laden flue gas within a specific temperature zone. In addition, it is important to properly mix the reagent with the flue gas. Finally, the mixture must have adequate residence time at temperature for the reduction reactions to occur. The chemical reactions for the processes are represented by:

The acceptable temperature range for either reaction is 1400 to 2000F (760 to 1093C), although temperatures above 1700F (927C) are preferred. Below 1600F (871C), chemical enhancers, such as hydrogen,

are needed to assist the reactions. As the temperature increases within this range, the ammonia or urea may react with available oxygen to form NO_x. This reaction becomes significant at temperatures above 2000F (1093C) and may become dominant as temperatures approach 2200F (1204C).

The application of SNCR technology to boilers which by design have the suitable gas temperatures in the upper furnace is an attractive use of the technology. Examples of this boiler type are those applied to municipal solid waste and biomass firing. (See Fig. 18.) Multiple injection levels are used to maintain NO_x reduction efficiencies at acceptable levels as boiler load changes. Based on operating experience, four or more injection levels may be required for larger units. Multiple levels are required because the flue gas temperature profile changes with boiler load and the reagent injection point must be adjusted accordingly. To determine the most appropriate and effective injection locations, it is common practice to perform both numerical and chemical kinetics modeling of the furnace and combustion.

When using ammonia reagents with SNCR, it is important to control the excess unreacted ammonia. As flue gas temperatures are reduced, the excess ammonia can react with other combustion species, primarily sulfur trioxide (SO₃), to form ammonium salts. The major ammonium products formed are ammonium sulfate [(NH₄)₂SO₄] and ammonium bisulfate

Fig. 18 Typical SNCR application for a municipal solid waste boiler.

(NH_4HSO_4). Ammonium sulfate, typically formed when ammonia concentration exceeds SO_3 concentrations, is a dry, fine particulate (1 to 3 microns in diameter) that may contribute to plume formation. The ammonium bisulfate, typically formed when SO_3 concentration exceeds the ammonia concentration, is a highly acidic and sticky compound which, when deposited on downstream equipment such as economizers and air heaters, contributes to significant fouling and corrosion. The ammonia may also attach to the ash and affect its reuse or market value.

While NO_x reduction levels of 70% are possible under carefully controlled conditions, 30 to 50% reductions in NO_x emissions are more typically used in practice to maintain acceptable levels of reagent consumption and ammonia slip.

Most of the current applications for these technologies have been on stoker-fired and fluidized-bed boilers, where the appropriate temperature range and residence time are available. (See also Chapters 16 and 17.) In large utility units (see Fig. 19), the proper temperature range occurs in the convection pass cavities, making application, especially on retrofits, more challenging. For these applications, overall control may be limited to the 20 to 30% range. New boiler applications may require special design of the boiler convection pass with a dedicated open cavity in an optimal temperature window for the reactions to occur, although with current NO_x emission requirements this technology may be limited to lower NO_x fuels and processes. Other flue gas constituents, such as CO, may also affect the potential reduction achievable with SNCR.

Most SNCR process development has centered on optimization of the basic process. The use of natural gas or other injection agents above the reagent injection zone have been studied and installed with some success to extend the useful NO_x reduction temperature range and achieve greater NO_x reduction. A combination of SNCR and SCR catalyst to control ammonia slip has also been studied.

Reagent equipment and injection

The SNCR system consists of storage and handling equipment for the ammonia or urea, equipment for mixing the chemical with the carrier (compressed air, steam or water), and the injection equipment. Much of the equipment is similar to the SCR storage and handling equipment. The key component, the injection system, consists of nozzles generally located at various elevations on the furnace walls to match the expected flue gas operating temperature. The number and location of the nozzles are established by the supplier and are based on obtaining good reagent distribution within the flue gas.

One major difference between the ammonia and urea based processes is that the ammonia is usually injected

into the gas stream in a gaseous state, whereas the urea is injected as an aqueous solution. The urea technology requires a longer residence time for reactions due to the time required to vaporize the liquid droplets once they are in the gas stream. Aqueous ammonia systems may also be injected as a liquid with additional residence time required for vaporization.

Emerging technologies

A variety of advanced post-combustion NO_x control systems are at various stages of development and demonstration. Many of these are combined NO_x and SO_2 control systems. While the SNCR and SCR systems discussed here basically feature dry reduction of NO_x by ammonia or urea, advanced systems under development offer a variety of options, for example wet (aqueous) or dry absorption by solids, absorption plus oxidation by a liquid, and absorption plus reduction by a liquid. Technologies include low temperature NO_x oxidation with injection of an oxidizing agent like ozone, where NO_x is converted to soluble species that are easily removed with a water wash. Another example is the injection of a chelating agent to flue gas desulfurization (FGD) slurry to enable NO_x scrubbing. Although high NO_x reduction is claimed, further development and demonstration of these systems are required.

Coal-fired utility boiler selective catalytic reduction system retrofit.

wheel, and associated hardware. Rotary atomization far dominates (90+%) the utility and large industrial installed technology base. This is primarily because the rotary design provides higher slurry flow capacity per atomizer and better performance with higher solids slurries. Both systems have proven reliable and capable of consistently achieving low SO₂ emissions. Key performance requirements for SDA atomizers include:

1. ability to handle variable slurry flow rates,
2. rapid response to flow rate changes,
3. uniform spray coverage of the SDA chamber,
4. low susceptibility to pluggage and build-up, and
5. ease of removal for servicing.

For rotary atomizers, the spray droplet size distribution is a function of the speed of rotation, wheel diameter and wheel design as well as, to a lesser extent, reagent slurry feed properties including the flow rate, viscosity, density, and surface tension.⁴ Increasing the wheel speed reduces the droplet size at the cost of higher power consumption. Note that for a rotary unit, atomization quality is not sensitive to the diameter of the exit nozzles and so does not degrade as the nozzles wear from erosion by the reagent slurry. In addition to the slurry properties, key design criteria for dual-fluid nozzle atomizers include the nozzle exit orifice dimensions and orientation, air pressure, and air-to-slurry ratio. Water spray from a typical dual-fluid atomizer with multiple exit orifices is shown in Fig. 11. For this system, minimizing formation of large

(+100 micron) drops from primary atomization or the coalescence of sprays from multiple atomizers is a key criteria for successful operation.

Fig. 12 shows a compact selective catalytic reduction/SDA/BH installation for a 550 MW power plant. At this site, the two SDA chambers, each with a single rotary atomizer, treat approximately 1,800,000 ACFM (850 m³/s) of flue gases from a pulverized coal-fired boiler burning Powder River Basin coal to reduce SO₂ emissions by 94%.

Process description

The quantity of water in the reagent slurry introduced into the SDA is controlled so that it almost completely evaporates in suspension, leaving the solids exiting the spray chamber with a free moisture content of 1 to 2%. SO₂ absorption takes place primarily while the water is evaporating and the flue gas is adiabatically cooled by the spray. The difference between the temperature of flue gas leaving the dry scrubber and the adiabatic saturation temperature is known as the *approach temperature*. Flue gas saturation tem-

Fig. 9 Spray dryer absorber cutaway.

peratures are typically in the range of 115 to 125F (46 to 52C) for low moisture bituminous coals and 125 to 135F (52 to 57C) for high moisture subbituminous coals. The *stoichiometry* is the molar ratio of the reagent consumed to either the inlet SO₂ or the quantity of SO₂ removed in the process. Both definitions are in common use. Reagent stoichiometry and approach temperature are the two primary variables that control the scrubber's SO₂ removal efficiency. The optimal conditions for SO₂ absorption must be balanced with practical drying considerations. The approach temperature selected must be consistent with the atomizer feed slurry solids loading for efficient drying of the reagent solids. The *spraydown*, or difference between the inlet and outlet flue gas temperatures, and the solids loading of the atomizer feed slurry, determine how much reagent may be introduced to the process.

The predominant reagent used in dry scrubbers is lime slurry produced by slaking a high-calcium pebble lime. The slaking process can use a ball mill or a simple detention slaker. SDA systems that use only lime slurry as the reagent are known as *single pass* systems. Some of the lime remains unreacted following an initial pass through the spray chamber and is potentially available for further SO₂ collection. Solids collected in the ESP or baghouse may be mixed with water and reinjected in the spray chamber. This solids *recycle system* is used at most utility SDA installations to make use of the available alkalinity inherent in the flyash and to minimize reagent use. Some of the recycled

Fig. 11 Dual-fluid atomizer.

Fig. 12 B&W's SDAs and fabric filter baghouse provide an integrated SO₂ and particulate removal process.

solids form an inert core supporting the finer lime solids on the surface, thereby exposing more lime surface area for SO₂ absorption. The flyash may be removed from the flue gas before the SDA by a pre-collector. This is common practice in Europe where marketing of the flyash from coal-fired utility boilers is a well-established industry practice. Even with flyash pre-collection, a recycle system results in more efficient lime utilization.

The process is controlled by monitoring the flue gas temperature at the SDA outlet to control the amount of water or recycle slurry added to the atomizer feed. SO₂ emissions at the stack are compared to a desired operating set point and the lime slurry flow to the atomizers is adjusted to reduce the outlet SO₂ as necessary. For a rotary atomizer, the atomizer spindle, which connects the motor to the atomizer wheel, is monitored continuously for vibrations to provide an early indication of unbalance or plugging of the wheel.

Process flow diagram and mass balance

A typical SDA process flow diagram is shown in Fig. 13. The flue gases, with or without pre-collection of the flyash, enter the spray dryer absorber where the gas stream is cooled by the reagent slurry spray. The mixture then passes on to the baghouse for removal of particulate before entering the ID fan and passing up the stack. Pebble lime (CaO) is mixed with water at a controlled rate to maintain a high slaking temperature that helps generate fine hydrated lime (Ca(OH)₂) particles with high surface area in the hydrated lime slurry (18 to 25% solids). A portion of the flyash, unreacted lime and reaction products collected in the baghouse is mixed with water and returned to the process as a high solids (35 to 45% typical) slurry. The remaining solids are directed to a storage silo for byproduct utilization or disposal. The fresh lime and recycle slurries are combined just prior to the atomizer(s) to enable fast response to changes in gas flow, inlet SO₂ concentrations, and SO₂ emissions as well as to minimize the potential for scaling.

Process mass balances for recycle and single pass SDA system designs for a typical application are presented in Table 8 while the power requirements are provided in Table 9. In this example, use of the recycle system reduces lime consumption by 3141 lb/h (1424.7 kg/h), or 42% over that expected with single-pass operation. The stoichiometry for the single pass system is 1.78 on an inlet SO₂ basis compared to 1.04 for the recycle system. Note the difference in acceptable approach temperatures for long-term operation of the two systems. The 7% solids feed slurry with the single pass system requires operation at a 45F (25C) approach temperature or above for adequate drying while a 30F (17C) approach is used with the recycle system.

Dry scrubber chemistry

The mechanism of SO₂ absorption in an SDA is similar to that attained by wet scrubbing when viewed on the level of what takes place in the individual slurry droplets. Most of the reactions take place in the aqueous phase; the SO₂ and the alkaline constituents dissolve into the liquid phase where ionic reactions pro-

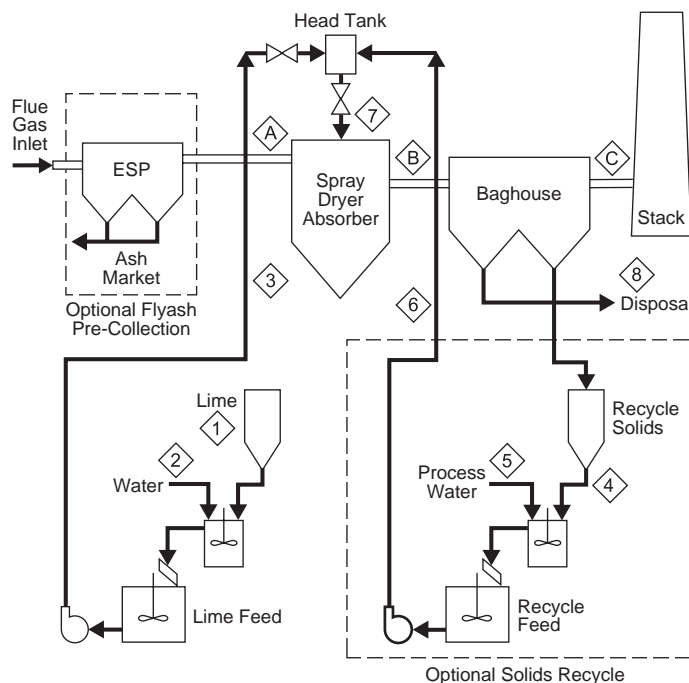

Fig. 13 Dry scrubber FGD system flow diagram (see Table 8 for mass balance).

duce relatively insoluble products. The reaction path can be described as follows:

These reactions generally describe activity that takes place as heat transfer from the flue gas to the slurry droplet is evaporating water from the droplet. The rate-determining reaction may vary at different stages of the drying and absorption process. The high pH in the droplet environment (10 to 12.5) helps maintain a low concentration of acid in the liquid phase that enhances SO₂ absorption from the gas stream. Rapid SO₂ absorption occurs when liquid water is present. The drying rate can be slowed down to prolong this period of efficient SO₂ removal by adding deliquescent salts to the reagent feed slurry. Salts such

*Process water addition to lime slurry for atomizer feed to achieve desired SDA outlet temperature.

as calcium chloride also increase the equilibrium moisture content of the end product. However, since the use of these additives alters the drying performance of the system, the operating conditions must be adjusted (generally increasing the approach temperature) to provide for good long-term operability of the SDA and the ash handling system. Ammonia injection upstream of a dry scrubber also increases SO₂ removal

performance. SO₂ absorption continues at a slower rate by reaction with the solids in the downstream particulate collector.

An SDA/baghouse combination also provides efficient control of HCl, HF and SO₃ emissions by the summary reactions of:

Table 9
Typical Power Requirements for 500 MW
SDA/Baghouse System in Table 8

Baghouse accessories, kW	445	445
ID fan power	6780	6880
Total	8645	8090
% of net 500 MW output	1.73	1.62

Proper accounting of the reagent consumption must include these side reactions, in addition to the SO_2 removed in the process.

The SDA process can make use of a variety of water sources for preparation of the reagent slurry and cooling of the flue gas. River water, well water, cooling tower blowdown, municipal waste water treatment effluent, and seawater have all been used successfully in SDA applications. In general, lime slaking requires good quality water with limitations on the sulfite, sulfate and TDS concentrations being the primary concerns for producing good quality fresh reagent slurry. Preparation of the recycle solids slurry and humidification of the flue gas to the desired operating temperature can be achieved with lower quality water sources. Selection of the process operating conditions must also consider the chloride content of the water sources to avoid problems with drying the reagent slurry and potential corrosion.

Sulfur trioxide (SO_3)

SO_3 and acid mist formation

Sulfur trioxide (SO_3) is formed directly in the combustion of sulfur-containing fuels, and indirectly by the conversion of small quantities of flue gas SO_2 to SO_3 in the presence of iron, some ash constituents such as vanadium, and some selective catalytic reduction (SCR) catalysts. Under normal operating conditions in coal-fired boilers without SCR systems, 0.75% of the SO_2 typically is converted to SO_3 . High vanadium containing ashes can increase this range to 2%. Conversion of SO_2 to SO_3 by SCR catalysts is dependent upon SO_2 concentration, gas temperature, and catalyst formulation with a typical range of an additional 0.7 to 1.5%. Catalysts have been formulated with relatively low SO_2 to SO_3 oxidation potential.

As the flue gas temperature falls below 1000F (538C), SO_3 begins to react with water in the flue gas to form sulfuric acid vapor, H_2SO_4 . By the time the flue gas exits the air heater, virtually all of the SO_3 has reacted to form H_2SO_4 .

Sulfuric acid condenses on metal surfaces beginning in the temperature range of 200 to 300F (93 to 149C) and results in corrosion of metal surfaces in flues, air heaters, dry ESPs and fans. Acid dew point curves are presented in Fig. 14. In addition, in units with wet scrubbers, any significant residual sulfuric acid mist can cause visible plume or opacity problems (blue plume), visible several miles from the power plant. Wet scrubbers are not effective in removing acid mists because the rapid flue gas quenching in the scrubber produces submicron aerosol mists which are not easily collected (20 to 30%). Dry scrubbers in combination with downstream baghouses are effective in removing H_2SO_4 (> 95% typical). Finally, in units equipped with SCR systems, excess ammonia (NH_3) leaving the SCR can react with SO_3 to form sticky, acidic particles of ammonium bisulfate (NH_4HSO_4) which can foul air heaters.

Control methods

Sorbent injection The injection of wet or dry alkali compounds (usually calcium or magnesium oxide compounds), typically in the furnace, after the SCR, or upstream of the particulate collection device has been shown to be an effective means of controlling $\text{SO}_3/\text{H}_2\text{SO}_4$. Sorbent injection has the advantage of low capital cost, but has very high reagent cost due to the high stoichiometric ratio (4 to 8) that is needed to achieve 80 to 90% $\text{SO}_3/\text{H}_2\text{SO}_4$ control. Dry ESP performance may be adversely affected by removing the SO_3 from the flue gas (see Chapter 33).

Humidification Cooling the flue gas by humidification upstream of an existing dry ESP will allow the dry ESP to collect some sulfuric acid. It is possible to operate a dry ESP at 20F (11C) below the acid dew point without encountering excessive corrosion. 20 to 40% sulfuric acid removal can be achieved in some instances. This is possible because the acid is absorbed on the flyash rather than on the metal surfaces of the dry ESP. Careful attention must be paid to thermal insulation integrity and in-leakage of seal air streams.

Ammonia injection Ammonia injection upstream of the dry ESP has been used to control acid mist. However, there can be problems with ash handling, since the ash tends to be more cohesive. It is also possible that excess ammonia will react with the SO_3 to form

Fig. 14 Dew point versus concentration.

submicron aerosols that are difficult to collect. Capital costs are low, but reagent costs are high.

Wet precipitator To achieve very high removals of acid mist, a wet ESP can be used. For a utility boiler, the wet ESP would be used downstream of the wet FGD system.

Either a stand-alone arrangement or an integrated close-coupled wet ESP can be used to control SO_3 ; however, the standalone arrangement is typically more costly than the integrated design and consumes considerable additional space. Fig. 15 shows the integrated design.

The submicron nature of the acid mist can only be treated in a multi-field unit. Acid mist removal efficiencies of 80 to 90% can be achieved. For example, if the inlet is 34 ppm_{dv}, less than 5 ppm_{dv} at the stack can be achieved. Wet ESP can also remove 80 to 90% of any solid particulate that is present, such as residual flyash from the dry ESP and the small amounts of gypsum that result from the wet FGD moisture separator wash system. Even if a wet ESP is not included in a wet FGD project today, careful thought should be given to future needs. The addition of a wet ESP to an existing wet FGD system may not be possible if provisions are not made before the initial wet FGD system installation.

Fig. 15 Integrated wet ESP and wet FGD system.

Chapter 36

Environmental Measurement

Environment related measurements at modern power plants are primarily performed to determine compliance with government regulations. However, measurements are also necessary to monitor and optimize process performance, assess guarantees, calibrate continuous emission monitoring systems (CEMS) and verify design information. As discussed in Chapter 32, fossil fuel power plants emit air, water and solid pollutants.

This chapter focuses on measurements for monitoring air pollution control systems and, in particular, equipment for controlling sulfur dioxide (SO_2), nitrogen oxides (NO_x) and particulate emissions. Special emphasis is placed on measurements associated with wet SO_2 scrubbing systems which involve perhaps the most complex process.

Post-combustion emissions can be controlled by the use of one or more of the following systems: 1) particulate – electrostatic precipitators (ESP) or fabric filters (baghouses), 2) NO_x – selective catalytic reduction (SCR) systems or selective noncatalytic reduction (SNCR) systems, and 3) SO_2 – wet or dry flue gas desulfurization (FGD) scrubbing systems or other forms of sorbent injection. These systems are discussed in Chapters 33, 34 and 35. In each case, the flow rate and composition must be measured for the associated gas, liquid and solid streams. In addition, the overall stack emissions are monitored and recorded.

Instrumentation

Primary measurements taken on environmental equipment include pH, liquid level, solids level, solids concentration (density), continuous emission monitoring for regulated pollutants, static and differential pressure, temperature and flow of liquid, flue gas, air and steam.

Chapter 40 discusses the measurement of pressure, temperature and fluid flow.

pH measurement

The acidic or alkaline nature of a liquid stream is monitored by measuring pH or the potential of hydrogen which is expressed as the negative log of the hydrogen ion concentration ($-\log_{10} [\text{H}^+]$). This is the most important parameter in controlling wet FGD systems. pH measurement is also important in water softening,

acid neutralization, and other auxiliary processes. The alkalinity, or lack of acidity, is generally proportional to the reagent use in the FGD system. Solutions with a pH less than 7 are considered to be acidic; those having a pH greater than 7 are alkaline.

pH measurements are used to control the feed of fresh reagent slurry to the wet FGD system. (See Chapter 35.) A bleed stream of recirculation slurry is passed through one or two pH sensors. The outputs are typically combined with signals for boiler load, SO_2 level, fresh reagent slurry density and flow to establish the flow of fresh reagent to the FGD absorber module. An increasing pH reduces the fresh reagent feed flow and a decreasing pH increases the flow.

pH is measured by means of electrodes and a voltmeter. The electrode (Fig. 1) is an electrochemical device comparable to a battery whose voltage changes with pH. In combination electrodes, one of the half-cells is the measurement electrode or pH sensing bulb and the other is the reference electrode or reference junction. Because the measurement electrode reacts to the pH of the solution, its potential is variable though repeatable. Theoretical electrode output varies from +414 mV at a pH of 0 to -414 mV at a pH of 14. The actual output is sensitive to the solution concentration at a reference temperature of 77°F (25°C).

The reference electrode completes the electrical circuit and produces a comparative voltage, so changes in the overall sensor are only a function of changes in the measuring electrode. The reference electrode is comprised of a potassium chloride (KCl) salt solution with a controlled amount of silver chloride (AgCl) dissolved in it. An Ag/AgCl electrode is placed into this electrolyte. The reference potential is a function of the KCl and AgCl concentrations. For example, a 1.0 M (molar) KCl electrolyte produces an offset (E_x), or voltage difference from theoretical, of -8 mV, while 3.3 M KCl produces a -45 mV offset (E_x). The difference, which is consistent across the entire range, is compensated for by standardization or zero adjustment.

The pH sensor is also affected by temperature. The slope (mV per pH unit) changes 1 mV per 5°C (see Fig. 2). Temperature is compensated for by slope or temperature adjustment or by automatic temperature compensation.

Fig. 1 Combination pH electrode (laboratory version).

The pH electrode used in wet FGD processes may be subject to fouling and aging. This is compounded by the slurry's abrasive or scaling nature which can cause plugging of the liquid junction. This junction is the point where the KCl reference solution meets the solution being measured. The liquid junction can be a small hole or may be made of fiber, wood, porous ceramic, Teflon or kynar. It holds the electrolyte in the probe and enables the electrolyte to form a salt bridge with the measured solution.

There are three types of pH sensors: dip, flow-through and insertion. The dip sensor is inserted into the tank and can be removed for maintenance and calibration. The flow-through sensor is placed in a flowing stream of process solution. The insertion sensor is a variation of the flow-through sensor, but does not require sample lines. It is inserted through packing and a valve into the flowing stream. To maintain or calibrate the insertion sensor, it is retracted through the valve, which is then closed to isolate the process.

All sensor types have advantages and disadvantages. The dip sensor is easy to maintain but prone to leakage from scrubber vessels that operate at positive pressure. Sample lines for flow-through sensors can plug. Both flow-through and insertion types are subject to high rates of erosion. All types are subject to scaling, although ultrasonic cleaning devices that are designed to remove brittle, insoluble coatings have been used with some success. Ultrasonic cleaners work best if used intermittently, but they can cause probe breakage.

The pH meter is a voltmeter that measures the electrode potential, converts the potential at a given temperature into pH terms, and corrects for nonideal behavior. pH meter operation depends upon proper standardization and calibration. This is best done with stable pH solutions known as buffers. Four of the best buffers, measured at 77F (25C), are pH 4.01, 6.87, 9.18 and 12.45 because they are traceable to the National Institute of Science and Technology (NIST).

Standardization (offset or buffer adjustment) is best done over the pH range anticipated. Standardization adjusts the offset so the meter reads 0.0 mV at pH 7.0. Calibration, or slope adjustment, compensates for alterations in an electrode's response to pH changes. To perform the calibration, the buffer should span the pH of the measured solution. For example, if the expected process pH is 5.4, then a buffer near pH 4 is preferred. The standardization/calibration procedure is summarized below:

1. standardize using a pH 6.87 buffer,
2. calibrate with a buffer that spans the process pH using a different adjustment than that used for standardization (calibration or slope), and
3. use the correct temperature setting, use an automatic temperature compensator or use the same temperature for the two buffers and the process.

Liquid level

Liquid level measurement is needed in any liquid storage tank that is not of the overflow design to control flow into and out of the tank. Examples in a wet FGD system (Chapter 35) include the tanks for absorber slurry recirculation, reagent storage, thickener underflow and quench recycle. In a typical dry FGD system, slurry levels in the lime feed slurry tank, recycle slurry tank and atomizer head tank are monitored. Common liquid level measurement devices are

Fig. 2 Typical pH electrode response as a function of temperature.

Table 1
Common Liquid Level Measurement Devices for Environmental Control Systems

Sensor Type	Theory of Operation	Environmental Control System Applications	Comments
Differential pressure	Measures differential static pressure with sensors or pressure taps mounted on the wall of the vessel. The sensor contacts the fluid.	Slurry tank level. This technique is often used with a ram valve or a flush system.	Reliable, subject to plugging in slurry application. Two types are used — flange mounted and extended diaphragm.
Ultrasonic	Emits ultrasonic pulse to the liquid surface. The transit time of the return pulse reflected from surface is converted to the liquid level.	Open tanks containing most fluids or slurries.	Sensors do not contact the liquid. Some problems result from waves, dust, vapor, foam, etc. Background noise can often be filtered electronically.
Electrical capacitance	Detects level by measuring the capacitance between the probe and the tank wall.	High/low level alarm. Discrete level capacitance probes can detect liquid surface.	Some problems with solids buildup or scale.
Float	Float moves up and down with level. The float is on an arm inserted into the vessel or within a housing.	Clean water, mill product tanks (nonscaling): high/low level alarm or constant tank volume.	Magnetic float types are available but are not considered good for scaling applications.
Radio frequency (phase tracking)	Detects an electrical signal which passes through a sensor and is reflected back at both the liquid surface and the bottom of the sensor. The signal phase shift provides a continuous indication of level.	Liquid and solids level.	Relatively new, promising technology. The electric field is much larger than the conductors.
Optical	Detects changes in light intensity.	Sludge level in thickeners.	For sludge level, the change in light intensity is measured at a fixed distance from the surface.

listed in Table 1. In SCR NO_x reduction systems, aqueous and anhydrous ammonia storage tank levels are monitored.

Differential pressure level transmitters are the most common for absorber recirculation tank level control because of their proven reliability. However, they are not the most accurate because of errors due to changes in slurry density or errors due to flue gas pressure above the liquid level.

Other liquid level devices have varying degrees of accuracy due to the tank conditions. For example, most tanks used in FGD systems contain slurry and are therefore agitated, causing waves or a vortex on the surface. The liquid surface level in the absorber tower recirculation tank is also disrupted by: 1) the very high spray flow rates impinging on the surface, 2) foaming due to gas released during the reactions or entrained by the spray, and 3) oxidation air sparged into the tank. Sensors immersed in the slurry also tend to scale. Some level devices use stilling wells to reduce the effect of agitation and to shield the level probe from spray.

Solids level

Many types of sensors used for measuring liquid level are also used for solids level measurement. However, solids level measurement presents some unique problems due to the often dusty environments, the uneven level caused by bridging or normal angles of repose characteristic of the solids, or the changes in density or properties due to compaction or aeration.

For environmental equipment, solids level measurement is used mainly for storage silos (ash, lime, limestone, gypsum) but is also used for hoppers on precipitators or fabric filters. Types of silo measurement devices include electrical capacitance, ultrasonic, and radio frequency (phase tracking) sensors. In addition, load cells or strain gauges that measure the weight change of the silo as it fills or empties are common. Another type of solids level device is a cable measurement system in which a weight or float is lowered automatically from the top of the bin or silo. When the float reaches the solids surface, loss of cable tension is detected. The device then measures the distance traveled by counting electronic pulses as the float retracts. The measured level is therefore the silo maximum level less the distance traveled by the probe. This device should not be used when the silo is being filled.

A typical device used to determine high hopper level is a nuclear transmitter and detector. When the ash level rises above the sensor, the strength of the signal from the nuclear source to the receiver is decreased. This signal is converted to a level indication. There have been objections to the use of this type of device due to the nuclear material present and licensing requirements.

Another high/low solids level device is the paddle wheel, which includes a motor that turns a paddle. When material is present, rotation of the paddle stops. The increased torque of the motor as it attempts to turn the stopped paddle triggers a microswitch alarm.

Finally, vibrating probes are sometimes used for single point solids level detection. The vibration of a piezoelectric transducer-driven probe inserted into the vessel is dampened by contact with material. This is detected as a voltage change, which is electronically amplified to yield a level indication. The capacitance probe is a similar device.

Solids concentration (density)

The most commonly used devices for density measurement are nuclear absorption meters (see Fig. 3). These devices measure the absorption of gamma rays from a radioactive source, and the degree of absorption is proportional to the solids content. Nuclear density meters do not contact the slurry; instead, they are installed on the outside of a slurry pipe. Some disadvantages of nuclear density meters are:

1. The signal is not linear with solids content unless a linearizer is used. If accurate chemical analysis of the slurry is available, the device can be pre-calibrated.
2. For some models, a nuclear license is required in the United States (U.S.) and in most other countries.
3. The device does not distinguish between suspended and dissolved solids.
4. Errors can result due to the buildup of solids or scale in the pipe.

Nuclear density meters are typically low maintenance devices. The inaccuracies mentioned above are routinely verified by manual sampling and measurement. Low level sources which do not require a site license have been used successfully in wet and dry FGD applications.

Other devices used for density measurement include differential pressure and ultrasonic devices and vibrating reed instruments. The reed instruments electronically convert the slurry dampening effect on electrically-driven coil vibrations to a density measurement.

Pressure, flow and temperature

Pressure, pressure differential, flow and temperature measurements are common in environmental system applications. They indicate process performance, energy consumption, operational problems and ability to meet design or operating requirements. Theory, instrumentation and application for these devices are discussed in detail in Chapter 40. Selected uses in environmental systems are discussed in Chapters 33 through 35. Comments with particular importance in environmental systems include:

Fig. 3 Nuclear absorption meter for density measurement.

1. Slurries tend to be highly erosive and potentially corrosive, and provision must be made for appropriate environments.
2. The presence of solids in liquid or gas flows can lead to plugging of measuring devices. Continuous purging systems are frequently included to ensure long-term operation.
3. Temperature monitoring can be particularly important for freeze protection, crystallization prevention, thermal gradient prevention (thickeners and clarifiers), corrosion prevention (precipitators, fabric filters, dry FGD systems and flues/ducts) and general process control. Elastomeric linings and fiberglass or plastic components must be protected from high temperatures. Unlined steel stacks must be protected from low temperatures.

Continuous emission monitoring systems

Early power plant emission measurements focused on providing information for combustion control. The manual Orsat gas analyzer, which sampled oxygen (O_2), carbon monoxide (CO) and carbon dioxide (CO_2) flue gas concentrations, was used extensively. However, this analyzer is not a continuous monitor and requires a trained operator.

Power plants are required to continuously monitor key emissions to maintain compliance with operating permits. In addition, continuous emission monitoring systems (CEMS) permit process control of the emissions control equipment and the combustion system.

During the 1980s, CEMS were used primarily to measure particulate (opacity), O_2 , SO_2 , NO_x and CO_2 . By the early 1990s, CEMS to monitor CO, hydrogen chloride (HCl), ammonia and volatile organic compounds (VOC) were introduced for commercial combustion applications.

The common methods for continuously measuring flue gas constituents are described in Table 2 and are further detailed in Table 3. All of the analyzers are similar in that they use a measuring cell and a reference cell. They are set to zero with air or a calibration standard, the span is set with a calibration standard, and a sample is taken. The result is obtained by comparing the voltages detected across the sample, the zero standard and span standard.

There are three types of analyzers – extraction, dilution-extraction, and in situ.

In the extraction method (Fig. 4), a sample of flue gas is withdrawn from the process stream and directed to an external analyzer for the constituent concentration determination. This type of analyzer is typically used where there are short distances between the sample point and the analyzer. The probe and sample line are often heated to prevent condensation from interfering with the measurement. Because the gas sample is typically drawn by vacuum to the external analyzer, sample line leaks can compromise the integrity of the sample.

The dilution-extraction method uses a carrier/dilution media, typically instrument quality air, which is supplied to the extraction probe in the flue gas process stream. Problems associated with dirty, wet and corrosive flue gases are drastically reduced by the 50

Table 2
CEM Technologies

Technology	Operating Characteristics
Infrared radiation (IR)	An infrared beam passes through a measurement filter and is absorbed by the constituent gas. A light detector creates a signal which is used to monitor concentrations.
Ultraviolet absorption (UV)	A split beam, with optical filters, phototubes and amplifiers, measures the difference in light beam absorption between the reference and sample.
Chemiluminescence	NO_x is measured by first converting any NO_2 to NO , then reacting with ozone to convert all the NO to NO_2 and its characteristic light generating effect. Ozone does not react with NO_2 .
Flame ionization detection	Hydrocarbons are ionized with strong light. The signals are received by the flame ionization detector.
Transmissometer	Light is passed through the stack where it is reflected by a mirror on the opposite side. The quantity of light returning is proportional to particulate matter and aerosols in the flue gas. (See Fig. 5.) Alternatively, the receiver may be placed on the opposite wall.
Electrochemical cells	The voltage measured when a gas sample is injected into a solution with a strong base is compared to a reference voltage.
Chromatography	A sample, zero and calibration gas are eluted through a column. The output as measured by flame photometric or thermal conductivity detectors is compared.

to 200 dilution ratio provided by the sample probe. Precise dilution is assured by accurately controlling the dilution air pressure which yields a constant air flow. The air flow creates a vacuum on the downstream side of a critical sample orifice. The gas sample rate, limited by sonic flow through the orifice, is therefore held constant. Furthermore, because the sample lines from the probe to the analyzer are under positive pressure, minor sample line leakage does not affect the integrity of the sample concentration as it would in a vacuum system. This method has gained wide acceptance in utility and other systems where long sample lines are required.

In situ analyzers, such as that shown in Fig. 5, provide measurement of flue gas concentrations directly in the process stream. Several types of detection devices are available, and all are based on absorption spectroscopy. Since gas stream particulates can reduce the level of light transmission, ceramic filters are used to exclude these particles. A single in situ probe can measure several gas species and opacity. Problems with in situ analyzers generally occur in the optic or

electronic components. Because a separate analyzer is required for each sample point, installations that require multiple sample points frequently find the extractive systems more cost effective.

Continuous analyzers generally require flue gas conditioning. Sample conditioning includes filtration to remove particulate (see Fig. 6), chilling to remove water, heating to maintain process temperature, and dilution (used with extractive monitor and in situ probe).

The need for conditioning coupled with zero and span calibration make extractive systems complicated,

Fig. 4 Extraction stack/inlet CEM system.

Fig. 5 In situ transmissometer system.

costly, and vulnerable to plugging, corrosion and leaking. These systems are also slow to respond due to the time lapse between sampling and analysis. In situ systems use conditioning but do not rely on long sample lines. These systems have faster response, fewer components and better availability than extractive systems. However, they are prone to interference and fouling and are less accessible for service. Extractive systems can be expanded by adding sample points as shown in Fig. 4. It is important to consider the location and ambient conditions in which CEMS equip-

ment is placed. Many of the problems associated with CEMS can be traced to dirty conditions, excessive heat or cold, vibration, humidity, etc.

Monitoring process performance

Environmental control systems involve physical and chemical processes. Chemical methods are used to maintain desired removal or emission levels, avoid operating problems, improve reagent utilization, improve process efficiency, troubleshoot equipment, and monitor process changes.

In a wet FGD system, the quality of the reagent and the recirculating slurry stream are monitored. Analysis is more critical for processes that produce a usable byproduct such as gypsum. In this case, the analysis extends into product purity and feed stream impurities. The quality of the reagent is normally measured extensively when the reagent source is selected. Later it is evaluated if the source is changed or process problems occur.

Tables 4 through 7 list the important analyses for common wet FGD systems. Additional analyses are required for makeup water streams, sodium-based FGD systems, dual loop systems, regenerative systems, ex situ oxidation processes, water treatment, and sulfuric acid or SO₂ recovery processes. However, the major species and methods would be similar to those presented in Tables 4 through 7; only the concentrations would vary. The analyses common for spray dry FGD

Table 4
Limestone Quality Analysis (Wet Limestone FGD Systems)

Parameter	Suggested Method*	Suggested Frequency	Use of Data
Reactivity	pH stat test followed by particle size measurement	Duplicate analysis of candidate limestones	Compared to reference to determine acceptability.
Grindability (Bond Work Index)	Laboratory ball mill test	Duplicate analysis of candidate limestones	Limited by specification of wet milling system design.
Particle size of limestone as delivered	Sieve method	Duplicate analysis of candidate limestones then monitor monthly	Limited by specification of wet milling system design.
Inerts	Acid dissolution	Duplicate analysis of candidate limestones then monitor weekly for gypsum systems	Quality indicator; important for gypsum systems.
Carbonate	CO ₂ evolution, Ba(OH) ₂ absorption, alkalinity titration	Duplicate analysis of candidate limestones then monitor weekly for gypsum systems	Check reagent quality; important for gypsum systems.
Calcium and magnesium	AA, IR, EDTA titration	Duplicate analysis of candidate limestones then monitor weekly for gypsum systems	Check reagent quality.
Limestone slurry solids content, % by wt	Gravimetric	Daily	Check density meter and indicate problems in milling circuit.
Limestone slurry particle size	Wet sieve	Daily	Troubleshooting problems in milling circuit or process such as low utilization or poor gypsum quality.

* Many methods have been standardized through the American Society for Testing and Materials, Philadelphia, Pennsylvania.

Table 5
Lime Quality Analysis (Wet Lime and Spray Dry FGD Systems)

Parameter	Suggested Method*	Suggested Frequency	Use of Data
Slaking rate	ASTM Method C-110-76a	Duplicate analysis on all candidate limes	Temperature rise rate is related to reactivity and lime quality.
Grit	Acid dissolution	Duplicate analysis on all candidate limes	High grit levels indicate poor lime quality.
Weight loss on ignition	Gravimetric	Duplicate analysis on all candidate limes	Weight loss is an indirect measure of lime quality via carbonate and hydroxide content.
Available lime index	Rapid sugar test	Duplicate analysis on all candidate limes	Lime quality.
Calcium/magnesium	Atomic absorption (AA) EDTA titration or Ion Chromatograph (IC)	Duplicate analysis on all candidate limes then as needed to check reagent quality	Analysis is required for processes producing a usable byproduct or high magnesium lime systems.
Lime slurry solids content, % by wt	Gravimetric	Daily	Check density meter calibration and indicate slaker performance.

* Many methods have been standardized through the American Society for Testing and Materials, Philadelphia, Pennsylvania.

systems are presented in Table 8. The lime quality analysis in Table 5 is applicable for wet lime or spray dry FGD systems. In general, there is significantly less process chemistry monitoring for a spray dry FGD system.

Performance testing

As with any system, performance tests are conducted on environmental control systems to determine if the units are operating properly. A typical new environmental control system might include low NO_x burners, SCR, ESP, wet FGD scrubber modules, and gypsum processing equipment. The ten most common parameters measured to determine performance for such a system include:

1. system pressure drop,
2. particulate emissions,
3. stack opacity,
4. NO_x emission concentration,

5. SO₂ removal efficiency and SO₂ emissions,
6. makeup water requirements,
7. reagent consumption,
8. gypsum purity,
9. mist eliminator carryover, and
10. electric power consumption.

Other performance parameters that would be measured depend on the type of system. Performance testing is usually extensive and expensive. Multiple performance tests may be completed for a new environmental control system depending on specific contractual requirements. An initial test may be followed by additional testing after a defined period of operation.

Sample location selection

Selecting the sample locations is the first step in the performance test and is often incorporated in the design of the environmental control system. Outlet sampling is not difficult if it is done in the stack. However, the inlet and intermediate samples are more difficult to obtain. In Fig. 7, the system inlet at the far left is a section of flue followed by an immediate upward bend. The dry precipitator outlet is at the induced draft (ID) fan inlet. Fig. 7 also shows test ports in the downward flue section after the absorber tower and at the stack entrance. Test port locations are selected to give the best flow profile within the plant layout limitations.

The number and location of traverse points are selected using U.S. Environmental Protection Agency (EPA) Method 1. Application of Method 1 is illustrated in Fig. 8. The distance downstream from the flow disturbance, which in this case is the stack inlet, is 138 ft (42.1 m). This is more than 8 diameters ($138/16 = 8.6$). The upstream distance to the stack exit is 5 diameters. Therefore, 12 traverse points are required by Method 1. For rectangular flues, Method 1 is applied by first determining an effective or equivalent diameter which is calculated as follows:

Fig. 6 Extractive sample probe with dust conditioning.

Table 6
Recirculation Slurry/Blowdown Analysis (Wet FGD Systems)

Parameter	Suggested Method*	Suggested Frequency	Use of Data
pH	2-buffer method calibration or grab sample	Once per shift by grab sample, daily by buffer method	Troubleshoot pH meter and maintain process efficiency.
Slurry suspended solids content	Gravimetric	Weekly	Calibrate density meter and maintain process efficiency.
Cations: Ca ⁺⁺ and Mg ⁺⁺ primary; K ⁺ and Na ⁺ secondary	IC, AA, ICP or wet chemistry methods	Daily for Ca ⁺⁺ and Mg ⁺⁺ in calcium-based systems	To calculate stoichiometry and monitor process chemistry.
Anions: SO ₃ ⁻ , CO ₃ ⁻ , SO ₄ ⁻ and Cl ⁻ primary; F ⁻ and NO ₃ ⁻ secondary	IC or wet chemistry methods	Daily for SO ₃ ⁻ , CO ₃ ⁻ , SO ₄ ⁻ , Cl ⁻	To calculate stoichiometry, measure chloride concentration, and monitor process performance and gypsum production.
Dissolved metals: Fe, Mn, Al, etc.	AA	Infrequently	Process troubleshooting.
Additives: adipic acid, dibasic acid, formate, thiosulfate, scale inhibitors, etc.	IC or wet chemistry methods	Daily	Determine or correct dosage.
TDS (total dissolved solids)	Gravimetric	Weekly	Calibrate density meter for suspended solids; important for mag-lime, high chloride or suspended solids.
Dissolved alkalinity	Acid-base titration	Weekly	Measure alkali loss in filter cake of mag-lime process; important for mag-lime or sodium systems.
Settling tests	Graduated cylinder	Weekly	Predict thickener performance and assist process troubleshooting.
Filter leaf test	Filter and weight	During startup	Predict filter cake properties.
Particle size distribution	Coulter counter or laser diffraction	During startup	Determine settling or dewatering characteristics; important for gypsum systems.

* Many methods have been standardized through the American Society for Testing and Materials, Philadelphia, Pennsylvania, and the Electric Power Research Institute, Palo Alto, California.

$$DC = \frac{2LW}{L + W} \quad (1)$$

where

DC = equivalent diameter
L = length
W = width

Then a matrix layout is used for sample location selection. The cross-section is divided into as many equal rectangular areas as there are traverse points, and the sample is taken at the centroid of each area.

Gas-side measurements

For a performance test, a combination of EPA Methods 5 and 8 is the most often used procedure to simultaneously measure particulate, SO₂, and SO₃ or acid mist (H₂SO₄) levels. The Method 5 sampling train, shown in Fig. 9, is used with Method 8 impingers shown in this figure. The data obtained from this traverse also represent EPA Methods 1 through 4. Results include gas velocity by S-type pitot tube (Fig. 10)

and CO₂, O₂, moisture, SO₂, particulate, and SO₃ or H₂SO₄ levels. The following calculations are used:

Determination of moisture content in stack gas

$$B_w = \frac{(MWC)(1.34)}{[(MWC)(1.34)] + \frac{(DGV)(P_m)}{T_m}(500)} \quad (2)$$

where

B_w = moisture fraction
 MWC = impinger weight gain, g
 DGV = sampled dry gas volume at meter conditions, ft³
 P_m = pressure at meter, in. Hg
 T_m = temperature at meter, R
1.34 = constant for converting grams of H₂O to liters of H₂O vapor at standard conditions, l/g
500 = conversion of cubic feet at meter conditions to liters at standard conditions, 1 R/ft³/in. Hg

Note: Low NO_x burners and other NO_x control options are incorporated with the boiler.

Fig. 7 Typical test port locations indicating compromises made in measurement due to equipment arrangement.

Determination of flue gas molecular weight – dry basis

$$M_d = \left[\frac{(44)(\% \text{ CO}_2 \text{ dry}) + (32)(\% \text{ O}_2 \text{ dry})}{+ (28)(\% \text{ N}_2 \text{ dry})} \right] \times 0.01 \quad (3)$$

where

M_d = molecular weight of gas on dry basis, lb/lb-mole
 44 = molecular weight of CO₂, lb/lb-mole
 32 = molecular weight of O₂, lb/lb-mole
 28 = molecular weight of N₂, lb/lb-mole

Determination of flue gas molecular weight – wet basis

$$M_w = M_d(1 - B_w) + 18B_w \quad (4)$$

where

M_w = molecular weight of gas on wet basis, lb/lb-mole
 M_d = molecular weight of gas on dry basis, lb/lb-mole
 B_w = moisture fraction, lb-mole H₂O/lb-mole wet gas
 18 = molecular weight of H₂O, lb/lb-mole

Determination of gas humidity

$$H = \frac{18B_w}{M_d(1 - B_w)} \quad (5)$$

Fig. 8 Stack dimensions and sampling port locations for EPA Method 1.

Table 7
Dewatering System Analysis (Wet FGD Systems)

Parameter	Suggested Method*	Suggested Frequency	Use of Data
Thickener or hydroclone underflow solids, %	Gravimetric	Daily	Troubleshoot process and calibrated lime density meters
Clarified water, water analysis (anions, cations, suspended solids)	See Table 6	Weekly	Monitor dewatering system performance
Supernatant, filtrant solids content, % by wt	Gravimetric	Daily	Monitor filter cloth status
Gypsum Quality Analysis			
CA ⁺⁺ , Mg ⁺⁺ , Na ⁺ , K ⁺ , Fe ₂ O ₃ , R ₂ O ₃ , SiO ₂	AA or ICP	Weekly	Product purity and properties
Cl ⁻ , SO ₄ ⁼	IC	Daily	Product purity and properties
SO ₃ ⁼ , CaSO ₃ · 1/2 H ₂ O	Iodimetric titration	Daily	Product purity and properties
Moisture content	Gravimetric	Daily	Important for marketable gypsum and monitoring dewatering system performance
Surface area	BET analysis (subsieve sizer)	Startup or process change	N ₂ gas is condensed on surface and absorbed; N ₂ corresponds to surface area
Combined water	Heat to 482F (250C)	Weekly	Gypsum purity
Mean particle size	Coulter counter, Sedigraph plus sieve analysis or laser diffraction	Startup or process change	Product purity and properties
Aspect ratio	Scanning electron microscope	Startup or process change as required by end users	Product purity and properties
Total water soluble salts	Sum (Na ⁺ + K ⁺ + Mg ⁺⁺)	As needed	Product purity and properties
Flyash	Determined as acid insoluble	Daily	Determined as acid insolubles along with silica (SiO ₂) and other impurities
pH	Electrode	Daily	Product purity and properties

* Many methods have been standardized through the American Society for Testing and Materials, Philadelphia, Pennsylvania, and the Electric Power Research Institute, Palo Alto, California.

Fig. 10 S-type pitot tube with sampling probe.

where

H = gas humidity, lb H₂O/lb dry gas
 B_w = moisture fraction, lb-mole H₂O/lb-mole wet gas
 M_d = molecular weight of dry gas, lb/lb-mole
18 = molecular weight of H₂O, lb/lb-mole

Determination of stack gas velocity

$$V_s = 85.49 C_p \left(\frac{T_s \Delta P}{P_s M_w} \right)^{1/2} \quad (6)$$

where

85.49 = pitot tube constant in the following units:

$$\frac{\text{ft}}{\text{s}} \left(\frac{(\text{lb} / \text{lb-mole})(\text{in. Hg})}{(\text{R})(\text{in. H}_2\text{O})} \right)^{1/2}$$

V_s = velocity of the flue gas, ft/s

ΔP = average differential pressure measured by S-type pitot tube, in. H₂O
 T_s = average gas temperature in duct, R
 P_s = absolute duct pressure, in. Hg
 M_w = wet gas molecular weight, lb/lb-mole
 C_p = S-type pitot tube correction factor (normally 0.84)

Volumetric flow rate – actual conditions

$$Q_{ac} = 60 V_s A \quad (7)$$

where

Q_{ac} = actual volumetric flow rate, ACFM
 V_s = velocity of the flue gas, ft/s
 A = cross-sectional area of the duct, ft²
60 = conversion factor, s/min

Volumetric flow rate – dry standard conditions

$$Q_{sd} = \frac{528 Q_{ac} P_s (1 - B_w)}{29.92 T_s} \quad (8)$$

where

Q_{sd} = dry volumetric flow rate at standard conditions, DSCFM
 Q_{ac} = actual volumetric flow rate, ACFM
 B_w = moisture fraction, lb-mole H₂O/lb-mole wet gas
 T_s = average gas temperature in duct, R
 P_s = absolute duct pressure, in. Hg
528 = standard temperature, R
29.92 = standard pressure, in. Hg

Total particulate and H₂SO₄ – grains/ACF

$$C_a = \frac{(0.001)(15.43) M_n}{V_m} \quad (9)$$

where

C_a = concentration of specie in the flue gas at duct conditions, grains/ACF
 M_n = mass of specie collected, mg
 V_m = dry gas volume sampled as measured by dry gas meter, ACF

0.001 = conversion of milligrams to grams, g/mg
15.43 = conversion of grams to grains, grains/g

Total particulate, H₂SO₄, condensible total particulate and condensible H₂SO₄

$$C_s = \frac{(0.001)(15.43) M_n (29.92) T_s}{V_m Y (528) P_s} \quad (10)$$

where

C_s = concentration of specie in the flue gas at dry conditions, grains/DSCF
 M_n = mass of specie collected, mg
 T_s = average gas temperature in duct, R
 V_m = dry gas volume sampled at meter, DCF
 Y = meter correction factor
 P_s = average gas pressure in duct, in. Hg
0.001 = conversion of milligrams to grams, g/mg
15.43 = conversion of grams to grains, grains/g
29.92 = standard pressure, in. Hg
528 = standard temperature, R

Total particulate, H₂SO₄, NO_x and SO₂ – lb/h

$$C_m = C_s (1.428 \times 10^{-4}) (60) (Q_{sd}) \quad (11)$$

where

C_m = mass flow rate of specie in the flue gas, × lb/h
 C_s = concentration of specie in the flue gas at dry standard conditions, grains/DSCF
 Q_{sd} = dry volumetric flow rate at standard conditions, DSCFM
60 = conversion of minutes to hours, min/h
 1.428×10^{-4} = conversion of grains to pounds, lb/grain

Total particulate, H₂SO₄, NO_x and SO₂

$$E = \frac{20.9 C_m F_d}{60 Q_{sd} (20.9 - \% O_{2ds})} \quad (12)$$

Table 8
Spray Dryer FGD System Process Analysis

Parameter	Suggested Method	Suggested Frequency	Use of Data
Lime slurry solids content	Gravimetric	Once per shift	Confirm process meter
Recycle slurry solids content	Gravimetric	Once per shift	Confirm process meter
Flue gas wet bulb temperature	Manual	Startup, fuel change	Process troubleshooting
Flyash alkalinity	Acid titration	Startup, fuel change	Process troubleshooting
Baghouse ash free moisture	Gravimetric	Startup, process change	Process troubleshooting
Process water TDS (total dissolved solids)	Gravimetric	Startup, water source change	Confirm operations
Slaking water anions	Wet chemistry	Startup, water source change	Process troubleshooting

where

- E = emission rate on a dry basis at 0% O₂, lb/10⁶ Btu
 C_m = mass flow rate of specie in the flue gas, lb/h
 F_d = dry F-factor at 0% O₂, determined from fuel analysis, DSCF/10⁶ Btu (see Equation 17)
 Q_{sd} = dry volumetric gas flow rate at standard conditions, DSCFM
% O_{2ds} = O₂ in the gas on a dry basis, %
20.9 = O₂ in air, used with % O₂ in the gas to correct to 0% O₂, %
60 = conversion of minutes to hours, min/h

SO₂ – parts per million (ppm) wet

$$C_{ppm,w} = \frac{(32.03) N (V_t - V_{tb}) (V_{soln} / V_a) (1 - B_w)}{V_d \times 2.66} \quad (13)$$

where

- $C_{ppm,w}$ = gas SO₂ concentration on a wet basis, ppm wet
 N = barium standard titrant normality, meq/ml
 V_t = volume of barium titrant used for sample, ml
 V_{tb} = volume of barium titrant used for blank, ml
 V_{soln} = total volume of impinger solution, ml
 V_a = volume of sample aliquot used, ml
 B_w = gas moisture fraction, g-mole H₂O/g-mole wet gas
 V_d = gas volume sampled at dry standard conditions, DSCF
32.03 = number of milligrams of SO₂ per milliequivalents, mg SO₂/meq
2.66 = conversion of mg/SCM to parts per million, mg/SCM / ppm

SO₂ – ppm dry

$$C_{ppm,d} = \frac{20.9 C_{ppm,w}}{(1 - B_w)(20.9 - \% O_{2ds})} \quad (14)$$

where

- $C_{ppm,d}$ = gas specie (SO₂) concentration on a dry basis, corrected to 0% O₂, ppm dry
 $C_{ppm,w}$ = gas specie (SO₂) concentration on a wet basis, ppm wet
 B_w = moisture fraction of the gas, lb-mole H₂O/lb-mole wet gas
% O_{2ds} = O₂ in the gas on a dry basis, %
20.9 = O₂ in air, used with % O₂ in the gas to correct to 0% O₂, %

NO_x – ppm dry and ppm wet

NO_x is evaluated directly by monitoring systems as parts per million, dry basis. It can be converted to ppm wet if needed by solving Equation 14 for $C_{ppm,w}$.

Collection/removal efficiency – total particulate, H₂SO₄ and SO₂

$$C_{eff} = [(C_{in} - C_{out}) / (C_{in})] \times 100 \quad (15)$$

where

- C_{eff} = collection/removal efficiency, %
 C_{in} = concentration of matter at inlet, lb/10⁶ Btu
 C_{out} = concentration of matter at stack, lb/10⁶ Btu

Percent isokinetic

$$\% I = (V_n / V_s) \times 100 \quad (16)$$

where

$$V_n = \frac{V_d T_s 29.92}{60 t A_n 528 P_s (1 - B_w)}$$

and where

- % I = % isokinetic
 V_s = average flue gas velocity in duct during sampling, ft/s
 V_n = average sample gas velocity through the nozzle during sampling, ft/s
 V_d = dry gas volume sampled at standard conditions, ft³
 t = elapsed sampling time, min
 A_n = cross-sectional area of nozzles, ft²
 B_w = gas moisture fraction, lb-mole H₂O/lb-mole wet gas
 T_s = flue gas temperature in the duct, R
 P_s = absolute pressure in the duct, in. Hg
60 = conversion from minutes to seconds, min/s
528 = standard temperature, R
29.92 = standard pressure, in. Hg

The % isokinetic value is used as a measure of how representative the sample is of the actual flue gas. Generally, if the % isokinetic is between 95 and 105%, the sample is considered acceptable.

F-factor

The F-factor used in making emissions rate calculations was developed from chemical and combustion analyses of the fuel (reference EPA Method 19). This factor is the ratio of the theoretical volume of dry gases at 0% excess air (O₂) given off by complete combustion of a known amount of fuel, to the gross caloric value of the burned fuel. The data generated from the ultimate analysis of the fuel are used to calculate the F-factor as follows:

$$F_d = (10^6) \frac{3.64(H) + 1.53(C) + 0.57(S) + 0.14(N) - 0.46(O)}{HHV} \quad (17)$$

where

- F_d = dry F-factor at 0% O₂, DSCF/10⁶ Btu
HHV = higher heating value, Btu/lb
 H = hydrogen in the fuel, % by wt
 C = carbon in the fuel, % by wt
 S = sulfur in the fuel, % by wt
 N = nitrogen in the fuel, % by wt
 O = oxygen in the fuel, % by wt

F-factors are constant for a given fuel category (within ±3%). Standard average values approved by the EPA are:

Fuel	DSCF/10 ⁶ Btu
Bituminous coal	9780
Oil	9190
Natural gas	8710
Wood bark	9600
Wood chips	9240
Municipal solid waste	9570

The F_d factor is used to convert the measured pollutant concentration to an emissions rate in lb/10⁶ Btu by:

$$\text{lb/10}^6 \text{ Btu} = F_d C_{\text{ppm,d}} K \frac{20.9}{(20.9 - \% \text{O}_{2,\text{d}})}$$

Where K is the conversion factor from ppm_d to lb/scf.

$$K \text{ NO}_x = 1.194 \times 10^{-7}$$

$$K \text{ SO}_2 = 1.660 \times 10^{-7}$$

Particulate and SO₂ removal efficiencies

The SO₂ and particulate removal efficiencies are determined by inlet and outlet sampling using Equations 12 and 15.

Stack opacity

Stack opacity is determined by the installed transmissometer or by EPA Method 9 which is a visual method by a certified observer.

NO_x concentration

NO_x concentration is determined by EPA Method 7. This measurement is taken in the stack on a composite sample. NO_x concentration may be adjusted to design conditions from actual test conditions.

NH₃ concentration

NH₃ concentration is determined by EPA Method CTM-27. This measurement is taken at the SCR outlet on a composite sample before the air heater. NH₃ concentration may be adjusted to design conditions from actual test conditions.

Condensible particulate matter

New regulations limit the amount of total particulate matter finer than 10 microns (PM₁₀) which includes both solids and vapors which may condense in the atmosphere to form particulates after the flue gas exits the stack. These condensibles may include H₂SO₄ and VOCs. EPA Methods 201 and 202 are designed to measure the condensible fraction of particulate emissions. There is some concern that Method 202 may overstate the condensibles by inclusion of SO₂ which is not purged from the impingers before the analysis.

Makeup water requirements

Makeup water requirements are measured at the appropriate terminal point with a certified flow meter. Adjustments from test conditions may be necessary due to variations in gas volume or temperature or other process deviations from design conditions.

Reagent consumption

There are two common ways to measure reagent consumption. The first method is to measure the solid reagent flow (for lime/limestone systems) using a cali-

brated weight belt feeder. The measurement is time averaged. This mass flow method is cumbersome because the initial and final storage tank volumes and densities must also be measured. This method is best done over a period of at least 24 hours. The second and preferred method is chemical analysis. For a wet FGD system, the reagent consumption is calculated from the stoichiometric ratio, limestone (or reagent) analysis, and gas side measurements by the following equation:

$$LS = \frac{100 (SR) (SO_2)}{64 (CaCO_3)} \quad (18)$$

where

LS = limestone consumption, lb/h

SR = stoichiometric ratio (see Chapter 35)

SO₂ = SO₂ removed, lb/h

64 = molecular weight of SO₂, lb/lb-mole

100 = molecular weight of CaCO₃, lb/lb-mole

CaCO₃ = available CaCO₃ in limestone (wt fraction: lb available CaCO₃/lb limestone)

Reagent consumption may be adjusted for deviations from SO₂ removal rate and mass flow (or concentration) design conditions.

Gypsum purity

A composite sample of gypsum, taken over the test period, is analyzed as outlined in Table 7. Adjustments may be necessary for flyash contamination, chloride concentration, and inerts if the inlet levels to the FGD system substantially deviate from design.

Other test methods

There are numerous other procedures for measuring system parameters. The example in this chapter is a formal performance test; other methods could be used. SO₂ can be measured with a CEMS or by other temporary instrument methods following EPA Method 6. Particulate level can be measured by EPA Method 5 or 17 or alternate methods such as the probe shown in Fig. 11.

Mercury emissions measurement

Continuous or semi-continuous measurement of mercury emissions is a developing technology that will be used to assure compliance with future regulation of mercury emissions from coal-fired boilers. Various monitors under development share common features of sample pre-treatment, adsorption of mercury onto a gold trap and then periodically purging the mercury from the trap and quantitatively measuring the mercury using cold vapor atomic spectroscopy (CVASS), atomic fluorescence spectroscopy (AFS) or Zeeman-modulated atomic spectroscopy (Pavlish, 2003). The measurement challenges include low concentrations (typically less than 10 μg/Nm³), fouling with particulates, and interference from common flue gas constituents such as SO₂, HCl and NO_x. An alternative method accepted by the EPA involves drawing a measured flue gas sample volume through a carbon trap for a specified time period (1 month for example) and then measuring the mercury in the carbon trap to calculate an

Fig. 11 Probe detail, isokinetic dust sampling.

emission rate in lb/TBtu. ASTM Method D6784-02 is the validated and accepted stack sampling test method for measuring mercury speciation and total mercury in coal-fired flue gas (see Fig. 12).

The future of environmental measurement

Advances in environmental measurement techniques will certainly continue. Technologies such as fiber optics, video imaging and Fourier transform infrared analysis (FTIR), which have been used successfully in the laboratory, are expected to move into the field. Measurement will be extended to include other air and water pollutants, and air toxics monitoring will become increasingly important.

Section V

Specification, Manufacturing and Construction

This section begins with an in-depth discussion of the specification, evaluation and procurement process for large capital expense items. This includes discussions about project scope, terms and conditions, and general bid evaluation. Also discussed are power system economics, and procedures for the evaluation of equipment characteristics in terms of justifiable expenditures. Examples and calculations are included for both utility and industrial units.

This is followed by a discussion of the manufacturing processes for fossil fuel-fired equipment. Welding and metal removal techniques, as well as fabrication of the various components and component parts, are covered. Examination and quality control are also discussed. The section ends with a discussion of various construction techniques, labor requirements, on-site considerations, safety issues, and post-construction testing prior to unit startup.

Chapter 37

Equipment Specification, Economics and Evaluation

Accurate and complete technical specifications are critical to the successful development of any new project. Steam generating and environmental emissions control systems are complex and typically require the evaluation of many competing factors to select the equipment and potential options that best meet project needs.

Each application of new or upgraded equipment has a number of unique factors and requirements that need to be identified and communicated to the equipment or system designer/supplier. Specifications should be developed to document these needs. However, the developer of those specifications should also allow the equipment designers flexibility to adapt their products to best meet the true requirements of the project. There are often multiple options or alternative solutions that can be considered. The solution should be selected after evaluating the initial capital investment in conjunction with several variables including the relative longer-term operating and maintenance cost benefits, feasibility of obtaining required regulatory construction and environmental permits, ability to meet varying operating conditions during the life of the equipment, and costs associated with the disruption or outage of existing equipment during construction or tie-in.

The following discusses some of the primary factors that should be considered when developing and planning a project requiring new or upgraded steam generating or environmental control systems. It describes key technical and commercial criteria that should be developed and communicated to the equipment suppliers.

Project feasibility studies and technology selection

Before detailed equipment specifications can be developed, groundwork is required to establish the basic project needs and evaluate major alternatives. Some aspects that should be evaluated during the early feasibility stages include:

1. steam capacity requirements,
2. range of plant operating conditions,
3. steam cycle conditions (pressure/temperature),
4. fuel type(s),
5. combustion technology,
6. site location and arrangement logistics, including construction feasibility,
7. stack emissions and air quality control system technology,
8. reagent type(s),
9. solid waste disposal logistics, and
10. water quality and treatment.

For a utility power plant, the need for new generating capacity is identified from the forecast of both peak and average long-term electrical demand (load). The overall power and steam generation plan must also recognize unit retirements within the system, spinning reserve, reserve for scheduled and unscheduled outages, and current generating equipment mix. The specific power plant type selected is based upon an evaluation of the amount and type of demand, assessment of current boiler types and sizes within the system, long-term fuel availability and cost, condensing water supply, new equipment types available, environmental impact and, in many cases, public opinion. Extensive feasibility studies are typically conducted to provide such data.^{1,2}

For an industrial installation, the needs are usually tied to process steam or heating requirements. The timing of equipment addition, the steam flow rate, and the frequency of operation are governed by the application. In addition, with the growth of cogeneration and independent power production, steam supply needs have been increasingly influenced by the demands of electrical power production. In all cases, the steam flow requirements will determine the type, size and number of steam generating units. Particular attention should be given to the variety, cost and availability of fuel sources. Process byproducts, waste materials and waste heat offer potential low-cost sources of energy that can be used to displace the use of higher-cost traditional fuels to meet industrial steam generation needs.

For projects involving addition of emissions control systems to existing boilers, many of the design conditions for the system are typically established by the current boiler operations. However, issues such as technology selection, reagent type(s), solid waste dis-

posal, and water treatment requirements should be considered and evaluated during early stages of project development. It may also be important to evaluate potential future changes in environmental permitting requirements and operating conditions, such as the use of an alternate fuel type, that could affect equipment sizing or even technology selection.

For repair and retrofit projects, the evaluation is focused on the scope being considered. However, appropriate additional consideration should be given to other factors potentially being affected by the repair or retrofit. Examples include delivery schedule to meet outage requirements, changes in emissions rates, and effects on auxiliaries such as fans and downstream equipment.

During these early stages, it is often helpful to obtain input from the equipment suppliers. On large, complex projects, some plant owners and project developers have found it valuable to form a strategic alliance or partnership with a qualified equipment supplier. As the project develops, such a business model can help to evolve the design of a unique or customized new system. This alternative business structure will be discussed later in this chapter.

Specifications

Once the major feasibility issues and alternatives have been evaluated and established, specifications need to be developed. These specifications provide a *definition* from which the primary equipment or system will be designed and by which that equipment will be integrated into the overall project.

Specifications can vary in detail but as a minimum, performance and functional requirements need to be defined. The basic design is derived from the functional requirements of the application. The equipment designer needs to know the key characteristics of all major system inputs and all performance output requirements. This information is essential for setting vital system design parameters such as size, capacity, materials, equipment redundancy level, etc.

The design specification for new or replacement steam generating equipment should include at least the following information:

1. steam flow characteristics
2. steam temperature and pressure conditions
3. feedwater supply
4. fuel type(s) and characteristics, including ash properties
5. boiler efficiency requirements
6. emissions requirements
7. performance guarantees and test conditions

The design specification for new or replacement environmental control systems should include at least the following information:

1. conditions and composition of flue gas and flyash entering the system
2. emissions performance requirements
3. reagent type(s) and characteristics
4. solid byproduct quality requirements
5. wastewater quality limitations
6. makeup water composition
7. performance guarantees and test conditions

The specification should also define how the equipment or system design will be integrated into the overall project. The following is a list of typical project definition information that needs to be included in a specification to an equipment supplier:

1. complete scope of work, including the definition and location of all terminal and interface points within the overall plant or existing facilities;
2. site-specific requirements, design conditions, layout/arrangement limitations, delivery logistics, and access restrictions, among others;
3. plant standardization requirements (if applicable);
4. project schedule, including equipment delivery, construction and startup/commissioning, consistent with the scope of work definition;
5. commercial contract terms and conditions; and
6. evaluation criteria/factors to be used in assessing design and operating tradeoffs.

Beyond these items, it is usually appropriate to only specify material and workmanship quality requirements, allowing potential suppliers to apply their experience and knowledge to propose the most dependable and cost-effective design.

Performance – steam generating equipment

Performance specifications, defining the functional requirements for utility, industrial and environmental equipment, are summarized in the following section. For steam generating equipment, this generally consists of steam flow, steam temperature and pressure, feedwater temperature and quality, fuel, boiler system efficiency, emissions requirements, and performance guarantees.

Steam flow Primary performance specifications include the steam flow requirements. For utility and other units that produce steam for electric power generation, these usually include:

1. maximum continuous rating (MCR),
2. performance load steam flow rate (to match optimal turbine heat rate load),
3. minimum steam flow rate,
4. type of service (base load, cycling or peaking), and
5. expected cycle of operation.

In power station practice, typically one boiler is matched to an individual turbine-generator set ranging from 25 to 1300 MW. Depending on the load requirements, one or more steam generating units are purchased. In general, economies of scale dictate the purchase of the fewest number of units possible to meet overall load and system requirements.

For some industrial units, specified steam flow requirements include:

1. maximum steam flow capacity,
2. turndown (ratio of maximum to minimum load), and
3. expected steam load pattern variations (daily, weekly or seasonal).

However, in some industrial applications the primary function of the steam generator is to consume or process a quantity of fuel. In such cases, the fuel input is specified and steam capacity is determined indirectly from the maximum fuel input rating.

Industrial unit operators frequently prefer multiple smaller boilers rather than a single large unit, giving them more operating flexibility while maximizing steam system availability. It is normally critical that the industrial process be available at all times and not be limited by the steam generating system. Typically, the number of steam generating units is established by assessing the load pattern, load duration, availability requirements, maintenance periods, types of boilers in the system, sources of backup steam or auxiliary power, and possible future expansion plans. Minimum standby requirements are set by the minimum required steam flow plus an allowance for routine maintenance and forced outages. Where the load is seasonal and steam is not a critical process requirement, standby may not be required. Where steam is required throughout the year, some level of economical excess capacity will be needed (see Table 1).

The number of units to be installed needs to be evaluated on the basis of total cost, including initial capital cost, when compared with tradeoffs in thermal efficiency and the true value of availability or cost penalty for unavailability. The cost for more, smaller units will be greater than the cost for fewer, larger units. However, if the larger units will be operated for a significant amount of time at reduced load, the effective thermal efficiency will be lower and operating fuel-related costs will be higher. In addition, installing a number of smaller units over time can defer capital costs until the additional capacity is required.

Steam temperature and pressure For utility applications, a turbine-generator set is generally specified, and therefore the turbine cycle selected will determine the pressure and temperature relationships. As part of the specifications, the complete turbine heat balance at various operating conditions such as minimum load, control load, and full load should be provided to give the designers more insight into system requirements. The turbine specifications will typically establish acceptable deviation limits in outlet steam temperature as well as the maximum rate of change. Constant pressure operation or variable pressure operation, each with advantages and disadvantages, may be selected to meet operator needs. (See Chapter 26.) Constant pressure versus variable pressure operation also has a significant impact on supercritical pressure boilers as referenced in other chapters. When the application calls for superheat and reheat steam conditions, the load range and load pattern will help determine the steam temperature control ranges. The benefits of higher steam temperatures at lower loads must be compared to the higher costs of providing an extended range. The evaluation penalties and allowable variations in steam temperature will also affect the type of temperature control system included. Allowance must also be made for pressure and heat loss from piping between the boiler outlet and the steam use location. Typically, the heat loss is negligible with today's insulation products and application techniques. It is normally left to the supplier to determine the appropriate design margin necessary to achieve the specified steam pressure and temperature conditions at the terminals.

In industrial applications where there may be some

flexibility in the selection of steam pressure and temperature, interaction with the steam system supplier may permit selection of a more economical set of operating conditions.

Feedwater The temperature and chemical analysis of the feedwater must be specified. The minimum required feedwater temperature is one of the components that establishes boiler output (firing rate) and the water chemistry will affect water treatment needs. Recommended water chemistry specifications are provided in Chapter 42. For small units, a deaerator treats the feedwater before it enters the boiler. The resulting feedwater temperature is typically 220 to 240F (104 to 116C). Oxygen in the feedwater must be minimized to prevent internal boiler corrosion.

In larger high temperature, high pressure boilers, feedwater heaters are used to improve cycle efficiency as discussed in Chapter 2. If increased output (MWs) is desired when feedwater heaters are out of service, then this design requirement needs to be conveyed along with the applicable feedwater temperature and steam flow conditions. If turbine heat balances are provided for all operating conditions as part of the specification, feedwater temperature requirements will inherently be included. In any case, the feedwater temperature needs to be specified for all boiler conditions over the load range.

Fuel The selected fuel has a major impact on steam generating equipment design and capital cost due to the type of combustion equipment, fuel delivery/processing equipment, fouling and erosion characteristics of the flyash, and heat transfer properties of the flue gas (including moisture content). Refuse fuel, biomass and most byproduct or waste fuels require significantly different combustion systems than pulverized coal, oil or natural gas and can also result in different boiler corrosion characteristics. Boilers designed to fire multiple fuel types require a compromise between the various fuels, particularly for steam temperature control. They therefore may be more expensive than boilers designed to burn a single fuel type. Furthermore, boilers designed to accommodate multiple classifications of a fuel type, such as bituminous and subbituminous coals, will require the application of some tradeoffs in the design of the boiler, fuel preparation equipment, and combustion system. Designing for multiple fuel types and classifications is especially challenging for supercritical boilers by further complicating the design requirements for the circulation system to accommodate a wider variation in heat transfer rates through the critical furnace steam/water circuits. Environmental equipment design require-

Table 1
Boiler Capacity with Standby Units

Total Number of Units	Number of Standby Units	Per Unit Capacity, %	Total Capacity, %
2	1	100	200
3	1	50	150
4	1	33	133
5	1	25	125

ments can also be significantly different when designed for multiple fuel types and classifications.

Complete analyses should be provided for all fuels being considered. For each fuel, ultimate analysis, proximate analysis, heating value and ash analysis should be provided in accordance with applicable American Society for Testing and Materials (ASTM) or equivalent international standard requirements. The buyer normally provides a range analysis that indicates the extreme values (low and high) for each constituent. However, a fuel analysis derived statistically from such constituents may represent an erroneous and unrealistic combination. It is best to provide a set of actual fuel analyses, which comprise the range, to enable suppliers to appropriately design and size the equipment. The analyses should be provided as moisture and ash free, moisture free and/or *as-fired*. Additional information needed includes as-received solid fuel sizing, liquid fuel viscosities, and liquid/gaseous fuel pressures. The effect of the fuel and ash on unit design is discussed in Chapter 21.

Boiler system efficiency Maximizing boiler operating efficiency minimizes fuel usage and reduces costs. To achieve the highest efficiency, heat traps are used to extract the last heat from the flue gas. Heat traps include air heaters and economizers. (See Chapter 20.) The temperature of the flue gas exiting the final trap should be low to maximize boiler efficiency. However, it should normally exceed the acid dew point of the gas to avoid corrosion and other operating problems in the last heat trap and in any downstream equipment. In addition, some environmental control equipment such as dry flue gas desulfurization (DFGD) systems requires the entering gas temperature to be somewhat higher for proper operation.

Utility applications commonly use both an economizer and an air heater. On other steam generating applications when a single heat trap is required, an air heater is usually chosen to aid in combustion of pulverized coal, wood or biomass. For other fuels, an economizer is frequently selected because of lower cost, possible increased efficiency, and reduced nitrogen oxides (NO_x) levels compared to an air heater installation (increased air temperatures can promote NO_x formation in the furnace).

If the boiler supplier is to design the heat traps effectively, the specification should include evaluation factors such as fuel cost and capitalization period. For competitive bids, it is also prudent for the buyer to specify the design exit gas temperature so that the impact on boiler efficiency between competing designs is normalized. Minimum exit gas temperature is typically set by corrosion and operating concerns of downstream equipment and should be consistent between boiler suppliers.

Environmental limits Meeting appropriate environmental emissions limits is essential. Joint discussions between the buyer, equipment suppliers and regulating agencies are recommended at early phases of project development to ensure a clear understanding of permissible and achievable emissions limits. Emissions controlled by the steam generating equipment include NO_x , carbon monoxide (CO), and volatile

organic compounds (VOC). These emissions have a significant impact on design requirements of the combustion system, boiler and NO_x control systems and therefore need to be defined. Further, test methods such as applicable Environmental Protection Agency (EPA) test methods, test duration, e.g., three-hour test period, and test conditions, e.g., boiler load range, should be documented to ensure each party has a common understanding of all requirements and conditions. Other emissions, captured by downstream environmental equipment, are discussed later in this section.

Performance guarantees Specific guarantees are normally a function of the scope structure discussed later in this chapter. They normally include items that can be controlled by a specific piece of equipment and items that support the overall plant performance. Ultimately these are capacity, net plant heat rate (NPHR), stack emissions, reagent use, and other operating factors such as water usage and waste disposal. Specific guarantees relating to the steam generator scope that impact NPHR and stack emissions usually include MCR capacity, boiler efficiency, auxiliary power consumption, water and steam side pressure drop, superheater and reheater steam temperature control range, spray water quantities, and NO_x , CO, and VOC emissions. If the spray water source is downstream of the feedwater heaters, then heat rate is not impacted by superheater spray and is therefore not considered. For subcritical drum type boilers, steam purity is commonly included.

Performance – environmental control systems

Flue gas conditions and design heat input Environmental control systems are designed to reduce the level of regulated pollutants such as NO_x , sulfur dioxide (SO_2) and particulate matter present in the combustion product gases (flue gas) that leave the steam generator. The size, function and design of these systems are dependent on the chemical composition, temperature and volume of the entering flue gas. If the environmental control system is to be supplied with the boiler as an integrated system, the boiler design conditions for steam requirements, feedwater, fuel (including the range of the chemical composition of the fuel and ash) plus the ambient conditions will provide the input required to define the range of flue gas operating conditions relevant to integrated system design.

If the environmental control system is to be supplied separately, the following information for the flue gas entering the system should be defined in the specification:

1. chemical analysis of the flue gas, including concentration of the pollutant(s) to be controlled,
2. temperature of the flue gas,
3. chemical analysis and type of flyash, and
4. flow rate of the flue gas (on a mass and volumetric flow rate basis).

It is important to provide the design range of each of these items at maximum and minimum operating loads to ensure that the system can accommodate normally expected operating variations. A chemical analysis of the design fuels and the boiler design heat

input rate are also helpful when correlating the specified flue gas conditions with the expected fuel(s) and establishing a consistent basis for emissions calculations reported per unit of heat input.

Emissions performance The environmental control system is typically designed to achieve a maximum allowable outlet emissions rate that is driven by the project air permits, other environmental regulations or performance objectives. Alternatively, in some cases, a minimum percent reduction performance rate may be required. The specification should define the required performance objective including the guaranteed emission rate at the stack for each controlled pollutant and specific test conditions. The specific test conditions include the test method to be used, test duration, measurement frequency and period over which the measurements will be averaged.

Reagents Many environmental control systems require a consumable reagent to create the chemical reactions required to control the target pollutant.

Selective catalytic reduction (SCR) and selective non-catalytic reduction (SNCR) type NO_x control systems use ammonia or urea based reagents. Various economic, plant logistics and permitting requirements affect reagent selection. Each type will require different equipment for storage, handling and use. Wet flue gas desulfurization (WFGD) systems have used a variety of reagent types including limestone, magnesium-enhanced lime and sodium based upon relative economics and specific performance requirements for each application. Dry flue gas desulfurization (DFGD) systems typically use lime.

Other additives and reagents can also be used for various performance enhancements and specialty processes.

The chemical composition of the reagent and the extent that composition is expected to vary should be specified.

Quality requirements for solid wastes and byproducts

The cost to landfill solid waste materials can vary significantly from project to project. Some projects depend on producing solid byproduct in a form that can be sold for commercial application. Coal flyash, for example, can be sold if the carbon concentration is sufficiently low. Such a limitation on carbon content may affect the design of the boiler's combustion system and/or coal selection, or may dictate the use of multiple stage particulate collection to capture most of the flyash prior to a dry FGD system.

Wet FGD systems can be designed to produce a grade of gypsum used in wallboard production. The specific requirements will affect the selection of dewatering equipment and may affect the design of the purge and wastewater treatment systems. Any requirements on the quality, purity or composition of a solid waste byproduct should be specified to the equipment supplier.

Process makeup water (FGD systems) Potential sources of makeup water should be identified and the analysis and range of contaminants defined. The analysis can affect the selection of system materials as well as the ability to achieve a specified byproduct quality requirement. Various plant wastewater

streams may be desirable to use as makeup water in a dry or wet FGD system, but the composition and quantity of each potential source should be reviewed and analyzed on a case-by-case basis.

Wastewater requirements Typically, a wet FGD system will require a portion of the filtrate water to be purged from the system to avoid excessive buildup of chlorides and/or fines. The purge flow rate is typically set to control to a maximum chloride concentration in the recycled slurry system which is also a function of the chloride concentration in the fuel. Higher design chloride levels will increase the corrosiveness of the slurry and more expensive materials will be needed for the absorber tower and outlet flue.

Performance guarantees Specific guarantees for environmental control systems are customized to fit the requirements and objectives of each project. If the environmental control system is provided as a separate, stand-alone system, performance guarantees must be tied to flue gas conditions that are specified at the system inlet.

Typical performance items guaranteed over the operating load range include:

1. emission levels for pollutants being controlled by the system being installed, and
2. gypsum quality (for wet FGD systems only).

Performance items guaranteed at a specific load condition include:

1. auxiliary power consumption,
2. reagent flow rate (limestone, lime, ammonia, other),
3. flue gas pressure drop across the system (if supply of induced draft or booster fans is not within the supplier's scope),
4. makeup water consumption rate, and
5. wastewater purge flow rate.

Project requirements

In addition to critical inputs required to size and select equipment, specifications should provide definition and direction for how the equipment supplier's work will integrate into the overall project.

Scope of work

Determining scope structure is a critical decision. The buyer may specify whether or not bids should be for a complete *turnkey* project, in which all components including erection are within the supplier's scope. Other approaches include *system island* scope and *equipment packages*.

Regardless of how the scope is structured, suppliers must understand the scope responsibility to ensure that the buyer's needs are met. If the project is executed without addressing ambiguous terminal points, scope can be missed and the project can face problems of schedule delay and unexpected costs. Scope definition is an evolutionary process that occurs during project development. Several types of documents are needed to define a project and ensure a common understanding of scope. The following should be included as part of a contract:

1. equipment listing and/or system descriptions,
2. division of work, including work scope provided by other parties,
3. terminal points listing,
4. process and instrumentation diagrams (P&IDs),
5. equipment arrangement drawing(s), and
6. definition of the extent of shop fabrication.

Degrees of scope breakdown structure There are a variety of general breakdown structures which are used in power plant steam generation and environmental system projects, each with its strengths, weaknesses, costs and risks. Key examples include:

1. Turnkey approach for the material supply and erection of a complete facility.
2. System island approach focusing on a major sub-system such as the boiler island, turbine island, and environmental equipment island, each including structural steel, architectural materials, process piping, auxiliary components, etc.
3. Equipment package approach focusing on smaller scopes such as individual components and related auxiliaries.

For larger scope approaches, operation and maintenance agreements or equity/financing arrangements may be included.

Considerations for scope breakdown The scope structure is dependent on the buyer's ability to manage the project and the selected commercial contracting structure. Different scope structures result in different impacts to the steam generating system. Listed below are a few items to consider:

1. If a turnkey project is pursued, some suppliers may be eliminated because of a lack of experience, inadequate financial backing to obtain required project security instruments, or their inability to support the magnitude of financial risk associated with large projects. As a result, the buyer may lose or disqualify potential suppliers who, otherwise, could provide good technology and services at a competitive price.
2. In a turnkey project, the selection of sub-suppliers may be affected by the turnkey contractor's evaluation process and work experience/relationships.
3. Physical interfaces must be considered to minimize the risk of missed scope relative to material, engineering, and construction. As the degree of scope breakdown increases, risks related to physical interfaces increase. Also, some scope is integral to equipment, such as the structural steel used to support a baghouse or dry scrubber. Piping and other equipment terminals need to be coordinated to properly meet in space (type, size and location) and so that the system is properly engineered from a stress analysis and performance perspective.
4. Environmental equipment sizing is dependent on the inlet gas conditions as well as the effects of potential variations in the operation of upstream systems (boiler, air heater, etc.). Proper margins should be considered to ensure that emissions limits are continuously met without adding overlapping lay-

ers of conservatism. If the equipment is oversized, a higher cost could be incurred unnecessarily. Equipment that is too small may under-perform or fail due to overloading caused by the effects of upstream systems. Purchasing a complete, integrated system from a single supplier allows the downstream systems to be designed using the supplier's experience and knowledge of the operating conditions of the upstream equipment. Purchasing as a complete package also eliminates the complications of performance risk responsibility that exist with a process interface point such as between the boiler and environmental equipment systems.

5. Performance interface risks also increase as scope is divided and performance guarantees are required for individual components. This risk can cause equipment within a particular system to be over-designed. It may also cause the operation of the facility to be less efficient because of margin added by suppliers to manage guarantee risk. For turnkey projects, overall unit performance, such as capacity, NPHR and emissions are critical and become contractual obligations. Other performance elements can be guaranteed separately as scope becomes further broken down to support the overall NPHR. The same philosophy could be applied to emissions. Guarantees for a piece of equipment may depend on the performance of other equipment. This can cause each supplier to assess their individual risk and apply appropriate margins. As a result, the overall system may be over-designed with margin applied on top of margin. Guarantee conditions would be based on the scope boundary and the more boundaries that exist, the more measurements are required to prove individual sub-system performance.
6. When a specification is prepared, consolidation of construction subcontracts should be considered. It may be more economical to consolidate electrical, civil, insulation and lagging, architectural, and related scope across the entire project rather than having multiple contractors responsible for the same work but in different areas. This will reduce interface risks and bring consistency to the project.

Site conditions and requirements There are numerous requirements specific to each project site and plant that should be communicated to the equipment supplier. If the supplier's work includes construction and extended balance of plant scope, site-specific requirements are especially critical. During a bidding process, it is often valuable for the equipment supplier and construction contractor to visit and investigate the site thoroughly to understand all site logistics.

Equipment arrangement The specification should clearly describe the site and include dimensioned plot plans showing the location of existing equipment, the expected location of new equipment and major locations for tie-in connections to existing plant services, among other items. The specification should also define any limitations or restrictions to be imposed on the equipment supplier. The supplier should be encouraged to arrange the equipment within these limitations for optimal overall cost.

Site access Rail, truck, barge and personnel access to the site should be defined. Sufficient lay down areas adjacent to the site generally reduce handling costs. However, provisions can often be made for off-site fabrication and extended modularization if space is limited and there is sufficient delivery access. It is important to state which existing equipment and facilities will remain operational or on-line during construction.

Site design criteria and applicable codes The specification should also include information on climate conditions and design codes that apply at the site, including:

1. seismic zone criteria,
2. wind load criteria,
3. snow load criteria,
4. range of ambient conditions for temperature and relative humidity,
5. soil design conditions, and
6. site altitude.

Also, the specification should identify if the new equipment will be located in an enclosed building or outdoors. Even in colder climates, some owners prefer to use as few building enclosures as possible.

Standardization requirements and design criteria It is important to define any plant standardization requirements that may have been developed to make operation and maintenance easier and more consistent throughout the plant. Such items could include common suppliers for valves, instrumentation, motors, etc. This can be done by providing a list of acceptable suppliers for certain equipment. However, caution should be taken not to over-specify equipment requirements. Different technologies can require different criteria and while clear performance expectations should be outlined, excessive detail may add unnecessary cost.

Project schedule The specification should accurately state project schedule requirements for engineering work and document submittals consistent with the scope and needs of multiple suppliers, equipment deliveries to site, construction and commissioning, startup and testing. The project schedule needs to be developed backwards from the required on-line date, allowing adequate time for equipment to be checked and commissioned after installation. Equipment deliveries should be scheduled to support the expected erection sequence, but also need to recognize lead-times required for engineering, procurement of raw materials, and fabrication. For projects involving the modification of or addition to existing equipment, the project construction schedule may need to be carefully coordinated around normally planned maintenance outages or lower demand periods. If the required outage span is of critical economic importance to the project, the incremental value should be defined to the bidders so that added construction costs for multiple shifts and peak labor can be evaluated and optimized. Typically, the value to the plant owner of having the equipment on-line sooner easily justifies the additional cost required to minimize an outage span. However, these tradeoffs need to be properly considered.

Commercial terms and conditions

A bid specification should identify the expected commercial terms that would apply to a resulting contract. Major clauses that are typically part of a contract include liability terms and limitations thereon, warranty, force majeure, contract completion dates, title and risk of loss, changes to the work, proprietary data, choice of law, cancellation, payment terms, and insurance. In many instances these are prepared and negotiated for specific projects to meet both supplier and buyer needs. In other cases, the United States (U.S.) Uniform Commercial Code, as adopted in the various states, or other laws, rules or regulations provide protection for the buyer and supplier in the absence of specific contract provisions.

Payment terms Matching payment terms to a supplier's cash flow needs minimizes project cost by reducing working capital requirements. *Milestone payments* provide a payment upon receipt of order, with additional payments following drawing submittal, major material orders, and completion of major component fabrication. *Progress payments* are made at given dates following project initiation.

Invariably, payment terms must balance two competing interests: the owner's desire to assure that the project will be timely completed in accordance with the contract, and the contractor's interest in assuring a positive cash flow. For this reason, many projects provide for some retained amount from each invoice, often 5%, which can be reduced or liquidated once the contract is completed. The contractor may be allowed to substitute a letter of credit or bond for the retention once performance guarantees are met.

Evaluation criteria

The design of steam generating units and environmental control systems involves complex tradeoffs between hardware options and operating costs. For the supplier to provide the best possible offering to meet the buyer's needs, it is important to include the general criteria and quantitative factors the buyer will use to evaluate competing proposals. The following is a list of potential key performance items for which quantitative evaluation factors should be provided, depending on project application:

1. boiler fuel efficiency,
2. main steam and reheat steam pressure drop,
3. auxiliary power consumption,
4. auxiliary steam flow,
5. reagent flow rate (ammonia, lime/limestone, etc.),
6. SCR catalyst life, and
7. flue gas pressure drop.

Other evaluation factors can include ash disposal costs, revenue from byproduct (e.g., gypsum) sale, and extended warranties, etc.

General bid evaluation

Once the specification has been prepared and proposals have been submitted, bids are evaluated. A consulting engineer may be used to help with the evaluation. Although the best bid is usually competi-

tive, it is not always the lowest price. A thorough review must consider whether the supplier has offered the intended scope, and any exceptions to the specification must be evaluated. Bid evaluation generally includes a review of scope, operating ease, maintenance and operating costs, service, design and construction features, hardware, schedule, experience, commercial terms, and price.

Scope

Scope of supply typically differs between suppliers. It is important to verify what items are explicitly covered in each bid. Inconsistencies between bids can be resolved by discussions with the suppliers and by assessing a cost for discrepancies in the bid evaluation.

Operating ease

Design differences will appear among the product offerings. Seemingly minor design features can significantly alter costs. It can be valuable to have boiler operators evaluate the benefit(s) of such design features.

Maintenance costs

Designs that require minimal maintenance provide ongoing cost savings. Areas that previously demanded high maintenance, such as refractory and brickwork, have generally been eliminated from modern boiler designs. Current gas-tight water-cooled furnace construction has replaced the tube and tile design. However, some corner seals, hangers, supports and spacers may still be high maintenance items if not properly designed. Pulverizer designs can vary widely resulting in significantly different annual maintenance costs. These factors can be incorporated into the final evaluation discussed later.

Operating costs

Annual boiler operating costs can approach the initial unit investment. Therefore, fuel and auxiliary power costs should be quantitatively evaluated. Based on estimated fuel cost, discount rate and the predicted unit life, present values can be assigned to calculate annual fuel and power costs. Other operating costs include reagent usage for emissions control systems, wastewater flow rate (water treatment system cost), and solid waste disposal costs, among others.

Service organization

The quality and capability of a supplier's after-market service department are important. An experienced staff can troubleshoot problems quickly and minimize costly downtime. Factors that should be considered when evaluating supplier alternatives include the proximity of the supplier's office or representative to the plant, the number of available personnel, and the training and experience of the service personnel.

Design features

A thorough bid evaluation must review the equipment's design and construction features and determine if certain technologies favor one supplier. Although some designs may present a low initial cost, accompanying higher maintenance requirements may quickly offset these savings.

Areas that should be reviewed include, but are not limited to:

1. furnace design and arrangement to determine how the supplier has accommodated the specified fuel characteristics in the proposed design to ensure that the effects of slagging, fouling, erosion and corrosion are minimized, while achieving low NO_x, CO and unburned carbon performance;
2. low NO_x burners to determine if they have been effective on a similar installation;
3. pulverizer design regarding maintenance requirements and degradation between overhauls; and
4. superheater supports.

If special design requirements were specified, the evaluator needs to ensure that each supplier accommodated the requirement. For example, if very rapid load change requirements are specified for a supercritical boiler, additional hardware may be required for the steam generator to comply.

Construction features

If the scope of work is limited to material supply only, the degree of shop fabrication and the extent of design for constructability offered by different bidders can vary and have a significant effect on the material installation cost. The degree of shop fabrication can range from supply of many small components to large prefabricated modules. Even seemingly minor differences can result in significantly different field labor requirements that need to be evaluated. The degree of shop fabrication on a given project is typically driven by transportation logistics and site access limitations. Plants located with good access to water transport can benefit from increased shop fabrication efficiencies, reduced construction risks, and reduced peak labor requirements at the site.

Schedule

As-bid schedules should be compared to one another and to the specification. A shorter overall project schedule can reduce project financing costs or increase revenue through early completion and startup. However, early delivery of some equipment does not necessarily reduce the overall project span if that equipment does not fall on the project's critical path. If the scope being proposed does bring the project economic benefit from a shorter span, then differences can be subject to a quantitative evaluation credit or penalty. However, if that credit is to be realized, sufficient commercial motivation (such as a bonus for early completion or liquidated damages for late performance) should be established in the contract to ensure that a bidder offers a realistic commitment.

Project management and project team

An equipment supplier's project manager and key project personnel can greatly influence project execution performance. It is the responsibility of this project team to ensure that the specified product is provided in accordance with the contract schedule and within project cost constraints. Sub-suppliers and vendors

must be managed effectively, the team needs to respond to buyer changes in scope and design, and communication with the buyer and other project entities must be maintained. The ability of the supplier's personnel to manage these critical functions can have a significant effect on project execution. It is in the buyer's best interest to review and evaluate the experience and capability of the personnel that a supplier will assign to a project, especially if the project is large in scope, complex, or has extraordinary requirements.

Experience

Demonstrated success in executing projects using similar equipment with similar scope and complexity is an important factor to ensuring success of using a selected supplier. If the technology being selected has limited commercial experience, the buyer must depend on the supplier's experience with similar technologies and ability to support performance guarantees. The buyer should contact organizations that have purchased similar units. Visits to operating installations can provide important insights.

Terms and price

Proposed payment terms and schedule should also be evaluated carefully. Differences in payment terms can represent a significant value to the project. However, deferred payments can also be expensive. Commercial terms and conditions essentially define the level of risk that a supplier will share with the buyer. The lowest cost can be achieved when the buyer and supplier share a reasonable amount of the project risk. Also, performance guarantees rely on a supplier's ability to back them up. This ability should be evaluated before awarding a contract.

Commercial structure

Another major decision is the commercial contracting structure. Traditionally, the developer of a capital equipment project will issue a tender for major equipment packages in which the owner or developer will manage the risks of integrating these packages.

Some projects such as those financed off-balance sheet (or *project financed*) need to have single-point guarantees of plant performance and construction schedule to address financial risks. An owner or developer may therefore need to employ a general contractor or possibly a consortium of companies that will manage the project integration risk and provide overall guarantees.

Another concept is to establish a strategic project alliance or partnership with one or several major equipment or system suppliers to jointly develop, manage, and share the risk of project integration and execution.

Traditional commercial structures

A company that is planning a major capital equipment project, such as a new coal-fired power plant, must work through many of the following development process steps to obtain corporate management approvals, project financing, local community support and any required government permits:

1. Define basic needs, objectives and goals.
2. Explore critical logistics and feasibility.
3. Identify permitting requirements.
4. Assess potential alternate approaches or technologies.
5. Optimize design requirements to meet the goals and objectives.
6. Evolve a plan and timetable for development and implementation.
7. Secure capital financing.
8. Identify internal and external resources needed to develop and execute the project.
9. Develop specifications for the equipment and system packages that will be purchased.
10. Evaluate bids and select supplier(s).

Traditionally, the project developer will work through these steps using in-house resources or by hiring a consulting engineering company to support the project feasibility and development activities. The equipment supplier can also be a key resource in a number of these areas. However, because the traditional procurement philosophy depends on maintaining competitive pressure on the qualified equipment suppliers, the opportunity to involve an equipment supplier in the developmental stages can be limited.

Traditional procurement methods require the equipment supplier to bid competitively to a fixed specification after most of these steps have been completed. The success of this approach depends on the expertise, oversight, direction and integration capabilities of the owner and its hired consultant to develop and define the specific scope and design requirements.

Selection of equipment suppliers is primarily based on low evaluated bid price. With emphasis on low capital cost and the need to compare technically equivalent offers, long-term value relating to operating costs, maintenance, and availability can be lost in the process. In addition, a low price may motivate the selected supplier to work in a manner that may not be in the interest of the owner during the execution of the contract in an attempt to avoid losses on a project with low profitability.

An owner also can find that project costs increase with changes in scope or design that evolve during the project. Changes are more costly when they occur later in the process as they will affect work already completed, and may impact the work and scope of other contractors/suppliers.

Collaborative partnerships/alliances

Recently, collaborative alliance-type business structures have been used to integrate the equipment supplier into the project development process. Such an approach allows the equipment supplier to contribute resources and expertise when the project is taking shape and project direction is still flexible. The equipment supplier can function as a team member or partner, rather than simply a service provider addressing a fixed specification.

In such an alliance, all parties can contribute to the final solution and can benefit from the result. This approach involves the major supplier(s) in the development phase of the project, a time when specific prod-

uct knowledge can best be applied. This establishes project design requirements that recognize plant operational needs, establishes appropriate levels of redundancy, and evaluates the layout of equipment to best facilitate erection and maintenance access. The ideal time to evaluate and optimize a project is during these early stages.

The commercial framework of an effective alliance should include a system of risk and reward incentives that will keep all partners motivated to work towards the common goals of project cost, project schedule execution, and equipment performance. Partners should be motivated to earn their profit by performing at or better than a set of measurable, mutually beneficial goals established for the project.

Benefits of a project alliance Large complex projects are well suited for collaborative alliances. Involving an experienced equipment supplier in the development of the plant design, definition of scope, and estimation of capital costs can bring significant value to the process and can avoid fatal flaws of assumptions that can be made during the initial conceptual stages of a project.

Once an alliance is established, the owner and the supplier can develop a relationship that capitalizes on the strengths of each organization as they work through the issues and move forward to creatively address challenges of operations, maintenance and project execution. Some of the benefits that can be realized from such an alliance program structure include the following:

1. Many aspects of the bid specification development, proposal development, proposal evaluation, supplier selection and contract negotiation processes are eliminated, saving time and money.
2. The project team can employ a cooperative approach to focus on optimizing the owner's true costs. Decision-making can focus on the best long-term value rather than on the lowest near-term capital cost.
3. The project specification can be prepared interactively, allowing innovative solutions to be identified, more thorough project planning to be implemented, and false starts to be minimized.
4. The legal and financial framework is typically established at the beginning of the alliance and usually requires little adjustment during the life of the alliance.
5. Project resource assignment and loading are planned to achieve the best utilization of personnel from all participant organizations, eliminating redundancy and extra costs.
6. Open communication can be used in all aspects of planning and job tracking, which builds trust and minimizes conflict.
7. For multiple unit or multiple plant projects, lessons learned on earlier project phases can benefit later stages of the project. Implementing lessons learned is a key factor to achieving economic benefit over the duration of the alliance.

Factors to consider When considering the alliance option, the development process is inherently differ-

ent. The equipment supplier needs to be selected at a much earlier point in the process. Because this selection can not be based on competitively bid prices, other factors need to be evaluated to determine the relative degree of confidence that the candidate partner will contribute. Such factors include:

1. experience and success record for the technology required,
2. experience with other projects performed under an alliance agreement,
3. experience performing a project of similar scope, design and complexity,
4. qualifications, experience and capabilities of the project team that will be assigned to work on the project,
5. capabilities to manage cost and project risk to competitive levels through a combination of materials sourcing capability, systems project management and control, labor charge rates, and markups (overhead and profit) that would be applied against actual costs incurred,
6. degree that the partner will share and limit project cost overruns relative to a mutually developed target cost,
7. degree that the partner will share the financial risk associated with the operating performance of the equipment and systems to be supplied, and
8. degree that the partner will share the risk of project schedule performance to meet targeted commercial operation.

Power system economics

The relative economics of the options must be compared as part of the evaluation of alternate power systems or different product offerings. Unfortunately, this is not a straightforward, simple task. Large projects involve a complex series of time dependent cash flows which usually include an initial near-term investment in plant and equipment, and a long-term, uneven series of operating costs, maintenance costs and revenues from the sale of power or end product. This is further complicated by the time value of money and the effects of inflation. Money today is generally worth more than the same amount of money a year from now because of: 1) the potential interest which could be earned during the next year, and 2) the erosion in the future buying power due to inflation. The following provides a very brief overview of several methodologies used to place the total evaluated costs of different projects on the same financial basis so they can be directly compared. More comprehensive discussions of such evaluations are provided in References 3 to 6. This discussion is broken down into the following subsections:

- Constant versus current cost basis
- Definitions
- System cost evaluation
- Evaluation parameters
- Methods for evaluating operating costs
- Other considerations
- Examples

Constant versus current cost basis

Analyses are conducted on either a current or constant cost basis. The current cost basis presents costs as they would be expected to appear on a company balance sheet in the future while the constant cost basis does not include inflation.

The selection of the constant or current cost approach usually does not change the economic choice between similar projects. For nearer term projects, such as plant upgrades or the addition of small components, current costs are frequently used because of near-term impact. For longer term projects such as new plants, constant costs are frequently used as at least one of the evaluation tools so that the effect of inflation does not distort real cost trends. In either case, it is important to use the same basis for evaluating all alternatives. The examples provided below are evaluated on a constant cost basis.

Definitions

The following parameters provide the basis for the economic evaluation:

Discount rate (k) This is the cost of money for a power system owner and includes the weighted cost of capital for each class of debt and equity. Establishing the appropriate cost of capital or discount rate is increasingly complex. References 4 and 7 provide detailed discussion on the sources of funds and the evaluation of their costs. A simplified discount rate (k_c) estimate can be obtained from the following equation which takes into account that interest payments on debt are generally tax deductible expenses:

$$k_c = (FD) k_d (1 - TR) + (FE) k_e \quad (1)$$

where

FD = fraction of capital consisting of debt
 FE = fraction of capital consisting of equity
 k_d = annual debt interest rate
 k_e = annual stockholder return
 TR = fractional income tax rate

The annual debt interest rate and stockholder return reflect the anticipated impact of inflation and are used in current cost basis analyses. If a constant cost based analysis is desired, the *current cost* discount rate (k_c) can be related to the *constant cost* discount rate (k_f) through the escalation or inflation rate (e) in the following equation:

$$k_f = [(1 + k_c) / (1 + e)] - 1 \quad (2)$$

The escalation rate may have to be treated as a time dependent variable if it is expected to change significantly over the period of analysis.

Fixed charges Also referred to as carrying charges, these are the fixed annual costs associated with the initial capital investment and are generally incurred whether or not the plant is operated. The components include the return on investment, capital recovery (or depreciation), property taxes and insurance as well as federal and state taxes. Over the life of a new plant the annual revenue requirement declines because of

income tax effects and depreciation of the initial capital investment. However, a weighted average or levelized value is frequently used for evaluations. To obtain a levelized value the actual annual fixed charges are discounted to the present and then levelized using the equations discussed below. Annual fixed charge rates vary from 10 to 21% of the initial total capital investment.

Interest during construction This refers to the cost of money during construction prior to initial plant operation. It is not included if all project costs are incurred in a single year.³

Capacity factor This is the total power produced in a given period (typically one year) divided by the product of the net unit capacity and the given time period. It accounts for part load operation and outage times. The capacity factor varies over the plant life, typically climbing to a maximum in the first few years, remaining relatively constant for a period of several years and then falling as the unit begins to age.

Load factor This is the fraction of the full load or maximum continuous rating (MCR) at which the steam generating system is normally expected to operate for extended periods of time.

Net plant heat rate (NPHR) This is the total fuel heat input expressed in Btu divided by the net busbar power leaving the power plant expressed in kWh. Plant total energy efficiency (E) can be obtained from the following relationship:

$$E = \frac{3412 \text{ Btu/kWh}}{NPHR} \times 100\% \quad (3)$$

The *NPHR* typically varies with plant load.

Demand and auxiliary power charges These are the charges placed against the internal use of energy for auxiliary equipment. Separate rates are established by electricity and steam usage. The size of the charges depends upon the cost of fuel and other operating costs.

System cost evaluation

In the economic evaluation of steam generating systems, it is important to include all appropriate costs and expenses. Table 2 provides a list of typical capital, variable and fixed operating and maintenance costs which could be associated with a steam generating system installation. Capital costs basically include all expenditures for the purchase, installation and startup of the steam generating system and its auxiliaries. Care must be taken to ensure that different product offerings contain the same scope of work. To obtain the total plant investment, interest during construction, initial inventory items (such as fuel) and contingency are added. Variable operating costs include delivered fuel cost, other consumable material purchases, power and steam demand charges, and waste disposal or byproduct use.

Fixed operating and maintenance costs cover operating expenses which are likely to be incurred whether or not the plant is in operation. These change from year to year and generally increase as the plant ages. They also tend to vary with the unit load pattern, plant size, and primary fuel.

Table 2
Typical Steam Generating System Cost Items

Capital Costs

Boiler (nominal scope including burner system and air heater)
Fans and drives
Appropriate flues and ducts
Coal crushers
Pulverizers
Pyrite removal (pulverized coal units)
Dust collectors
Ash handling
Steam coil air heaters
Steam piping
Injection water piping
Startup pump and drive
Feedwater heaters and piping (if used)
Feedwater treatment
Selective catalytic reduction (SCR) system
Flue gas desulfurization (FGD) system (dry or wet)
Baghouse or electrostatic precipitator (ESP)
Wet ESP (if required)
Reagent storage and preparation systems
Reagent slurry pumps and piping
Gypsum dewatering system (if wet FGD system is used)
Tanks and sumps
Instrumentation
Controls
Foundations and electrical connections
Structural steel
Building
Platforms
Freight
Sales taxes
Site preparation
Erection/insulation/painting
Startup
Performance tests
Miscellaneous engineering and supervision services

Variable Operating Costs (Credits)

Primary fuel cost
Electrical and steam power demand:
Fan power
Pulverizer power
Recirculating pump power
Boiler feedpump power
Crusher power
Makeup water and chemicals
Wastewater treatment
Steam demand:
Sootblowers
Flue gas reheat
Air heating
Compressed air demand
Ash removal and disposal
Auxiliary fuel for low load stability
Other consumables (ammonia, limestone, etc.)
Credits for any byproduct sales

Fixed Operating and Maintenance Costs

Plant operators
Maintenance labor
Maintenance material
Chemical cleaning
Replacement material
Supervision
Other overhead items

In the financial evaluations, selected penalties or operating costs can be associated with superheater, reheat superheater and economizer pressure drops (steam-water side and gas side). Depending upon the buyer's perspective, these can be explicitly listed as separate operating costs or they may be indirectly accounted for as part of the general electrical and steam power requirements listed above. Reheat superheater steam side pressure loss is of particular interest because of its strong connection with thermal cycle efficiency.

Evaluation parameters

Present value With an economic life stretching many decades, power plants experience operating expenses over extended periods of time. It is necessary to account for the time value of money in evaluating projects which have differing initial capital investments and future expenses over several years. This is usually accomplished by using a *present value (PV)* calculation for each annual cash flow. The *PV* of a *future value* or payment (*FV*) in year *n* is defined as:

$$PV = FV(1 + k)^{-n} = FV(PVF) \quad (4)$$

where

$PVF = (1 + k)^{-n}$ = present value factor

k = interest or discount rate

n = number of years or periods at rate k

An alternate use of the *PVF* is to evaluate the future value of a present value:

$$FV = PV / PVF \quad (5)$$

Where a series of equal future annual payments, *A*, will be made for *n* years, the *PV* is defined as:

$$PV = A \left(\frac{(1 + k)^n - 1}{k(1 + k)^n} \right) = A (SPVF) \quad (6)$$

where

$SPVF$ = uniform annual series present value factor

$$= \frac{(1 + k)^n - 1}{k(1 + k)^n}$$

As with the single payment present value factor, *SPVF* can be used to convert a *PV* into a series of future equal payments for *n* years:

$$A = PV / SPVF \quad (7)$$

For illustration purposes, Table 3 provides values of *PVF* and *SPVF* for a discount rate of 6% from 1 to 30 years.

Levelization In evaluating various power system options, it is frequently desirable to compare weighted average annual values of future costs such as fuel instead of the lumped sum present values. Such a

parameter would be a levelized cost evaluated using the following equation:

$$\text{Levelized value} = \frac{\sum_{j=1}^n (FV_j) (PVF_j)}{SPVF} \quad (8)$$

where

PVF_j = present value factor for year j and rate k
 FV_j = future annual payment in year j
 $SPVF$ = uniform annual series present value factor in year n for discount rate k
 j = individual years up to n years
 k = annual discount rate

For the special case where the annual payment escalates or is inflated from an initial value of S_1 with a constant rate, e , the future value of the annual payment in year j is:

$$S_j = (1 + e)^j S_1 \quad (9)$$

The resulting levelization equation then becomes:

$$\text{Levelized value of } S = S_1 \left(\frac{1 - [(1 + e)/(1 + k)]^n}{k - e} \right) / SPVF \quad (10)$$

Methods for evaluating operating costs

There are several approaches to the evaluation of operating costs. The revenue requirements method and the capitalized cost method are reviewed here and examples are given. While each method used involves a large number of inherent assumptions, these are the dominant methods used to evaluate steam supply and emissions control equipment. See References 3 to 7 for more discussion.

Revenue requirements method This method determines the minimum gross receipts which are required to make each alternative pay its way. The alternative that requires the lowest receipt of revenues is the economic choice as it will permit profitable operation with the smallest revenues. This method takes into account the present value of all future expenditures and costs.

The capital (first cost) expenditure which is justified in order to put two alternatives on an equal basis is less than the difference in future revenue requirements. The future revenue requirements are converted to current dollars by multiplying each future expenditure by the PVF for each year in which the expenditure will occur. By summing the present value of the future revenue requirements, a total present value is determined. To convert this sum into a justifiable capital expense, it must be levelized, or converted to an equivalent equal annual cost. This is done by dividing the total present value by the uniform annual series present value factor (SPVF) (which is 13.765 for a 30 year period and 6% interest rate, used in the examples that follow). A tabulation of present

value factors (PVF) for 6% interest rate is shown in Table 3. Present value factors for other interest rates and evaluation periods can be evaluated from Equations 4 and 6. After converting the total into an equal annual cost, the justifiable capital expenditure is determined by dividing the annual cost by the fixed charge rate.

Capitalized cost method This method assumes that the equipment being operated has an infinite lifetime and that the costs of operating the unit will continue indefinitely. It is a simpler evaluation procedure to use than the revenue requirements method described above, but is not as exact or flexible in accounting for future changes in such items as fuel and maintenance costs which will change during the life of the unit.

The amount calculated using this method is the justifiable capital expense which can be spent to purchase the additional equipment and still give an operating advantage.

For example, if it is found that additional air heater surface will achieve higher unit efficiency, i.e., fuel savings over the lifetime of the unit, the additional air heater surface is justified if its capitalized cost is less than the cost of the fuel which can be saved over the remaining unit life net of any tax impact.

Other considerations

Risk All new projects involve some level of risk or uncertainty. Short-term projects using established technology typically are considered low risk while long-term projects using new, untried technology are generally considered higher risk. A number of approaches are used to account for the risk or uncertainty during project evaluations. One approach is to establish special guarantee provisions in the specifications and contract. This will typically increase the price from the suppliers since they assume more of the risk. A second approach is to increase the buyer's in-

Table 3
6% Compound Interest Factors

Year	Single Payment Present Value Factor (PVF)	Uniform Annual Series Present Value Factor (SPVF)	Year	Single Payment Present Value Factor (PVF)	Uniform Annual Series Present Value Factor (SPVF)
1	0.9434	0.943	16	0.3936	10.106
2	0.8900	1.833	17	0.3714	10.477
3	0.8396	2.673	18	0.3503	10.828
4	0.7921	3.465	19	0.3305	11.158
5	0.7473	4.212	20	0.3118	11.470
6	0.7050	4.917	21	0.2942	11.764
7	0.6651	5.582	22	0.2775	12.042
8	0.6274	6.210	23	0.2618	12.303
9	0.5919	6.802	24	0.2470	12.550
10	0.5584	7.360	25	0.2330	12.783
11	0.5268	7.887	26	0.2198	13.003
12	0.4970	8.384	27	0.2074	13.211
13	0.4688	8.853	28	0.1956	13.406
14	0.4423	9.295	29	0.1846	13.591
15	0.4173	9.712	30	0.1741	13.765

ternal contingency account in the project cost evaluation (see Reference 3). A third approach involves making adjustments to the discount rate to accommodate the level of risk or uncertainty with higher rates applied to riskier projects (see Reference 7). One or more of these options, as well as other approaches, may be used in the ranking of project options depending upon the buyer's internal needs.

Unequal periods When comparing project alternatives of equal life, the various evaluation techniques generally provide similar rankings. However, when project lives are significantly different, additional care must be exercised in performing the analysis and interpreting the results. As an example, the costs of additional future equipment replacement may need to be considered when short-term and long-term repairs to a particular equipment problem are considered. In addition, when interpreting the evaluation

results, each financial model uses different assumptions about capital reinvestment which could result in different project rankings.

Examples

Four examples follow which illustrate the use of the evaluation methodologies. The first two examples compare the use of the revenue requirement method and the capitalization method in evaluating the choice between a subcritical pressure 2400 psi utility steam cycle and a supercritical pressure 3500 psi utility steam cycle assuming that a new power plant is needed. Example 3 provides a comparison between two industrial boiler bids where one bidder has a higher price but higher boiler efficiency. Example 4 evaluates the lifetime auxiliary power difference between two industrial boiler bids. All of these examples are evaluated on a constant U.S. dollar basis, i.e., excluding inflation.

Example 1
Revenue Requirements Method Evaluation of 2400 psi and 3500 psi Steam Cycles

A) Problem: Determine the economic choice between a 2400 psi cycle and a 3500 psi cycle with 1000F superheat (SH) and reheat superheat (RH) temperatures using a constant cost basis.

B) Given:	Unit 1	Unit 2	
1. Throttle pressure, psi	2,400	3,500	
2. Temperature, SH/RH,F	1,000/1,000	1,000/1,000	
3. Plant size, kW	600,000	600,000	
4. Net plant heat rate (NPHR), Btu/kWh: 100% Load	9,000	8,860	
80% Load	9,000	8,860	
60% Load	9,180	9,040	
35% Load	10,080	9,920	
5. Fuel cost, \$/million Btu	\$2.00	\$2.00	
6. Evaluation period, yrs	30	30	
7. Interest rate or discount rate, %	6	6	
8. Maintenance costs	Same	Same	
9. Availability	Same	Same	
10. Operating costs (excluding fuel)	Same	Same	
11. Fixed charge rate, % (Interest, taxes, insurance, debt return)	14.0	14.0	
12. Plant capacity factors (Units 1 and 2)			
Years	1 to 10	11 to 20	21 to 30
100% Load	44%	23%	6%
80% Load	28%	23%	23%
60% Load	13%	34%	34%
35% Load	6%	11%	23%
10% Load	9%	9%	14%
	100%	100%	100%
Average capacity factor for period	76.30%	65.65%	52.85%
Average capacity factor for lifetime		64.93%	

C) Solution:

1. Cost of fuel consumed per year — 2400 psi unit
(h/yr) x capacity factor x kW load x Btu/kWh = Btu/yr
(Btu/yr) x (\$/Btu) = \$/yr

(a) Years 1 to 10

8,760 x 0.44 x 1.00 x 600,000	x	9,000	=	20,814 x 10 ⁹
8,760 x 0.28 x 0.80 x 600,000	x	9,000	=	10,596 x 10 ⁹
8,760 x 0.13 x 0.60 x 600,000	x	9,180	=	3,764 x 10 ⁹
8,760 x 0.06 x 0.35 x 600,000	x	10,080	=	1,113 x 10 ⁹
				<u>36,287 x 10⁹</u>

36,287 x 10⁹ x \$2.00/10⁶ = \$72,574,000/yr

(b) Years 11 to 20

8,760 x 0.23 x 1.00 x 600,000	x	9,000	=	10,880 x 10 ⁹
8,760 x 0.23 x 0.80 x 600,000	x	9,000	=	8,704 x 10 ⁹
8,760 x 0.34 x 0.60 x 600,000	x	9,180	=	9,843 x 10 ⁹
8,760 x 0.11 x 0.35 x 600,000	x	10,080	=	2,040 x 10 ⁹
				<u>31,467 x 10⁹</u>

31,467 x 10⁹ x \$2.00/10⁶ = \$62,934,000/yr

(c) Years 21 to 30

8,760 x 0.06 x 1.00 x 600,000	x	9,000	=	2,838 x 10 ⁹
8,760 x 0.23 x 0.80 x 600,000	x	9,000	=	8,704 x 10 ⁹
8,760 x 0.34 x 0.60 x 600,000	x	9,180	=	9,843 x 10 ⁹
8,760 x 0.23 x 0.35 x 600,000	x	10,080	=	4,265 x 10 ⁹
				<u>25,650 x 10⁹</u>

25,650 x 10⁹ x \$2.00/10⁶ = \$51,300,000/yr

2. Present value of fuel costs — 2400 psi unit
Fuel costs for period x PVF for period
= PV of fuel costs for period

(a) Years 1 to 10
\$72,574,000/yr x 7.36 = \$534,145,000

(b) Years 11 to 20
\$62,934,000/yr x (11.47 - 7.36) = \$258,659,000

(c) Years 21 to 30
\$51,300,000/yr x (13.76 - 11.47) = \$117,477,000

\$910,281,000

3. Cost of fuel consumed per year — 3500 psi unit
(h/yr) x capacity factor x kW load x Btu/kWh = Btu/yr
(Btu/yr) x (\$/Btu) = \$/yr

(a) Years 1 to 10

8,760 x 0.44 x 1.00 x 600,000	x	8,860	=	20,490 x 10 ⁹
8,760 x 0.28 x 0.80 x 600,000	x	8,860	=	10,431 x 10 ⁹
8,760 x 0.13 x 0.60 x 600,000	x	9,040	=	3,706 x 10 ⁹
8,760 x 0.06 x 0.35 x 600,000	x	9,920	=	1,095 x 10 ⁹
				<u>35,722 x 10⁹</u>

35,722 x 10⁹ x \$2.00/10⁶ = \$71,444,000/yr

(b) Years 11 to 20

8,760 x 0.23 x 1.00 x 600,000	x	8,860	=	10,711 x 10 ⁹
8,760 x 0.23 x 0.80 x 600,000	x	8,860	=	8,569 x 10 ⁹
8,760 x 0.34 x 0.60 x 600,000	x	9,040	=	9,693 x 10 ⁹
8,760 x 0.11 x 0.35 x 600,000	x	9,920	=	2,007 x 10 ⁹
				<u>30,980 x 10⁹</u>

30,980 x 10⁹ x \$2.00/10⁶ = \$61,960,000/yr

(c) Years 21 to 30

8,760 x 0.06 x 1.00 x 600,000	x	8,860	=	2,794 x 10 ⁹
8,760 x 0.23 x 0.80 x 600,000	x	8,860	=	8,569 x 10 ⁹
8,760 x 0.34 x 0.60 x 600,000	x	9,040	=	9,693 x 10 ⁹
8,760 x 0.23 x 0.35 x 600,000	x	9,920	=	4,197 x 10 ⁹
				<u>25,253 x 10⁹</u>

25,253 x 10⁹ x \$2.00/10⁶ = \$50,506,000/yr

4. PV of fuel costs — 3500 psi unit

(a) Years 1 to 10
\$71,444,000/yr x 7.36 = \$525,828,000

(b) Years 11 to 20
\$61,960,000/yr x (11.47 - 7.36) = \$254,656,000

(c) Years 21 to 30
\$50,506,000/yr x (13.76 - 11.47) = \$115,659,000

\$896,143,000

5. Saving in fuel costs — 3500 psi versus 2400 psi

PV of fuel costs	
2400 psi unit	\$910,281,000
3500 psi unit	\$896,143,000
PV of savings	\$ 14,138,000

\$14,138,000 / 600,000 kW = \$23.56/kW

6. Justifiable capital expenditure — 3500 psi versus 2400 psi

Justifiable additional expenditure =

PV of fuel cost saving
Fixed charge rate x PVF

PVF for 30 years at 6% interest = 13.76

Fixed charge rate = 14% = 0.14

Justifiable additional expenditure =

\$14,138,000
0.14 x 13.76 = \$7,339,000

Justifiable expenditure/kW =

\$7,339,000 / 600,000 kW = \$12.23/kW

D) Result:

- In terms of today's worth, the 3500 psi cycle will save \$14,138,000 or 23.56/kW in fuel costs over its life as compared with the 2400 psi cycle.
- The saving will justify the expenditure of \$7,339,000 or \$12.23/kW more for the 3500 psi cycle than for the 2400 psi cycle, all other factors being equal.

Essentially any auxiliary power usage, difference in boiler efficiency, or difference in net plant heat rate can be treated in the same manner as this example. This method basically converts the differences between designs into fuel costs. The fuel costs, which account for future load factor, cycle heat rates and future fuel costs, are converted into present day dollars using present value mathematics for the projected interest rate over the life of the unit. The justified capital expenditure can then be calculated.

Example 2 Capitalized Cost Method Evaluation of 2400 psi and 3500 psi Steam Cycles

A) Problem: Compare the economics of a 2400 psi cycle and a 3500 psi cycle using a constant cost basis.

B) Given: Same information as Example 1.

C) Solution:

1. Average NPHR — 2400 psi cycle — Btu/kWh

$$\begin{aligned} 100\% \text{ Load: } (0.44 + 0.23 + 0.06) \times 9,000 &= 6,570 \\ 80\% \text{ Load: } (0.28 + 0.23 + 0.23) \times 9,000 &= 6,660 \\ 60\% \text{ Load: } (0.13 + 0.34 + 0.34) \times 9,180 &= 7,436 \\ 35\% \text{ Load: } (0.06 + 0.11 + 0.23) \times 10,080 &= 4,032 \\ \hline &24,698 \end{aligned}$$

$$\text{Average NPHR} = 24,698/2.68^* = 9,216$$

* This is the sum of all capacity factors in Item B12, Example 1, except the factors for zero load.

2. Average NPHR — 3500 psi cycle — Btu/kWh

$$\begin{aligned} 100\% \text{ Load: } (0.44 + 0.23 + 0.06) \times 8,860 &= 6,468 \\ 80\% \text{ Load: } (0.28 + 0.23 + 0.23) \times 8,860 &= 6,556 \\ 60\% \text{ Load: } (0.13 + 0.34 + 0.34) \times 9,040 &= 7,322 \\ 35\% \text{ Load: } (0.06 + 0.11 + 0.23) \times 9,920 &= 3,968 \\ \hline &24,314 \end{aligned}$$

$$\text{Average NPHR} = 24,314/2.68 = 9,072$$

3. Capitalized value of heat rate difference

$$\text{Difference} = 9,216 - 9,072 = 144 \text{ Btu/kWh}$$

$$\text{Average capacity factor for lifetime} = 64.93\% = 0.6493$$

Capitalized value =

$$\frac{\text{NPHR} \times \text{kWh generation / yr} \times \text{Fuel cost}}{\text{Fixed charge rate}}$$

$$\text{kWh generation/yr} = \text{Capacity factor} \times \text{Capacity} \times \text{h/yr}$$

$$\text{Capitalized value} =$$

$$\frac{144 \times 0.6493 \times 600,000 \times 8,760 \times \$2.00 / 10^6 \text{ Btu}}{0.14}$$

$$= \$7,020,000$$

$$= \$7,020,000 / 600,000 \text{ kW} = \$11.70/\text{kW}$$

$$= \$7,020,000 / 600,000 \text{ kW} = \$11.70/\text{kW}$$

D) Result:

For these conditions the expenditure of up to \$7,020,000 or \$11.70/kW is economically justified for a 3500 psi unit versus a 2400 psi unit. (Note that this is quite close to the \$12.23/kW answer reached by the revenue requirements method in Example 1.)

The capitalized cost method of evaluation can be adapted to evaluate auxiliary power, boiler efficiency, or other operating costs by converting them to fuel cost.

Example 3 Comparing Industrial Boiler Bids with Differing Boiler Efficiencies and Capital Cost

A) Problem: Determine which of two boiler bids provides the most economical system offering.

B) Given:

- Boiler produces 600,000 lb/h superheated steam at 1550 psi and 955F ($H_g = 1460 \text{ Btu/lb}$ from Mollier diagram, Chapter 2)
- Boiler feedwater is 400F ($H_f = 375 \text{ Btu/lb}$, Chapter 2)
- Fuel cost = \$5.00/10⁶ Btu (gas)
- Load factor (average annual fraction of MCR) = 0.9
- Use factor (fraction of in service time) = 0.9
- Discount rate = 10%
- Constant dollar basis
- Expected unit life = 30 years
- SPVF = 9.43 (30 years; 10% discount rate)
- Bid No. 1 guarantees 86.5% efficiency with a price of \$10,400,000
- Bid No. 2 guarantees 87.5% efficiency with a price of \$11,200,000
- Income tax rate = 38% (composite)
- Depreciation tax factor = 0.17

C) Solution:

Equations:

$$\text{Unit input} = (\text{steam flow rate}) (\Delta H) (\text{load factor}) / \text{efficiency}$$

$$\text{Annual fuel cost} = (\text{per Btu cost}) (\text{annual unit output}) (\text{use factor})$$

$$\text{Net PV of fuel savings} = \Delta \text{ fuel cost} \times \text{SPVF}$$

For bid No. 1:

$$\begin{aligned} \text{Unit input} &= (600,000 \text{ lb/h}) (1460 - 375 \text{ Btu/lb}) (0.9) / 0.865 \\ &= 677.3 \times 10^6 \text{ Btu/h} \end{aligned}$$

$$\begin{aligned} \text{Annual fuel cost} &= (\$5.00/10^6 \text{ Btu}) (677.3 \times 10^6 \text{ Btu/h}) \\ &\times (8760 \text{ h/yr}) (0.9) = \$26,701,000/\text{yr} \end{aligned}$$

For bid No. 2:

$$\begin{aligned} \text{Unit input} &= (600,000 \text{ lb/h}) (1460 - 375 \text{ Btu/lb}) (0.9) / 0.875 \\ &= 669.6 \times 10^6 \text{ Btu/h} \end{aligned}$$

$$\begin{aligned} \text{Annual fuel cost} &= (\$5.00/10^6 \text{ Btu}) (669.6 \times 10^6 \text{ Btu/h}) \\ &\times (8760 \text{ h/yr}) (0.9) = \$26,396,000/\text{yr} \end{aligned}$$

$$\begin{aligned} \text{Difference between bids (savings before tax)} &= \\ \$26,701,000 - \$26,396,000 &= \$305,000/\text{yr} \end{aligned}$$

$$\begin{aligned} \text{Corporate income tax on savings} &= \$305,000 \times 0.38 \\ &= \$115,900/\text{yr} \end{aligned}$$

$$\text{After tax savings} = \$305,000 - \$115,900 = \$189,100/\text{yr}$$

$$\text{Net PV of savings} = \$189,100/\text{yr} \times 9.43 = \$1,783,200$$

$$\begin{aligned} \text{Difference in price} &= \$11,200,000 - \$10,400,000 \\ &= \$800,000 \end{aligned}$$

$$\begin{aligned} \text{Tax savings on depreciation} &= \Delta \text{ price} \times \text{depreciation factor} \\ &= \$800,000 \times 0.17 = \$136,000 \end{aligned}$$

(dependent upon government depreciation schedule and discount rate)

$$\begin{aligned} \text{Difference in price net of tax savings} &= \$800,000 - \$136,000 \\ &= \$664,000 \end{aligned}$$

D) Result:

Because the net present value of the energy savings (\$1,783,200) is greater than the net price for the more efficient unit after depreciation tax savings (\$664,000), bid No. 2 provides the more economical offering.

Example 4
Evaluating the Cost Impact of Different Auxiliary Power Requirements of Two Industrial Boiler Bids

A) Problem: Determine the economic impact of differing auxiliary power requirements of two boiler bids.

B) Given:

1. Power cost = \$0.025/kWh
2. Load factor = 0.9
3. Use factor = 0.9
4. Auxiliary power requirements

	Bid No. 1	Bid No. 2
	kW	kW
Component	at MCR	at MCR
Pulverizer	430	320
Coal feeder	3	3
Primary air fans	200	175
Forced draft fans	450	425
Auxiliary fans and blowers	30	30
Regenerative air heater	10	10
Total maximum auxiliary power	1,123	963

5. Assume the same discount rate, unit life, and SPVF as in Example 3.

C) Solution:

Total maximum auxiliary power corrected for capacity and load factors:

$$\text{Bid No. 1} = (1,123 \text{ kW}) (0.9) (0.9) = 910 \text{ kW}$$

$$\text{Bid No. 2} = (963 \text{ kW}) (0.9) (0.9) = 780 \text{ kW}$$

Annual power costs:

$$\text{Bid No. 1} = (910 \text{ kW}) (\$0.025/\text{kWh}) \times (8760 \text{ h/yr}) = \$199,290$$

$$\text{Bid No. 2} = (780 \text{ kW}) (\$0.025/\text{kWh}) \times (8760 \text{ h/yr}) = \$170,820$$

$$\text{Difference} = \$28,470$$

$$\text{Tax on difference} = \$28,470 \times 0.38 = \$10,820$$

$$\text{Difference net of tax} = \$28,470 - \$10,820 = \$17,650$$

$$\text{Net PV of difference} = \$17,650 \times 9.43 = \$166,440$$

D) Result:

The power system supplied as bid No. 1 will cost approximately \$166,440 more to operate than the system supplied under bid No. 2 on a present value basis.

Many factors are involved in specifying and evaluating the economics of a steam generating or emissions control equipment project.

Chapter 38

Manufacturing

The installation of a steam generating unit involves the design and manufacture of the components and final erection of the unit. The power generation industry has achieved unprecedented levels of quality and reliability in producing modern steam generating equipment. State-of-the-art design and manufacturing techniques as well as the use of advanced materials are key reasons for these gains.

Component manufacturing involves a variety of skills and unique manufacturing methods and requires facilities for virtually all welding, metal removal, metal forming and casting processes. Manufacturing operations are continuously evolving to meet the increased quality and productivity demanded by today's markets. These manufacturing and quality evolutions have enabled the fabrication of large, complex boilers of sizes and technical competence once thought to be unachievable.

Gaining functionality at low cost is an ever present goal in the mature fossil power equipment industry. Achieving high quality levels in manufactured components requires that the manufacturing facility focus on small details. It is, therefore, important for Manufacturing to participate early in design discussions. The resultant design-for-manufacturability improvements add value to the product. *Value engineering*, a structured approach that enhances the manufacturing process, is used by The Babcock & Wilcox Company (B&W) to maintain its leadership position in the industry.

Once a design approach is determined, communication of the design information to the manufacturing facilities must be accurate and timely. Today's computers, integrated systems, and communication technology provide unprecedented capability to handle these tasks.

Traditional techniques as well as innovations implemented by B&W to manufacture steam generating equipment are described in the following sections. For information specific to nuclear equipment, see Chapter 50.

Welding

Welding and welding related processes are central to boiler fabrication. These processes are used in manufacturing a large percentage of components produced by B&W. In addition, many of today's basic welding technologies were pioneered by B&W.

A *weld* can basically be defined as a coalescence of one or more materials by the application of heat localized in the region of the intended joint. For most welding processes, the induced heat raises the temperature of the material above the melting point to create a weld pool. The heat source is then removed, allowing the pool to solidify and creating a metallurgical bond between the joined surfaces. Depending upon the application, filler material may be added to the weld pool to fill a cavity between the parts being joined.

There are many welding processes from which to select. The choice is primarily based on the best method of generating and conveying the energy needed to create the weld. Electric arc welding is by far the most common group of processes used in fabricating fossil fueled steam generating equipment, although other processes also apply. The most widely used arc welding processes are gas tungsten arc welding (GTAW), gas metal arc welding (GMAW), submerged arc welding (SAW), shielded metal arc welding (SMAW) and plasma arc welding (PAW). Of the non-arc welding processes, high frequency resistance welding (HFRW) and laser beam welding (LBW) are the most common. Table 1 summarizes the advantages and disadvantages of each process and provides examples of steam generator applications. The *Welding Handbook* and other sources provide specific information on the distinguishing features, attributes and limitations of each process.¹

Selecting a welding process requires consideration of several factors. The composition of the materials and the anticipated service conditions dictate the appropriate filler material. Base material composition also affects the use of preheat and post weld heat treatment to control the resultant hardness of the material and to minimize the susceptibility of the weld to cracking. Also, the structural mass of the component and the orientation and design of the weld joints influence the welding processes selected and the process parameters used. The quality and productivity associated with each welding process must also be factored into the selection.

Welding automation

A given welding process can be performed in a number of ways. Historically, the most common approach was manual welding, in which the operator moves the welding torch along the joint to be welded and makes the

Table 1
Comparison of Welding Processes

Process	Advantages	Disadvantages	Applications
LBW	Very deep penetration Very high quality Little distortion Good mechanical properties	High capital expense Equipment difficult to maintain Not portable Very good fit-up needed	Weld overlay of tubes and panels
GTAW	High quality Low capital expense Readily automated	Shallow penetration High operator skill required Low productivity Arc radiation hazard	Tube-to-tube weld root pass Join superheater and economizer tube sections
GMAW	Moderate productivity Moderate quality Readily automated	Shallow penetration Contact tip wear requires periodic stoppages Arc radiation hazard	Panel wall repair and attachments Tube-to-tube welds
PAW	Deep penetration High productivity High quality	Complex process Difficult to maintain High capital expense Arc radiation hazard	Sootblower tube-to-tube welds
SAW	Very high productivity High quality Operator protected from arc radiation	Limited in welding position	Header fabrication Water wall fabrication
SMAW	Very low capital expense Very portable	Can not be automated High operator skill required Lower weld quality Low productivity	Repair Tube-to-header welds
HFRW	Very high productivity High quality	High capital expense Very limited in application	Tube manufacturing

necessary adjustments to the welding equipment. However, automation of welding processes has become very common because it provides more consistent quality and lower costs as compared to non-automated processes.

One form of automation is *orbital* welding, used with the GTAW process to join superheater and economizer tube sections. In this process, the welding head is driven around the outside diameter (OD) of the tube to produce a weld. A computer coordinates the motion of the welding head, the weld filler wire feed rate and the process parameters to maintain high weld quality.

Robotic welding and cutting are also commonly used. Robots are used in a number of boiler-related welding applications including seal welding of tangent tubes in a Cyclone furnace, fabricating coal pulverizer components, applying nonferrous overlay cladding to steam generator tubesheets as well as nozzle bores, and making complex tube-to-tubesheet welds inside small diameter bores. The flexibility of robots also promotes their use in plasma cutting of nozzle openings in shells and to contour burn nozzle mating surfaces. A number of robot types, including rectilinear, articulated arm, cylindrical coordinate and gantry style units are used in fabricating boiler components (see Fig. 1).

Automated determination of weld joint positions has also been implemented. Electromechanical devices, called *probes*, are used to track the weld groove to ensure proper placement of the weld head during submerged arc welding. An alternative guidance method, which has been used with the GMAW process, is *through the arc* tracking. This method senses the welding arc's electrical characteristics to guide the weld head. A more recent development for GTAW, GMAW and PAW is laser-based vision tracking, in which a non-contact sensor determines the torch position within the groove and adjusts the torch as necessary. This type of sensor also allows automated adaptive control of the welding process parameters by real time response to changes in weld joint topography.

Metal removal

Metal removal is performed either to prepare a component for another manufacturing operation, such as in machining weld joint preparations, or to produce a finished shape. Traditional machining processes are considered to be either chip removal or abrasive removal. The chip removal operations used in steam generation equipment production include turning, mill-

Fig. 1 Robotic welding.

ing, drilling, boring and broaching, while grinding, sanding and grit blasting are examples of abrasive operations. Nontraditional metal removal operations, such as electro discharge machining (EDM) and arc gouging, are also used.

B&W's fabricating shops have a variety of manufacturing equipment ranging in size from small hand tools to machines with 100 t (91 t_m) programmable rotary tables. Larger pressure vessels require larger machine tools. For example, the vertical boring mill shown in Fig. 2 can accommodate a part 16 ft (4.9 m) in diameter and 10 ft (3.0 m) high, while the horizontal boring mill in Fig. 3 has a rotary table capable of supporting 100 t (91 t_m).

As in other manufacturing areas, the most apparent innovation in machining is computer control of the equipment. Part configurations, programmed off line, are transmitted by distributed numerical control (DNC) to many machines on the shop floor. (See Fig. 4.) More

Fig. 3 Horizontal boring mill.

recent user-friendly computer numerical control equipment also permits sequences to be programmed by the machine operator. Computer numerical control (CNC) machining centers with automatic tool changing are common. In addition, multi-spindle computer numerical control drills are often used to prepare steam generator tube bundle support plates. (See Chapter 50.) These and other refinements permit some machine tools to be accurate within 0.00005 in. (0.00127 mm).

CNC thermal cutting machines, oxy-fuel and plasma, make use of downloaded computer generated nesting programs to maximize material use. The addition of a multi-station CNC punch, featuring an integral plasma burning head, complements the thermal cutting tables.

Electrical discharge machining (EDM) removes metal by spark erosion between an electrode and the work piece. In this process, intricate shapes matching those of the solid carbon electrode can be burned into the work piece. The solid electrodes are being replaced in many cases by CNC wire electrode machines.

Automation is increasing as computers often control entire shop sections. Material, automatically moved into storage buffers, then to CNC machines, is scheduled and routed using computerized identification systems. Probes are often used to check the final machined dimensions.

Forming

Forming is the permanent plastic deformation of a work piece accomplished by applying mechanical forces, through tooling, to the work piece. The primary objective of forming is the production of a desired shape.

Basic forming elements include the material to be formed, the tooling to change the shape, the lubrica-

Fig. 2 Vertical boring mill.

Fig. 4 Computer numerical control machining.

tion between the tools and the work piece, and the machine used to hold the tooling and to apply the forces needed to form the material.

In sheet forming operations, the forces are primarily applied in the plane of the sheet. The thickness is not constrained between opposing tools but may change due to in-plane strains. Sheet forming operations also include tube forming processes using an internal or external tool and sometimes both. Most sheet forming operations are performed cold.

B&W's principal forming applications are in the areas of plate and tube bending. Plate is bent to form large cylindrical shells, while tubes are bent to form flow loops or offsets. Two methods are used to bend plate for steam drum fabrication. Press die forming is used to make half shell courses (two seam welds) while roll bending is used to form full round shell courses (one seam weld). (See Chapter 50.)

Tube forming is done primarily on draw benders. The clamp die, bend die and pressure die are always used while the wiper die and mandrel are only required for tight radius bends with thin wall tubing. Forming dimensions are typically expressed relative to the diameter of the tubing being bent. For example, a 1D bend has a centerline radius equal to the tube diameter. Tubes with wall thickness greater than 10% of the OD do not require a mandrel or wiper die for forming.

A variation of draw bending is *boost bending*. Here the tube is clamped ahead of the bend die and an axial force is applied to push the tube into the bend region. This shifts the neutral axis toward the outside of the bend to reduce thinning on the outside and increase thickening on the inside.

The application of computer numerical control to bending, as shown in Fig. 5, is highly advantageous for tubes containing multiple bends of the same radius. The tube is fed into the bender, gripped by the axial transporter and moved to a reference location. All bends are then made automatically as programmed. The transporter rotates the tube for out-of-plane bends and feeds it axially to the next tangent point.

Castings

Castings are used throughout modern boilers and steam generating equipment. The choice of castings over other manufacturing processes, such as fabricated or machined components, is driven by functional design requirements and by final part configuration. Geometry often dictates the casting process as the least costly production method.

Castings are produced from an array of materials, from simple grades of irons and steels to complex alloys and proprietary metal chemistries and heat treatments. Material choice for particular applications is determined by tradeoffs between the function of the part

Fig. 5 Tube bending by computer numerical control.

and the design parameters, compared to the ultimate cost of the part.

Castings are produced using a multitude of processes including sand casting, permanent mold, die casting, investment casting, lost foam casting, and vacuum casting. The process selected is established by the material being poured, the part configuration and size, and the required tolerances. The weights of individual castings in modern steam generating equipment can range from a few ounces to many tons.

Process control is critical in producing quality castings. Process is even more important when castings are subjected to severe operating conditions (e.g., wear metals in coal pulverizers). Because of this control requirement, B&W operates its own foundry, producing pulverizer wear metal components from proprietary high chrome irons. (See Fig. 6.)

Fabrication of fossil fuel equipment

Drum fabrication

A large steam drum, complete and ready for shipment, is shown in Fig. 7. The drum consists of multiple cylindrical sections, or *courses*, and two hemispherical heads. Large stubs and nozzles along its length serve as flow connections for the steam generating and superheating surfaces of the boiler. The large nozzles along the bottom and on the hemispherical heads are connections for the downcomers, which carry water to the various generating system circuits.

Drum fabrication begins by pressing flat plate into half cylinders or by rolling the plate into full cylindrical shells. When short shell sections must be used because of material dimensions or heat treatment re-

Fig. 7 Utility steam drum ready for shipment.

quirements, the plate is rolled into a cylinder. For large drums, the plate is pressed into half cylinders then welded longitudinally, forming a course. The drum length is achieved by circumferentially welding the required number of shell sections. Longitudinal and circumferential welds are made using the automatic submerged arc process.

Drum heads may be hot formed by pressing or spinning flat plate in suitable dies. The heads are attached to the completed cylinders by circumferential welds.

Automatic welding techniques are often used to join the various shell courses and heads. Fig. 8 shows a two wire submerged arc welding machine on a longitudinal seam. Filler wire is continuously fed to the weld area, which is completely covered by a granular flux to prevent oxidation and enhance metal properties. The electrode carriage, moving along the weld joint, is guided by a seam tracker. Depending on the plate material, the material thickness and the configuration of the weld, multiple passes may be required.

For submerged arc circumferential welds, the drum is rotated while the welding head and flux applying

Fig. 6 Casting process at foundry.

Fig. 8 Welding longitudinal drum seam with double submerged arc welding machine.

equipment are stationary. An electromechanical guidance device may also be used to keep the arc tracking the weld groove.

Prior to and throughout all welding operations, pre-heat may be applied to minimize stresses and metallurgical transformations. In some cases, heating is maintained after welding until the vessel has been stress relieved.

Engineering advances in designs and the use of high strength, high temperature alloys have required the development of new weld techniques. This is especially true for stainless steels, Inconel® and other high nickel alloys. The tungsten inert gas (TIG) process is often specified to attain full root penetration. These processes also assure a uniform inside surface contour that does not interfere with fluid flow.

Nozzles and stubs are machined from hot forged billets, pipe or tubing. Larger connections may be integral with the heads, formed from rolled plate, or made from heavy wall pipe as shown along the bottom of the drum in Fig. 7. Attachments are manually welded to the drum with the shielded metal arc process using coated electrodes, by automatic satellite welding with the submerged arc process, or by semi-automatic welding with the metal inert gas (MIG) process. Other techniques are being developed that will significantly contribute to welded joint quality and increase the deposition rate of weld metal. Narrow weld grooves in thick plates are used to reduce weld volume in the joint.

Every carbon steel drum in which the material thickness is greater than 0.75 in. (19.1 mm) must be subjected to a final post weld heat treatment. In some cases, several short cycle stress relief operations may be applied to reduce preheating. For applications requiring high impact strength, formed heavy plate is water quenched to cool it rapidly. This heat treatment is followed by a normal stress relief.

All longitudinal and circumferential drum welds and the adjacent base material must be subjected to radiographic examination. For this purpose extensive radiography (x-ray) equipment is available. (See Fig. 9.) Ultrasonic evaluations are used where x-ray examinations are difficult or impractical. Surface and subsurface defects may be located using magnetic particle examination. Liquid penetrant examination also reveals surface flaws.

After all pressure parts have been welded, the vessel is ready for the finishing operations, including the installation of attachments and internals.

Headers as terminal pressure vessels

Headers are used in steam boilers to connect two or more tubes to a circuit. Headers can be fabricated from seamless tubing, pipe or hollow forgings. Access to their interiors is gained through the use of handholes. Headers vary in diameter from 3.0 in. to 48 in. (76.23 to 1,219.68 mm.) OD and can reach lengths in excess of 100 ft (30 m). Fig. 10 shows superheater headers nearing completion. Headers can be either shop installed to components such as panels and sections or shipped to the job site for field installation into the boiler.

Fig. 9 Drum weld testing with linear accelerator.

To fabricate a header, several pipes or hollow forgings are first joined by submerged arc welding. The ends of the header stock may have spherical or elliptical forged heads welded in place, or may be machined to accept a welded-in flat closure plate.

Completion of the header includes drilling and machining the tube and nozzle openings, and fitting and welding the nozzles and stubs (Figs. 11 and 12). Other attachments are added by manual or semiautomatic welding followed by heat treating, cleaning and finishing steps. These operations are conducted following strict quality control procedures.

Tubes as heat transfer surfaces

Tubes, in a variety of arrangements, are the heat absorbing surfaces and flow circuits in today's steam generating units (see Figs. 14 and 15). Tubes range in size from 0.875 to 5.0 in. (22.23 to 127.0 mm) OD and may be plain, finned or studded. Finned and studded tubes are used to create extended surface in some furnace wall

Fig. 10 Superheater headers nearing completion.

Fig. 11 Header drilling on vertical boring mill.

Fig. 12 Orbital welding.

of straight tube that are first bent, then welded together to give the proper configuration.

Close return bends are made by first hot upsetting a section of straight tube to increase the wall thickness at the bend location. Bending and hot sizing then form the tube to the desired configuration. The prepared bends are joined by computer controlled orbital GTAW to form a section. Upsetting and hot bending operations are often replaced by CNC booster bending. All other bends in a section are typically cold formed.

To complete a wall panel or section, support lugs, brackets and, in the case of panels, wall boxes are welded into position. Sections are hydro tested at 1.5 times design pressure, as required by the American

panels or sections to aid in heat transfer. Fig. 13 shows an opening in a wall panel surrounded by studded tubes. Materials used include carbon steel, chromium molybdenum alloys, composites with a metallurgically bonded stainless steel, or Inconel cladding over carbon steel.

Tubes can be shipped loose to the job site for field installation, or shop assembled into panels. Fabrication of a membrane panel begins by placing a metal strip between each row of tubes. This strip is then welded to the tubes on automatic equipment, which can perform numerous welds simultaneously (Fig. 15). A gas-tight metal wall surrounding the enclosed volume is created in the boiler by the membraned wall panels. The membraned wall panel design eliminates the need for a pressure-tight casing and reduces field erection costs.

Walls are typically assembled in panels up to 10 ft (3.0 m) wide and 90 ft (27.4 m) long, although larger panels have been fabricated. The panels may be formed into various configurations by using one of two bending machines (Fig. 16). To further reduce field erection costs, some panels and sections are preassembled into modules. Headers are often welded to these modules to complete the assembly (see Fig. 17).

Convection superheater surface uses continuous tube sections. A typical horizontal superheater section, shown in Fig. 18, is made from relatively short lengths

Fig. 13 Studded wall panel manufacturing.

Fig. 14 Hopper panel fabrication for a spiral wound universal pressure boiler.

Society of Mechanical Engineers (ASME) Code. Sections and panels are generally painted prior to shipment. Wall panels are often painted white to reflect light and thereby enhance worker vision within the boiler during erection.

Fig. 15 Wall panel membrane operation.

Longflow economizers

A *longflow economizer* is an assembly of finned tubes and headers installed within a process recovery boiler (see Chapter 28). The economizer absorbs much of the residual heat from the low temperature flue gases to improve boiler efficiency.

Value engineering has been beneficial in redesigning a longflow economizer, reducing manufacturing costs, lead time and field erection costs. One economizer design change eliminates bending the tube ends before fitting them into the inlet and outlet headers. The ends may be swaged to a smaller diameter in an automated process where the outside diameter and inside diameter (ID) of the swaged section remain concentric. Fins, formed from cold rolled flat stock and sheared to size, are automatically submerged arc welded on both sides to a shot blasted tube. All welds are then inspected. The tube ends are welded to inlet and outlet headers in jigs to form platens, which are furnace stress relieved. Finally the platens are assembled into an economizer module in a fixture. This fixture, with stiffeners added, is also used as a shipping frame for the unit. The frame is then used at the job site to lift the economizer module into the boiler (Fig. 19).

Structural steel and casings

As much as 11,000 t (10,000 t_m) of structural steel may be required to support a modern utility boiler. Most of this steel is available in standard mill shapes, however some members are fabricated from plate material into T- and H-shaped sections using submerged arc welding.

In modern units, water or steam cooled tubes constitute the basic structure of the boiler enclosure. Most boilers also contain non-water-cooled or cased enclosures. (See Chapter 23.)

Fuel preparation and burning equipment

B&W manufactures a great variety of burners for many fuels including oil, gas, coal, refuse, black liquor, wood bark, combinations of fuels, and specialty fuels

Fig. 16 Wall panel bending.

Fig. 17 Overhead view of wall panel construction.

(see Fig. 20). Because many similar or duplicate burners are built, product standardization and volume manufacturing techniques have evolved. This includes the manufacture of Cyclone™ furnaces (Fig. 21).

Cyclone barrels, ranging from 5 to 10 ft (1.5 to 3.0 m) in diameter, are fabricated using many duplicate tubes which are bent to a semicircular shape and joined to form a cylinder. Jigs, fixtures and power tools are used for these repetitive operations.

Cyclone furnaces are completely shop assembled in erection frames which are also used for stress relieving the final product. This permits close quality control to assure that ASME Code and B&W standards are met. Before shipment, a refractory coating is applied to the studded inside surfaces and the outside is

covered with a protective casing. See Chapter 15 for further details on Cyclone furnaces.

The B&W coal pulverizer is another product that benefits from standardization, although some variations are required due to installation configurations. B&W's EL pulverizer series, for smaller boiler applications, has been supplemented by the B&W Roll-Wheel™ series. A large B&W Roll Wheel pulverizer has the capacity to grind 105 t (95 t_m) of coal per hour. (See Chapter 13.)

The top, intermediate and lower pulverizer housings are fabricated from plate material. Other components such as tires and grinding ring segments for B&W's Roll Wheel pulverizers, and balls and rings for B&W's EL pulverizers, are cast from wear resistant parts.

Fig. 18 Superheater sections.

The pulverizer gearbox which is a welded and machined fabrication encloses precision bevel and helical gears. Each pulverizer gearbox assembly is run tested before being shipped.

Tube manufacturing

Thousands of feet (meters) of tubes made from a variety of steels and alloys are required for a large steam generating unit. Tubes are used for heat transfer and steam generating surfaces, including furnace walls, floors, roofs, and in superheaters, reheaters, economizers and air heaters.

Two types of tubes are used: seamless and welded. Each has applications within the boiler based on user and ASME Code requirements that define diameter, wall thickness and chemistry. (See Chapter 7.)

Seamless tubes Seamless tubes are pierced from solid rounds of steel, which are produced in electric arc furnaces. The process is carefully monitored to produce quality steel consistent with application requirements.

Tubes for boiler application are furnished hot finished or cold drawn, depending on size, tolerance and finish desired. Metallurgically, the two are similar; the differences are surface finish and manufacturing tolerances. For certain applications, the surface finish of the tubes is critical to reduce the pressure drop. To obtain a smooth, even surface and close tolerances, stainless tubing is generally finished by cold drawing. This process also permits grain size control in final heat treatment, which is important in high temperature applications of austenitic stainless steels. The production of seamless tubes requires special tools and careful control of heating and manufacturing procedures.

Electric resistance welded (ERW) tubes The ERW tube making process begins with a coil of high quality, fully killed steel strip that has been shot blasted for surface cleanliness. The strip is uncoiled and leveled and its edges are skived to remove defects. Passing through sequential forming rolls, the tube edges are fused without filler metal by an electrical current of 450 kHz. An exclusive feature of the process is on-line electronic weld imaging, which determines weld integrity. This is typically joined at the welding station by ultrasonic testing.

ERW tubing is typically produced in sizes from 1.0 to 4.5 in. (25 to 114 mm) OD with walls from 0.095 to 0.650 in. (2.413 to 16.51 mm) in carbon, carbon-molybdenum and alloy steel grades. Tubes can be delivered as cold drawn and normalized.

Engineering-manufacturing interface

Communications between the key areas of manufacturing and engineering are essential in achieving state-of-the-art manufacturing. As in other manufacturing areas, computers are largely responsible for many of the improvements. Information such as design data and drawings can be electronically transmitted to the manufacturing facilities thereby reducing total product lead times.

Value engineering, a logical planning tool, has also streamlined projects from the engineering analysis through the manufacturing steps. The reduction of component complexity and improvements in product quality and delivery are results of this technique. Equally important as computerization and value engineering is the early participation of manufacturing personnel in the product design.

B&W's manufacturing emphasis continues to be on high quality, competitively priced boiler components and complete factory-assembled boilers as described in Chapter 27 (see Fig. 22). State-of-the-art engineering designs, innovative manufacturing processes and the highest levels of quality control assure that components meet all codes and customer specifications.

Quality assurance and quality control

The quality assurance department establishes procedures and controls to assure that all products conform to product technical requirements. Quality con-

Fig. 21 Cyclone furnace manufacturing.

Fig. 22 Factory-assembled boilers in various stages of completion.

trol personnel in the manufacturing plants work to ensure that all products meet applicable codes and specifications.

The ASME Boiler and Pressure Vessel Code (see Appendix 2, Codes and Standards Overview) provides rules for the safe construction of boilers and other pressure vessels. In the United States, these rules are also usually part of state laws. The ASME Code is written by industry members, inspection agencies and users of boilers and pressure vessels. It strikes an acceptable balance between safety, functionality and manufacturability.

Section I of the Code, *Power Boilers*, requires a boiler manufacturer to have the fabrication procedures, as well as the design and material selection, monitored by a third party inspector. This authorized inspector is usually employed by an insurance agency and is licensed by the National Board of Boiler and Pressure Vessel Inspectors. In plants that produce a large volume of boiler components, this inspector may be a full-time resident. The inspector checks drawings, reviews material certifications, inspects welds, reviews radiographs, witnesses hydrostatic tests and monitors the general workmanship achieved by the fabricator. At the completion of a job, when the inspector is satisfied that the parts comply with all aspects of the Code, the inspector signs the ASME Code data sheet.

All welding performed on power boilers and pressure vessels must be done by Code-qualified personnel. The personnel must be trained to use the correct filler material, welding positions and processes. In addition, they must be trained to apply any required preheat and post weld heat treatments. All welding

procedures must be qualified to assure consistent, high quality welds. To maintain the qualifications of the welding personnel and assure appropriate implementation of procedures, B&W operates welding training centers and employs trained instructors at its manufacturing facilities.

Nondestructive examination

Nondestructive examination (NDE) provides the mechanism for quality control of base metals and weldments. There are four predominant methods of nondestructive examination that pertain to the pressure vessel industry: radiography (RT), ultrasonics (UT), magnetic particle inspection (MT), and dye penetrant inspection (PT). Radiography and ultrasonics are used for volumetric examination, while magnetic particle and dye penetrant inspection techniques provide for surface examination.

Radiography (RT) Radiography (x-ray) has been a primary weld quality control technique for many years. The two types of equipment commonly used are x-ray machines and gamma ray equipment.

The choice of using x-ray machines or gamma ray equipment is based on the mobility of the part to be examined and the availability of an x-ray facility. X-ray units can best be used in shops where fixed position equipment is available. Gamma ray equipment may be used to reduce the time needed to examine a circumferential weld seam. This examination is done by locating the isotope, usually cobalt-60, on the centerline of the unit, wrapping the outside diameter of the weld seam with x-ray film and exposing the film through remote control. Gamma ray equipment is

usually preferred for field use or when the component can not be readily moved.

To assure correct exposure time, a small three hole penetrometer is placed on the object being x-rayed which causes an image to form on the film. The penetrometer thickness and hole size are specified in applicable regulatory documents. When properly used, an image of the holes appears on the film. Flaws of equal or larger size are expected to appear on the film as well. The ASME Code specifies acceptance standards with respect to the size of porosity and slag inclusions. It also specifies those welds that must be radiographed in pressure vessels and pressure part fabrications.

Real-time radiography permits viewing the weld seam on a video screen while the radiographic process is occurring. The results may also be recorded on video tape.

A significant advantage of radiography over other nondestructive methods is that a permanent film record is made of each inspection. These records are retained for at least five years or as required by a contract.

Ultrasonics (UT) UT examination has proven to be a valuable tool in evaluating welds, plate and forgings of pressure vessels. This examination can be applied to most sizes and configurations of materials.

In generating the sound for ultrasonic testing, piezoelectric materials are used. When pulsed by an electric current, these materials vibrate and generate a sound wave. In addition, when the materials receive sound wave vibrations, they also generate electronic impulses. These impulses may be viewed on an oscilloscope to locate a defect in the material or weld. Sound is generated in frequencies typically ranging from 200 kHz (1 Hz = 1 cycle/s) to 25 MHz.

Electrical pulses are directed from an oscillator to a transducer that is applied to the material being examined. A liquid couplant is used for good contact between the transducer and the material being examined. The transducer generates high frequency sound that is directed into the material. If a flaw is encountered, some of the sound is reflected to the transducer, which in turn generates an electrical impulse. This impulse is then displayed on an oscilloscope, showing the size and location of the defect. With proper manipulation of the transducer, the entire sample can be examined. Flaw acceptance standards are given in the ASME Code.

In addition to flaw detection, ultrasonic techniques are used to measure material thicknesses.

Magnetic particle examination (MT) Magnetic particle examination can only be used on ferrous materials. This nondestructive examination technique will involve either the dry method, using alternating current (AC) or direct current (DC), or the wet method, using normal or ultraviolet light for examination. All procedures involve generating a magnetic field in the part being examined. A flaw on or near the surface becomes discernible by the accumulation of magnetic particles. The method used depends on the size, shape and surface condition of the material being tested.

Magnetic particle examination provides an inexpensive method of determining the surface and near surface condition of the materials being tested. The process can be used in the manufacturing facilities or in the field.

Liquid penetrant examination (PT) In contrast to magnetic particle examination, liquid penetrant examination can be used on ferrous or non-ferrous materials, however the process only reveals surface flaws. All examinations begin by coating the surface with a red dye. The bulk of the dye is removed by wiping the surface with a cloth, leaving dye in any small discontinuities that exist on the surface of the material being tested. Dye remaining in surface flaws of the material is made visible by applying a white developer.

Fabricators use liquid penetrant examination for welds or base metals of non-ferrous materials, such as stainless steel or Inconel. This examination can be performed during manufacturing or in the field. The equipment is inexpensive and portable and personnel can be easily trained to perform the inspection.

Quality control of fossil fuel equipment

A quality control system must be maintained throughout all manufacturing operations. The initial step is the inspection of incoming material to assure that it conforms to the purchase order requirements and the appropriate ASME Codes.

In addition to examinations stipulated by the Code, B&W performs other nondestructive tests as process quality control measures. Shop butt welds in boiler wall panels and superheater, reheater and economizer sections are radiographed. In addition, stub-to-header welds are examined by magnetic particle examination. These components may also be hydrostatically tested.

Internal and external cleanliness of pressure parts is an important part of quality control. Tube IDs are cleaned with sponges while ODs are shot blasted and coated with a rust inhibitor. Steel balls are blown through sections and panels with compressed air to ensure that the components are free of internal obstructions.

In-process and final inspections, which consist of checking critical dimensions and verifying that all required nondestructive examinations have been completed, are part of the quality program. A final inspection of truck and rail car loading is made to assure safe delivery of components to the job site.

Technologies

The development and use of state-of-the-art manufacturing technologies have continued to be important to B&W. The company maintains an entire group which is dedicated to manufacturing technology research and development.

Work has been conducted to improve all aspects of the welding operations, including planning, materials, processes, new applications and automation. In the area of weld planning, computer based models have been generated to assist in weld procedure optimization. When commercially available alloys are found to be lacking in a given operation, new materials which can provide the required mechanical and corrosion properties are developed.

Improved welding procedures are continuously being developed for the common processes as well as for the more exotic processes, such as explosion welding,

laser welding, electron beam welding, plasma MIG and variable polarity plasma arc welding. In the area of welding automation, B&W has advanced off-line programming and sensor technologies to improve the flexibility of automated systems.

Dramatic changes in manufacturing are occurring with the continuous development of advanced computer technologies. Newer machine tools will provide greater accuracy in motion control, repeatability and in process measurement. Bends can be made in se-

quence rather than in a batch mode, thereby reducing part inventories. Heat treating has improved with computer control of furnace temperatures and atmospheres. Inspection is being automated through the use of computer controlled coordinate measuring equipment, vision systems and real time radiography. Furthermore, manufacturing operations are being integrated with computers on a plant wide basis to facilitate material flow and to apply statistical process control tools.

Chapter 39

Construction

Construction plays a major role in the success of any project. The construction organization must employ erection techniques that complement the designers' skill and the fabricators' craftsmanship. Sound field assembly is essential for correct functional performance of the completed installation. Efficient and safe execution of any project requires that components be on the job site at the right time along with the necessary tools, equipment, labor and supervision. In addition to properly erecting the components, a successful construction organization possesses experience in estimating, planning, safety, quality control, cost analysis, labor relations, tool and equipment design, technical services, and finance and accounting. A competitive marketplace requires continuous improvements in quality, safety and cost, together with reduced construction schedules, as contractors and owners strive to minimize project costs and schedules. The most successful projects maintain communication between engineering and manufacturing operations, ensuring that field erection is a continuation of the shop fabrication process and not a completely independent event.

During initial project development, the construction plan and work performance logistics must be evaluated, then incorporated into the overall project design. Schedule requirements, together with safety and site-specific conditions, will affect the labor and erection methods that will be used.

A number of boiler types are small enough to permit shipment completely assembled. However, larger industrial boilers, central station boilers, and environmental systems are shipped to job sites in various stages of fabrication and subassembly. A central station boiler with its associated heat transfer equipment and auxiliaries may weigh more than 12,000 t (10,885 t_m), requiring the equivalent of 500 railroad cars to ship the material to the site over a period of several months. The modularized construction practices in use today result in some boiler components weighing 400 to 1000 t (363 to 907 t_m). Flue gas desulfurization (FGD or scrubber) and selective catalytic reduction (SCR) system modules for environmental retrofit work may weigh between 50 to 150 tons (45 to 136 t_m). In these cases, overland and barge shipments can become unique operations.

The field assembly of power generation facilities and the associated environmental equipment requires efficient, well engineered, well organized erection methods to permit installation within a reasonable time and at minimum cost without sacrificing quality and safety. Modularization of complex components together with continuous advances in computerized drafting, modeling, scheduling and tracking have become the norm for these complex or fast track projects. The cost of erecting a steam generating unit, such as that shown in Fig. 1 represents a significant part of the total investment in the plant.

Retrofitting an existing plant with environmental equipment presents a unique set of challenges requiring extensive planning and coordination between owners, engineers, manufacturers and constructors. (See Fig. 2.)

Fig. 1 Modern power plant construction includes appropriate environmental equipment.

Fig. 2 SCR retrofit construction.

Estimating and cost development

The estimating process begins with a complete understanding of the project work scope and specifications for performance. The estimator prepares a detailed list of work activities or tasks for the entire project utilizing specifications and drawings obtained from the owner and the component supplier's engineering function. Direct work hours for each labor category are then assigned to each activity based upon historical data and general experience. For example, insulation is estimated based upon the number of hours per unit area [ft^2 (m^2)] times the insulated area of the proposed equipment. The total hours for each craft and for the total project are then calculated. The totals are frequently corrected for a variety of factors, e.g., local labor productivity, overtime and site factors. To the direct labor total, indirect labor such as supervisors, foremen and housekeeping, etc., are added to produce a total project estimate.

Scope

Historical performance, accumulated through ongoing experience and applied through an estimating database, provides the basis for the initial estimate. The estimating process utilizes a variety of sources to develop a detailed understanding of a project's specific work scope. These sources include product specifications, equipment and layout drawings, site visits, customer interaction, engineering, and internal data developed from experience on similar projects.

Direct costs

The direct costs associated with field construction are developed and tied to a detailed task list by applying historical work hour rates associated with a specific quantity of material. These quantities may include tonnage, linear feet or square feet (meters).

Installation factors

Following the direct cost estimate, several specific factors are considered to finalize the direct work hour requirements for each activity. These factors include

local labor productivity, overtime and multiple shift work inefficiencies, repair difficulty factors, and site-specific conditions.

Indirect labor and support requirements

Once the direct work hour costs have been developed, indirect labor support requirements can be applied. These are driven by man days and individuals available for the project timeline. Examples include the general foreman, laborers, operating engineers, unloading crews, and any other individuals needed to support the installation labor activities.

Other factors

While detailed estimates are required for specific projects, total estimates for nominal scope jobs frequently fall into general ranges. For coal-fired utility boilers of nominal scope, erection work hours usually range from 1.25 to 2.0 work hours per kilowatt. In other cases such as retrofit SCRs or FGD systems, the estimates do not fit such ranges well because of the dramatically different equipment scopes and configurations possible for a given size unit.

The estimated time required to complete a project is related to the number of estimated work hours. There is a limit, however, for any given unit, to the number of workers that can be efficiently employed. If more than an optimum number are employed, the lack of adequate work space results in diminishing returns and excessive costs. Fig. 3 shows the typical number of weeks required for various work hour expenditures for a single boiler unit, and the maximum number of people utilized during peak operations.

Erection time span can also be affected by performing on a multiple shift or overtime basis. With these alternatives, significant additional costs can be incurred due to the inefficiency resulting from working longer hours, hours not worked, fatigue, or shift turnover inefficiencies.

Schedule and project plan development

The construction schedule is a key input to the integrated project schedules that focus on all of the disciplines needed to complete a given project.

Upon contract award, the construction project team

Fig. 3 Typical labor requirements for a single boiler unit.

conducts a detailed planning session. Typical participants include the project manager, scheduler/planner, project superintendent(s), and other contributors as selected by the project manager. The basis for this planning session is the scope of work as originally defined and estimated, and the existing conditions of the construction site. During the session, missed scope items or recent customer-initiated changes to the as-bid project are evaluated. The primary objective of this session is to document a detailed construction plan. The information inputs needed and the outputs from a successful planning session are shown in Table 1.

Projects are defined by a series of work activities arranged in a logical sequence. Detailed schedules are then developed by sequencing all activities according to their predecessor/successor relationships. These relationships are used to assign activity durations, and to allocate resources to complete the activity within the desired time period. Resource allocations typically include labor plus heavy and specialized equipment.

Work activities are arranged into a work breakdown structure and assigned activity codes. The activity codes allow the work to be sorted by contract, area of work, responsibility, component, or other required factors. These activities can then be used to monitor and track progress throughout the course of the project.

Schedules are established using computer-based scheduling systems. A broad range of detailed graphic schedules and reports, including time scale logic diagrams, bar charts, precedence diagrams, labor graphs, earned value curves and job completion percentages are derived from such systems. These outputs permit the overall coordination of several items: the work to be performed, labor by craft or specialty, erection equipment assignments, material deliveries, and critical resource requirements. The goal of the planning session is to initially define the project in enough detail to ensure that subsequent tracking and monitoring activities can effectively control all resources and job progress, identify positive and negative deviations, and prescribe necessary corrective actions.

The level of detail developed in the work breakdown structure is dependent on project complexity. Straight-forward, short duration projects may be broken down into less than fifty activities, whereas more complex, long-term projects may be defined by hundreds.

Construction project management

The successful completion of a large utility construction project requires a disciplined and proven approach for executing design, engineering, procurement, expediting, erection, inspection and commissioning. This approach is required whether the project involves new boiler erection, significant modifications to an existing unit, or the retrofit of environmental equipment. Detailed project execution plans are developed to ensure proactive control of scope, safety, quality, cost and schedule; report progress; identify deviations; forecast trends; take corrective actions when necessary; promote communications; and coordinate the activities of all participants. The project team is responsible to ensure that timely constructability reviews are per-

formed to integrate design and construction considerations, assuring a technically complete and constructable design.

An initial project kickoff period provides a detailed project definition before any engineering releases are authorized. This definition period permits all involved to clarify details and better define owner and engineering requirements. This phase is used to:

1. document owner design, operating and maintenance philosophy,
2. jointly review the specifications,
3. review subcontract vendor specifications,
4. allow the owner to review acceptable vendors,
5. establish procedures for project execution, and
6. firmly establish the project's schedule.

A project team is utilized to effectively manage and coordinate the multiple interfaces required for a large project. This team will establish all procedures and

controls required for the coordination and routing of documentation, design and engineering information, technical interfaces, and correspondence.

Once the construction phase of a project begins, the site organization serves as the primary conduit for communication. Regular project meetings keep all participants informed.

The key element of the project management approach is the scope-of-work document. Each working group involved in the project will develop a definition of objectives, scope of work for their activities, data collection needs, methodology or approach to the work, end products, responsibilities for all involved, time durations and schedules.

An integrated project schedule and report is developed to cover all activities by involved participants. Monthly progress reporting and performance measurements are completed using the earned value concept. Schedule trends/projections are evaluated with action plans formulated to regain or advance the schedule targets included in each progress report. Outstanding or new actions are included. Potential threats to the project's goals are identified with alternative suggestions to reduce or eliminate any negative impact.

Design for constructability

The Construction Industry Institute (CII) defines constructability as a process of optimum integration of construction knowledge and experience into project planning, design, procurement, and field operations to achieve overall project objectives.¹ CII recognizes that maximum benefits are achieved when people with construction knowledge and experience are involved with the project from its inception, and continue throughout its duration. The significance of this philosophy is best illustrated by Fig. 4. The ability to influence overall project costs is greatest at the beginning of the project and diminishes asymptotically with the progression of time.

In the past, the term *constructability* was generally associated with the quality of the various engineering groups' approaches to erecting components. Specifically, it referred to issues or potential assumptions made in association with the designer's intent that could preclude a component from being satisfactorily built or inspected (including errors and omissions). Information that lacked clarity was typically resolved through various means including drawing revisions, requests for information, engineering memoranda, and nonconformance reports. Resolution almost always increased cost as a result of rework and/or field delays while awaiting the design engineers' disposition. Many long-term projects now implement constructability reviews of these design outputs prior to the start of construction.

The endorsement of CII's philosophy and recognition of its inherent benefits provides the foundation for a successful project. The common goal is to ensure the timely delivery of quality steam generation and environmental control equipment that is erected safely, efficiently, and cost effectively, subject to specific project constraints. This is accomplished when the

project managers, superintendents, and construction engineers work hand-in-hand with the engineering groups early in a project's development cycle.

Since construction costs for some projects can exceed 50% of a total project, the cost of labor presents both the greatest opportunity and greatest risk for almost any project. A design for constructability seeks to minimize impacts and improve productivity through the elimination of rework and/or corrective action, improve material deliveries, and incorporate some type of modularization.

Implementation

Typical barriers to constructability implementation, as identified by CII, include lack of disciplined coordination, failure to dedicate an individual administrator, and improper funding for the overall program. For a constructability program to be effective, these barriers must be recognized and overcome.

Evaluation

To help evaluate constructability efforts, feedback is needed throughout the project. During construction, it is important to obtain an objective assessment of the design documents from contractors and subcontractors.

Coordination and distribution of design drawings will be monitored and reviewed prior to issuance for construction. Innovative approaches, erection sequences, and cost saving measures will be reviewed to assure that the final product exhibits construction-friendly components. Constructability will also contribute to minimizing interference with existing plant facilities, thereby minimizing the effects on the operating facility.

The benefits are most evident during the construction phase of a project once engineering and procurement are essentially complete. If flexibility in the project schedule has already been consumed by engineering and procurement, the cost impact on the project becomes significant. The cost of a day's delay early in a project is minimal, whereas, once construction has started, costs could exceed 100,000 U.S. dollars for each day of delay. Savings and benefits lie in the reliability and predictability provided to the construction plan through the efficient use of labor and equipment. Every job will have its share of delays due to late deliveries, equipment failure, and acts of nature. Therefore, the goal of constructability is to select those attributes of the project that can be controlled and then exercise maximum influence over those offering the largest payback. The proper utilization of constructability minimizes project risks such as labor availability and maximizes opportunities through productivity improvements.

Integrated design process for retrofits

The integrated design process requires close coordination of design, manufacture, shipping and construction processes. Retrofit projects for complex utility systems are unique and therefore require a significant amount of design integration. Several key steps are critical when these retrofit projects are considered:

1. Determine the detailed scope early in the process.
2. Define the general arrangement of all components in concert with existing structures and equipment.
3. Define the construction approach.
4. Perform joint project management, engineering and construction reviews of the design.
5. Iterate the second, third, and fourth steps to advance and evolve the design.

The design/construction team must share a common and detailed understanding of the defined scope as early as possible. This scope description and the resulting assignment of responsibilities establish the direction of the project team.

Project definition for all members of the design and construction team is not complete until participants have a clear spatial understanding of new equipment location within the existing facilities. Interferences are relatively inexpensive to resolve at the design stage, but can be devastating to the project budget and schedule if recognized during the construction process.

Large retrofit projects typically span 15 to 30 months from award to startup. This span is dependent upon the number of units to be retrofit, the complexity of the installation, and the unit's planned outage schedule. These projects are impacted by numerous site-specific constraints that may lengthen the overall project.

When the total project and schedule integration process is not followed, project management and engineering will typically initiate the design process and begin the fabrication of materials well before the involvement of the construction manager and/or superintendent. This approach generally results in project delays and increased costs after mobilization of the construction team. Joint planning and an ongoing review of the design by team members from project management, engineering and construction have frequently been shown to result in a high quality, safe, economical, and on-schedule project.

Integrating the different perspectives, knowledge and concerns of these three key project disciplines yields significant benefits. The first joint review only begins the process. Ongoing reviews generate the greatest long-term benefits. Significant design and construction decisions must be made in ways that balance the scope, schedule, and cost triangle to benefit the overall project.

Some of the key decisions that need to be addressed by the team are:

1. the best physical arrangement of the equipment,
2. supports for the new equipment,
3. utilization of existing or new steel,
4. defined and scheduled pre-outage, outage, and post-outage activities,
5. planned outage schedule,
6. definition of the erection sequence,
7. existing access limitations and additional requirements,
8. shop or field modularization, and
9. field labor availability.

A critical period occurs early in a project when scope, general arrangement, construction approach and

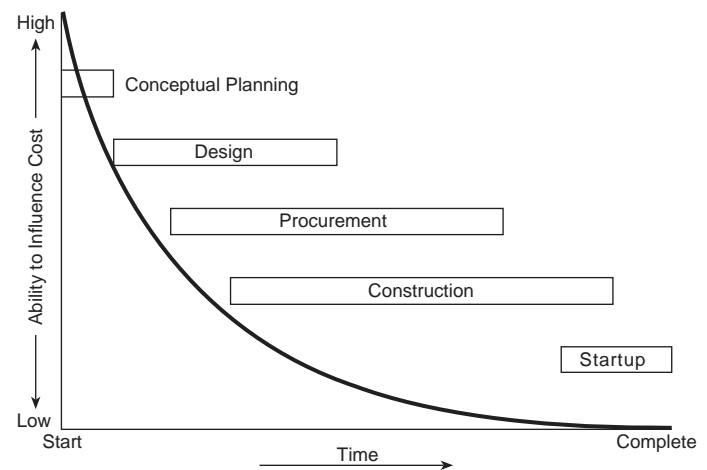

Fig. 4 The ability to influence cost diminishes as a construction project progresses.

schedule decisions are being defined and key subcontractors are being integrated into the project. Additional resources are needed to focus on technical, commercial and interface issues associated with subcontractors, architect-engineers, structural steel fabricators, and flue and duct fabricators. This support early in the project provides the necessary attention to effectively address schedule-critical activities during a time frame when resources are typically overloaded. Once these specialized functions are executed, these resources are dismissed and project team members then consult as required.

Construction technology

The construction of steam and power generation facilities, and all associated equipment, is a complex and challenging undertaking. Each project presents a unique set of objectives, subject to specific constraints and opportunities. Successful projects are the result of detailed planning and forethought, as well as the creative application of construction means and methods to deal with the constraints, and to take advantage of the opportunities. Critical decisions regarding product configuration, constructability, construction equipment selection and labor issues must be made early and followed throughout the project.

Traditionally, the construction site supervisor has acquired the necessary skills through experience, and therefore is well-qualified. Technological advances including computer-aided design, global positioning systems, and more powerful lift cranes have enabled construction engineers and technicians to support supervision by refining the planning process and expediting the work in the field.

Aggressive schedules, improved financial performance, increased scrutiny, and regulations regarding safety and quality require that projects are executed with increasingly refined margins for error, both technically and economically. The goals established for these projects include: 1) reduced field operations costs, 2) a minimal project time span, 3) the construction of a quality product, and 4) provision for a safe working

environment. The integration of technology into the construction process increases the opportunity to accomplish these goals through the proper, effective and innovative application of means, methods, techniques, tooling and equipment.

A construction technology group normally supports the field construction program. These engineers provide construction engineering services, construction logistics, and constructability reviews for each specific product and configuration. Typical outputs include recommended shipping sizes and configurations, rigging weight and center of gravity calculations, crane placement drawings, heavy lift and hauling plans, and structural analyses of existing facilities for imposed construction loads.

Approaches to construction – erection methodology

There are three basic approaches that may be used in a construction project: 1) *knocked down*, the traditional method, 2) *field modularization*, and 3) *shop modularization*. The knocked down approach is based on the erection of shop fabricated, standard-sized shipping units that readily fit on a truck/trailer or rail car. The standard shipping units are erected one piece at a time in *stick* fashion. Field modularization combines these traditional ship units into larger components, or modules, at the construction site for final installation. Off-site assembly, shop modularization, or prefabrication combine the traditional ship units into subassemblies at the manufacturer's plant.

Modularization is an integrated approach to power plant construction whose concepts must be incorporated at the earliest possible stages of a project's planning. The most successful projects have continued commitment to this approach by the customer, the equipment supplier, and the erecting contractor.

While modularization may be cost effective, the extent of effective modularization is site specific. Modularization divides plant materials into subsets, or modules, that are assembled before being brought to the construction site. (See Fig. 5.) The degree and extent of modularization can vary considerably. In its simplest form, a structural steel beam with shop-attached clip angles is a module. At the opposite end of the scale, a shop-assembled boiler complete with all trim piping, instrumentation, and insulation and lagging, or a 50-ton section of ductwork insulated and lagged is also considered a module.

Boiler components have been modularized for some time. Fig. 6 depicts furnace wall panels in which loose boiler tubing and membrane stock are welded to form the panels. Large modularized scrubber components are shown in Fig. 7.

A modularized project requires more engineering and design time than a conventional project. Planning must consider the water and land routes used for shipping the modules. Construction sites located on navigable waterways have the greatest potential for shipment of large modularized components. (See Fig. 8.)

Module unloading, site movements and erection procedures must be carefully considered. Special consideration must also be given to foundations, backfill-

ing and compacting at the site. Other concurrent site activities must be evaluated when planning for modularization.

Construction participation by all involved parties is required in planning any project to enhance constructability and identify intended erection methods. The erection method is influenced by the following factors.

Retrofit versus new plant installation The construction logistics associated with retrofitting, repairing or altering an existing unit are much different from those required for constructing a new unit. Logistics for new plant construction are further diversified, depending on whether the unit is to be built on an existing plant site, adjacent to existing units, or on a new site. Retrofit operations are generally performed in a pre-outage/outage/post-outage mode.

In planning retrofit work, an erection method that permits performing many tasks concurrently is chosen. This optimizes equipment and labor and minimizes outage times. When constructing on an existing plant site, the erection method must maintain a productive interface between construction activities and ongoing plant operations. Construction on a new site offers a contractor the greatest amount of freedom in selecting the most cost-effective, efficient method for executing the work; however, potential obstructions include those areas of work occupied by other contractors.

Plant arrangement The overall plant arrangement plays a key role in establishing the sequence for erecting components and equipment. Plant arrangement defines the available access routes for material flow from the laydown and storage areas to the final installation points.

Scope The scope of work directly affects the construction plan and completion of the construction. Tools and equipment needed for one phase of the project may also be influenced by the requirements of other phases.

Parameters Product and component parameters, including size, weight and shipping configurations, dictate the type and size of material handling equip-

Fig. 5 Large scrubber modular components on a barge.

Fig. 6 Raising furnace wall section into position.

ment and the need for special handling procedures, methods, jigs and fixtures. Material type, thickness, and required erection tolerances are considered in establishing methods for component alignment, welding, post weld heat treatment, stress relieving, and nondestructive examination.

Site conditions Existing site conditions and accessibility play major roles in determining the size, weight and configuration of the components to be shipped. Water accessibility represents the greatest opportunity for shipping large shop-assembled modules; otherwise, rail or truck shipments are required. If multiple transportation modes are used, the size of the component is limited by the most restrictive shipping method.

Shipping accessibility only partially controls the extent of material and equipment shipments to the job site. Upon arrival, the material must be off-loaded and transported to its storage area or final installation point. Material off-loading schemes depend upon the mode of shipment and the site conditions at the off-loading area. Transportation of the material is then limited by the width, overhead clearances and load limitations of existing roadways.

Contractor interface Interface with other contractors is an important part of a construction project. Once portions of the project have been completed by individual contractors, effective interfacing between con-

tractors is required to achieve certain location tolerances and to complete the erection.

Schedule The project schedule, including customer-specified start, finish and milestone dates, dictates the required erection sequence, labor needs and timing for project completion. The quality and skills of the local labor force play major roles in the erection plan and overall sequencing of the work.

Because cost is an important criterion governing selection of the erection method, the economic advantages and disadvantages of the other selection criteria must also be evaluated. Costs of construction operations versus component shipping configurations are often arranged in a matrix. The shipping configuration reflecting the lowest total cost is considered to be the most effective approach and becomes the preferred choice for erection. Tabulated construction costs are coupled with corresponding costs for component engineering, shop fabrication and assembly, and shipment to the job site to identify the most effective overall approach for a specific project.

Extent and location of field welds Overall product quality and constructability are enhanced by minimizing the number of field welds. The required welds must be readily accessible to allow the use of state-of-the-art equipment and processes.

Fig. 7 Modular components for an environmental control installation.

Fig. 8 A barge carrying SCR components is positioned for off-loading.

The scope of work to be performed and the component configuration influence the extent and location of field welds. The construction engineer must provide input regarding preferred field weld locations, suggested component configurations for these weld locations, and intended welding processes.

Construction engineering and rigging design

Background

Babcock & Wilcox Construction Co., Inc. (BWCC) takes an engineered approach to the execution of heavy lifts. Specialized tools, equipment, rigs, jigs and fixtures are provided for each project.

Modern construction includes modularized components that are erected on short timetables. To reduce construction and shipping costs, the weight of support steel components has been reduced. As a result, the calculation of imposed erection loads is critical.

In recent years, customer specifications have required the submittal of engineered rigging drawings and procedures prior to construction. These submittals often require the stamp of a licensed professional engineer.

Engineering principles

The construction engineer involved with product erection must be familiar with the product's construction details and function as well as responsible for the engineering, design and specification of all systems, tools, equipment, devices and mechanisms required for erection. This requires a command of engineering fundamentals and knowledge of principles taken from civil, structural, mechanical and electrical engineering disciplines.

Engineered systems

Engineered systems required to support construction operations may generally be identified by:

1. material handling (discussed below),
2. rigs, jigs and fixtures,
3. temporary supports, shoring and reinforcement of existing structural components,
4. access and protection structures,

5. temporary structures and construction facilities,
6. civil/site work, and
7. specialized tooling, machining and equipment.

Material handling and setting considerations

Like any phase of a construction project, material handling operations must be planned and integrated into the total construction plan. The size, weight and shipping schedules of material and components to be received and installed must be known in order to plan for storage area needs and to schedule crews and equipment. Special handling provisions and special inspection and storage requirements must be known and accommodated. In addition, the plant structure must be designed to support the loads involved during construction and the clearances required to get equipment in place.

Material handling plans must reflect actual site conditions including rail and truck access, locations and condition of haul roads, and availability and location of laydown areas and warehouses. Although most material shipped to a construction site can be handled with conventional construction equipment, material handling plans must identify any special equipment or fixtures required to handle large or unusual components.

Equipment used for material handling operations may generally be grouped by function into two categories: 1) transporting, and 2) lifting.

Equipment for transporting material is limited to that intended for on-site application, and does not include trucks, railroad cars or barges listed for material delivery to the job site.

A wide range of equipment is available for material transport and lifting on the job site. Selection and use depend on the configuration and weight of the material to be handled and the relative distance between transport points and available site clearances. Selected techniques and types of equipment that can be utilized for material transport and lifting are shown in Figs. 9 through 11.

While this listing is intended to provide an idea of the range of tools, methods and equipment available for material handling, it is not all inclusive. Various suppliers and manufacturers maintain and supply their own version of the generic equipment identified. The selection, specification and use of this equipment require a thorough construction engineering effort from the planning phase of the project through the execution of the work.

Fig. 9 Hydraulic platform trailer.

Depending on the equipment selected or available, various operations are involved to get the components to their final in-place position. These operations, represented in Fig. 12, may be accomplished by use of a single hydraulic crane or may require a sophisticated handling system custom designed for the application. (See Fig. 13.)

Serviceability

The serviceability of a material handling system is a measure of how well the system performs its intended function subject to conditions produced in its work environment.

Imposed loads and forces

The weight of the component being handled is a major consideration in the design and selection of the material handling system; however, component weight is not the only load imposed. All systems operate dynamically while simultaneously generating and being acted upon by forces that include steady-state and time-varying components. Forces are introduced by the operating environment, by the work being done, by the inertia of the masses put into motion, and by the weights of the load and the system components.²

Imposed loads are generally categorized as gravity or nongravity. Furthermore, both loadings may be static or dynamic. While dynamic loading must be recognized in designing the material handling system, the magnitude of acceleration/deceleration loads is small in most cases. As a result, static loading generally governs the system design.

Static gravity loading conditions are categorized as lifted load, dead load, live load, friction or impact.

The *lifted load* is the calculated rigging weight of the component being handled. This calculation must account for manufacturing variability and normally includes a safety factor. Shapiro suggests multiplying the calculated weight by 1.03 for mass produced items and by 1.07 for singular devices.²

Dead load is defined as the weight of the material handling system components themselves, independent of the component being lifted. In calculating this weight, the same considerations must be made with regard to potential dimensional variations in components. The suggested weight parameters act as multipliers as they relate to imposed loading or induced stress and as divisors as they provide stability or uplift resistance. The *imposed dead load* is the cumulative weight of all other components supported from the component being designed.

The *live load* is an allowance that accounts for the weight of construction personnel, scaffolding, ash (slag or dust accumulations), and snow or ice accumulations on the handled component. Because these loads are frequently unknown when the material handling system is designed, they are applied on the basis of a specified unit weight per surface area or a specified density per volume.

Friction loads are those associated with a body's resistance to movement. Friction takes on various forms depending on the system arrangement and load handling application.

Fig. 10 Hydraulic gantry system.

The coefficients of static, rolling and sliding friction define friction loads. Depending on the arrangement of load handling components, friction may become a significant part of the total design load.

Impact loads are associated with sudden shocks that occur during a load handling operation. An impact allowance (25% of the handled load) is typically applied in the direction of load movement. Minimal impact loading is achieved by moving components at constant, slow speeds.

Nongravity loading conditions include wind loading, seismic loading and stabilization. Most applicable codes and specifications have reduced these dynamic conditions to static load equivalents. For the purpose of material handling system design, these conditions are therefore treated as such.

Wind loading, when imposed on material handling system components, is evaluated and applied in accordance with Uniform Building Code (UBC) or American National Standards Institute (ANSI) guidelines.

Seismic loading is not a major design consideration for most material handling systems. Nevertheless, seismic forces may be evaluated with UBC or ANSI specifications.

Stabilization forces are those forces required to maintain lateral stability of compression and flexural structural members. This force is arbitrarily consid-

Fig. 11 Manitowoc crane.

Fig. 12 Configurations of typical lift cranes.

ered to be 2% of the total force developed in the compression zone of the member being stabilized. In the case of compression members, the compression zone is the total cross section; for flexural members, this zone is limited to the compression flange.

Load stability

Load stability is the inherent tendency of a load in equilibrium, either static or dynamic, to remain in equilibrium and to minimize any translational or rotational effects produced via the imposition of unforeseen forces and/or moments throughout the course of load handling operations. A rigging system (see Fig. 14) must be configured to ensure that load stability is

Fig. 13 Site-specific handling system for an environmental control installation.

maintained throughout the course of load handling operations. The specific conditions of equilibrium are stable, unstable, and neutral.

Load control

Load control is an assurance that the load will assume a predetermined, expected orientation without deviation throughout the course of handling operations or at any point in those operations.

Load distribution

Throughout the load handling operation, the component being handled seeks a position of static equilibrium. A lifted load always vertically aligns its center of gravity with the centerline of the lifting hook. Prudent arrangement and design of the material handling system is based on knowledge of the component's center of gravity as well as the magnitude of the resultant loads and forces acting on the system.

Depending on the handling operations involved, the relative position of a component's center of gravity with respect to its supports can vary with time. This variation produces a time-dependent variation in the magnitude of the support reactions, and thereby, the load imposed on the material handling system. Consider the steam drum illustrated in Fig. 15. Two separate sets of load blocks and rigging are used for raising the drum to its final position in the boiler support steel. Throughout the course of the raising operation, it may be necessary to incline the drum to clear local interferences with boiler support steel. As the drum is inclined at some angle θ from the horizontal, the load imposed on each set of blocks varies in accordance with the following expressions:

$$W_{L1} = \frac{1}{2} \left(1 + \frac{Y}{L} \tan \theta \right) W_L \quad (1)$$

Fig. 14 Typical rigging configurations.

Fig. 15 Steam drum lift and support arrangement.

$$W_{L2} = \frac{1}{2} \left(1 - \frac{Y}{L} \tan \theta \right) W_L \quad (2)$$

where

W_{L1} = portion of W_L supported by high end blocks

W_{L2} = portion of W_L supported by low end blocks

W_L = weight of component being raised

Y = $2 \times$ (transverse distance between longitudinal centerline of drum and centerline of lifting lugs)

L = center-to-center spacing between lifting lugs

Per these expressions, when the drum is horizontal, i.e., $\theta = 0$ deg:

$$W_{L1} = W_{L2} = \frac{W_L}{2} \quad (3)$$

That is, the rigging weight of the drum is shared equally by each set of load blocks. However, as the angle θ is increased, the load transferred to the blocks on the upper end of the drum is increased. Therefore, each set of load blocks, rigging and drum lifting lugs are conservatively sized to accommodate the total rigging weight of the drum (Fig. 16).

Design loading

The material handling system design loading is established by identifying the maximum of several critical load combinations and then multiplying this value by a safety factor of 1.10. Typical combinations include:

lifted load + dead load + live load + impact,
lifted load + dead load + live load + friction, and
lifted load + dead load + live load + impact +
greatest of wind, seismic or stabilization load.

Friction and impact loading are mutually exclusive events, and therefore are never considered to be a viable combination.

Other site considerations – storage

Storage is also a critical issue. Storage areas must be laid out and material placed in storage to provide

ready access to support the construction effort. Generally, a numbered grid system is used in laydown yards and warehouses to identify specific storage locations. Fig. 17 shows a typical storage layout.

To support the planned construction activities, material must not only be on site and available, but must be in good condition. In addition to inspection of the material upon receipt, the material and the storage areas are inspected periodically to satisfy specific storage requirements and to ensure proper protection of the material.

With the amount of material involved in most construction projects, it is essential that an effective documentation system be used. A complete listing of items to be received is needed to ensure that a complete inventory is maintained. For each item, material receiving and storage records must effectively document receipt and disbursement status, condition of the material, and current storage location.

Construction of a fossil fuel unit

The installation of a top-supported steam generating unit is unique in that the heaviest components are at or near the top and most other major components are hung from steel rods. Field assembly of the boiler begins by positioning the major upper components in a manner that provides a design deflection after completing the boiler installation. While the following discussion is primarily concerned with top-supported units, many of the basic procedures apply to all units.

Structural supports

The design of the supporting structural steel must consider the loading and stresses encountered during the installation of the boiler. The major construction-

Fig. 16 Typical utility boiler steam drum lift.

Fig. 17 Site laydown area.

imposed loads must be evaluated. Because certain structural members may be temporarily omitted to permit access for large subassemblies, the associated additional structural loads must also be considered.

Before erection is started, all foundations must be completed and checked for specification compliance. Because most large units are top-supported, as discussed in Chapter 26, erection of the structural supporting steel is the first step in building the unit. This is done by conventional methods, using cranes and derricks. Stairways and walkways are completed to the fullest possible extent to provide safe access to all parts of the unit.

Because many of the structural members govern the location of boiler and auxiliary components, supporting steel must be aligned with established building centerlines. After the structure has been aligned and plumbed, the members are rigidly connected with high tensile bolts or by welding before supporting any structural loads.

Assembly of pressure components

The construction schedule and plan include a timely sequence for installation of boiler components. The steam drum is usually the first major assembly placed in the structure. All large or heavy components, superheater modules, top headers, interconnecting pipes and wall tube panels are positioned, following the plan, in the boiler cavity while unrestricted space is available to access and hoist them.

Drums Drums for the largest boilers may weigh more than 400 t (363 t_m); they may be 100 ft (30.5 m) in length and may be located more than 200 ft (61 m) above the ground. To clear supporting steel, the drum may be inclined by as much as 60 deg (1.05 rad) during the lifting operation. Capacity and safety of the drum rigging are of primary importance in selecting the equipment and methods.

Fig. 16 shows a typical drum lifting arrangement using lugs that are shop-welded to the drum. Attachment pieces for the top of tackle blocks are located on temporary steel members above the boiler structure. These blocks should permit simple linkage connections at the top support and drum attachments. The capacity of the hoisting engine and the sizes of tackle blocks and wire rope are determined with ample safety factors.

When the drum is in its final position, it is supported from the top structural steel by U-bolts that permit linear movement with temperature variations. Fig. 18 shows a typical drum and support arrangement. The drum is a major anchor point for other boiler components and, for this reason, accurate location is important. The structural members, platforms and stairways that were omitted for drum erection are then installed.

Downcomers, headers and large pipes Plant access consideration is important and the sequential plan should be carefully followed in the erection of downcomers, loose headers and large pipes. These components are shipped in the longest lengths possible to avoid costly field welds. Large downcomers are often placed in the boiler cavity while steel is being erected and are moved to their final location when convenient. Without proper integration into the planning sequence, these components must be shipped in shorter lengths or additional structural steel must be omitted to provide clearances during erection.

Tube walls To reduce cost and the time required for field erection, a large percentage of furnace enclosure tubes are shop-assembled into membrane panels. B&W's preference is to furnish wide, long panels. However, as with any modularization approach, shipping and field conditions determine the panel sizes that can be provided. The wall panels are erected as-received from the supplier or, if conditions permit, the construction plan may include on-site assembly into larger wall sections. Panels may even be ground-assembled into complete walls with headers, casing, buckstays and doors attached.

Superheater, reheater and economizer These components can be furnished with loose headers and individual elements or in shop-assembled modules with or without headers. Again, the design features of the particular unit and project determine the degree of field or shop modularization. When large, heavy surface modules are to be erected, the construction plan normally includes early installation while access and hoisting clearance are available.

Tube connections Tubes are attached to drums or headers by welding, expanding, or a combination of the two (see Fig. 19). Generally, tubes that withstand pressures greater than 1500 psi (10,342 kPa) are expanded and seal-welded or welded to shop-attached stubs. Shop-assembled tube-to-header connections, such

Fig. 18 Radiant boiler steam drum in position.

as those in wall panels and superheater modules, are usually welded directly into the headers. (See Fig. 20.)

Design standards permit expanded tubes for low-pressure boilers. Tube expanding, or rolling, is a process of cold-working the end of a tube into contact with the metal of the drum or header tube hole or seat. The end of the tube is inserted into the hole and then plastically expanded by internal pressure; relieving of the pressure leaves the tube tightly seated in the drum or header.

A typical roller expander is shown in Fig. 21. This tool contains rolls set at a slight angle to the body of the expander, causing the tapered mandrel to feed inward when it is turned. For conditions of widely fluctuating temperatures and bending loads, the expanded joint must be seal-welded or replaced by a shop-attached tube stub.

Field welding

The welds that are made in the erection of a steam generating unit can be divided into two classes – those for assembly of plate and structural materials to support the unit and those for assembly of tubes, pipes and other pressure parts making up the steam generating unit. Welding on plate and structural materials is performed in accordance with the Structural Welding Code AWS D 1.1.

Welding that involves boiler pressure parts must conform to the requirements of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, The fabrication Codes reference ASME IX for Welding and Brazing Qualification require-

Fig. 19 Expanding tube connections.

ments. ASME IX provides the requirements for qualification of procedures and welding personnel.

Various conditions make field welding different in many respects from welding in the shop (discussed in Chapter 38). A typical field welding environment includes dust, wind, variable temperature, rain, high scaffolding, locations remote from supply and maintenance facilities, and a mobile labor force. Under these conditions, it is important to consider the selection of the welding processes and equipment. Key factors include simplicity, reliability, portability, ease of maintenance, and availability of spare parts. Equally important are the skills and availability of the workforce.

Manual and semiautomatic welding methods are therefore preferred for field erection of standard boiler components. While there is a continuing search for and evaluation of reliable automated welding equipment for field erection and repair, it is seldom used. For example, use of orbital gas tungsten arc welding (GTAW) or gas metal arc welding (GMAW) have seen limited applications due to the precise weld joint fitup requirements, development and tight control of welding parameters and technique, limited space restriction for the equipment, lack of highly trained operators and the associated cost and maintenance of the welding systems.

Fig. 20 Headers with shop-assembled stubs.

Fig. 21 Position of expander and mandrel after tube is expanded and flared.

Processes and equipment

Manual GTAW, shielded metal arc welding (SMAW), and flux core arc welding (FCAW) are the most common processes used in the field. (See Chapter 38, Table 1.) These processes are versatile and can be used on all field-weld materials utilizing equipment that is simple and easily maintained. In addition, most field welders are qualified for the GTAW and SMAW processes.

For welding non-pressure parts or making non-pressure attachments to pressure parts, there is increasing use of semiautomatic welding. Welders trained and qualified in GMAW or FCAW processes can make quality welds at significantly higher deposition rates compared to the GTAW or SMAW process.

As with the GTAW process, adequate precautions must be taken to protect the weld area from the elements, especially excessive wind. When a flux core welding electrode that is self-shielded, i.e., does not require external gas for protection of the molten weld puddle, is used for erecting boiler casing and other structural components, excessive wind must still be avoided.

Applications

Pressure welds Welds joining dissimilar metals are typically made in the shop because they are often difficult to make under field conditions and require special qualification. Field butt welds in tubes and pipes are made using pre-machined weld joints that have been covered with a protective cap. Thorough inspection and cleaning are still required before fitup and welding to avoid weld defects.

Butt welds may be made with an open groove joint or with a backing ring that is left in place. When an open groove joint is used, the root pass is typically made with the GTAW process because of the inherent better control of the inside weld surface contour. The groove is completed using the SMAW process.

When the weld joint contains a backing ring, the entire weld is usually made with the SMAW process. This method is normally used for the original erection of riser and downcomer piping. Rings are never used for furnace walls. However, they may be used for other pressure boundary tube welds depending upon engineering or customer requirements, and, if permitted, is the preferred method of fabrication.

Seal welds Seal welds are used to make mechanical joints fluid-tight. Joint strength is developed by pipe threads, tubes rolled into drum holes containing grooves, or header master handholes fitted with specially-designed plugs (see Fig. 22). The maximum size of seal welds made without post weld heat treatment is 0.375 in. (9.5 mm).

Special precautions are required to obtain sound seal welds; welding over pipe threads is not permitted. After seal welding, tubes should be lightly re-rolled. Handhole plug seal welds should be thoroughly cleaned and are preheated to avoid cracking.

Qualification of welding procedures and personnel

Welding qualification requirements are contained in the ASME Code, Section IX. The ASME fabrication Codes and the National Board Inspection Code (NBIC), published by the National Board of Boiler and Pressure Vessel Inspectors, references this Code for qualification of repairs and alterations to in-service boilers.

A welding procedure qualification test verifies that required mechanical properties are obtained when designated materials are welded by following a specific technique. BWCC has established many procedural qualification records based upon the ASME Code. These procedure qualifications support hundreds of welding procedure specifications.

A welder qualification test is required to verify that an individual has the skill to deposit sound weld metal in a given position while following an established welding procedure. Welders are qualified in accordance with ASME IX standards either at the job site or at simultaneous testing sites by participating organizations.

Thermal treatment

Preheat Preheating the weld metal is the most effective way of preventing cracks in low alloy steel welds because it reduces the cooling rate of the weld and base metal. The required minimum preheat temperature is specified in the field weld schedule and on BWCC's welding procedure specifications (WPS). Preheating methods include the use of electric-resistance blankets and oxy-gas or oxy-fuel torches. Special temperature-indicating crayons are used to assure that the proper preheat temperature has been attained. (See also Chapter 38.)

Post weld heat treatment Requirements for post weld stress relief are also specified in the field weld schedule. Electric resistance heaters are commonly used for field post weld heat. These heaters offer the advantages of ease of application and precise temperature control.

Codes, inspections and examinations

The ASME Code requires a valid ASME Certification of Authorization to install power boilers. To obtain an ASME Certificate of Authorization, an organization is required to maintain a Quality Control System that addresses the Code requirements. A review is performed by ASME to evaluate the Quality Control System and verify implementation. Once issued, the Certificate of Authorization is renewed tri-annually by review. A boiler installed in accordance

with the ASME Code must be inspected by an authorized inspector at various stages of assembly to assure that all Code requirements are met.

Section I of the ASME Code contains requirements for the installation of power boilers. ASME B31.1 contains requirements for the installation of boiler and non-boiler external piping. The state or jurisdictional authority maintains rules and regulations that govern the installation of boilers and establishes the applicable governing Codes. Section I of the ASME Code has been adopted by law in most states or jurisdictions.

Whereas ASME governs new construction, the NBIC governs repairs and alterations to boilers and other pressure-retaining items. The NBIC requires the repairs and/or alterations to comply, to the extent possible, with the original Code of construction. As with the ASME Code, the NBIC is mandatory only when adopted by a state or other jurisdictional authority.

Section I of the ASME Code specifies the nondestructive examination (NDE) requirements for new construction of power boilers. ASME B31.1 specifies the NDE requirements for boiler and non-boiler external piping. NDE requirements for repairs and alterations are specified in the NBIC. The type and extent of NDE must be considered during the proposal, planning and scheduling processes. For all construction, the applicable regulations and any additional NDE requirements exceeding the Code should clearly be specified in contract documents. The nondestructive technologies are discussed in more depth in Chapters 38 and 45.

Construction of environmental equipment

Regulatory requirements associated with the Clean Air Act Amendments of 1990 caused many fossil fuel-fired electric generating plants in the United States (U.S.) to install, or plan for the installation of, emission reduction equipment. Many stations installed sulfur dioxide (SO_2) scrubbers in the early 1990s which were then followed in the early 2000s by the installation of selective catalytic reduction (SCR) systems for nitrogen oxides (NO_x) removal.

While erection of environmental equipment is significantly different from boiler erection, many of the same principles and attributes of boiler erection apply. A modularized approach generally pays signifi-

cant dividends over stick-built construction at the job site. The project benefits in both labor savings and in the potential for a reduced site completion schedule when high-cost field labor is replaced with lower-cost shop labor.

The construction principles utilized for environmental equipment are the same. However, the method of construction differs significantly. SCR projects predominantly consist of structural steel and fabricated plate, while FGD system projects consist of fabricated plate, structural steel, process equipment and piping. There is little in the way of operating equipment with the exception of dampers, sonic horns or sootblowers, ammonia vaporization equipment, and some piping and instrumentation. In these installations, the chemical process required to support the operation utilizes additional equipment to handle the lime or limestone reagents and gypsum removal and drying.

Most SCR projects are designed with the reactor and flues bottom-supported off structural steel. The primary component of FGD systems is the absorber tower which is independently bottom-supported on a separate foundation. For SCR systems, close coordination is required between steel erection activities and the installation of the interconnecting flues and reactor. Complicating matters on a retrofit project is the space available for the SCR. The process temperature for most SCR systems requires the boiler flue gas to be taken from an area immediately downstream of the economizer, and before the air heater inlet. On large boilers, this tie-in point can be more than one hundred feet (tens of meters) above ground level. Also, since a reactor can contain nearly a million pounds (450,000 kg) of catalyst at a significant elevation above grade, concerns for overturn and uplift forces may require a complex foundation design.

At many sites constructed decades ago, little consideration was given to future expansion and therefore, current space limitations are a serious concern. Many projects are faced with a significant rerouting of the boiler exit gas to a point where space is available for either an SCR or FGD system. The flue gas must then be routed back to continue its path through the air heater for SCR applications or to the stack for FGD systems. Each project poses a unique set of circumstances.

Sequencing and modularization

Early in the project, specific information about the weight of ductwork sections and equipment must be estimated. Many times the module boundaries are easily identified, due to equipment terminal points or expansion joint locations. Other times, sound judgments must be made, based on experience. The erector is the prime contributor to determining splice locations that are best from a variety of standpoints, including access, crane capacity and geometry.

The resulting erection sequence can then be used in establishing schedule priorities for detail design, material procurement and fabrication. To allow maximum flexibility for installation, schedule priorities should be developed in accordance with erection plans. Receiving materials far in advance of the time required at the job, or in a sequence that does not sup-

Fig. 22 Welded handhole fitting for higher pressure boilers.

port planned erection, results in increased handling costs. Without the proper materials, the constructor is forced to work on activities that deviate from the intended plan, increasing overall project cost.

The erector should complete a constructability review prior to the issuance of key design outputs. This review often uncovers missing or incorrect information. Early identification of potential problems can alleviate costly field rework or production delays due to additional engineering evaluations and the resulting drawing revisions.

Once modules are identified and an erection sequence is established, the project team interacts with plate fabricators for delivery options. A modular construction approach provides the project team with the opportunity to review and approve the manufacturer's plan for component fabrication. This process may result in on-site productivity improvements as the constructor advises on alternative shipping configurations and rigging requirements, and gains valuable information about the material to be received, thus helping to identify the extent of preparatory work that will be required on site prior to erection.

Fig. 23 is a typical arrangement for an SCR retrofit project. Identified in the figure are module boundaries utilized for design, procurement, planning and erection activities. The individual modules are installed in a defined sequence to maximize efficiency and minimize erection time. This sequence, which usually starts from the lowest to the highest point, builds from the reactor back to the boiler and involves the erection of sufficient steel to set the outlet or bypass flues. Once the initial flues are set, steel progresses again to the point where additional flue sections can be set and the reactor built. Ideally, horizontal runs of ductwork are bottom-supported, and require that the support steel is first installed beneath the duct. Structural engineers should be aware of the construction/erection plan so that the steel erection sequence and requirements support the equipment's erection sequence. These activities require close coordination with the design engineers to ensure that the uncompleted steel structure is adequate to support the initial duct sections as they are installed. Cover-plating the existing steel is frequently required prior to imposing additional loads from the new structure and can be a time-consuming and costly effort. If present, lead-based paint must be abated from existing steel prior to any welding or grinding operations. The use of bolt interface connections rather than welded connections could minimize lead abatement requirements. Close coordination with plant operations is also required as a result of the numerous interferences with plant utilities supported from the columns or beams being modified.

Tie-in to the unit is the last activity phase, accomplished during a planned unit outage. Depending upon planned unit outages, however, there is flexibility in the erection sequence. Many times a tie-in outage occurs before construction of the SCR is initiated, especially if the plant has a major outage scheduled well in advance of the SCR completion. In these instances, a gas bypass flue is installed which allows the construction of the SCR during unit operation. This re-

quires dampers and blanking plates to allow the balance of construction to take place subsequent to the tie-in. The blanking plates allow safe entry to the flues during plant operation. However, this approach generally impacts the erection sequence and potentially impacts the total construction cost. A second, shorter outage is then required to make the final tie-in of fluework.

Construction safety

A comprehensive safety program must be implemented at each construction site. The objective is to promote an awareness of safety among personnel and create a safe working environment to prevent injuries. BWCC has developed a Safety Program Manual in support of a construction site safety program. The manual has been specifically designed for construction and includes the requirements of 29 CFR 1926 Safety and Health Regulations for Construction by the Occupational Safety and Health Administration (OSHA). The contents of the Safety Program Manual include, but are not limited to, the safety procedures outlined in Table 2.

Internal cleanliness of pressure parts

Manufacturing and shipping

Many problems can develop during operations because of dirt or other foreign matter in the circulating system of a boiler. During the fabrication of drums, tubes, headers, pipes or other pressure parts, precautionary measures must be taken to assure internal cleanliness. For boilers that use welded stub construction, the ends of all tubes and pipes, as well as the stubs in the drums and headers, are closed with metal caps and sealed with plastic tape. This usually makes it unnecessary to clean these components in the field. Inevitably there are a few closure caps displaced during shipping, unloading and handling. In such instances, the construction crew must examine the components involved, perform any necessary cleaning, and replace the caps as soon as possible.

Field assembly

Boiler pressure parts should be searched before handhole and manhole closure fittings are installed. Reasonably straight tubes between headers or drums may be probed by passing a ball through them. Bent tubes that will not clear themselves of foreign material by gravity may be probed by blowing a tight-fitting sponge through them. The butt welds in small diameter tubes are examined radiographically for misalignment or obstructions that may cause flow restrictions. Headers are checked with a light and mirror immediately before the end handhole fittings are installed.

No foreign material may enter the pressure part system during assembly. Closures are left in place until removal for welding or positioning equipment. If shop-installed closures are removed to permit installation, temporary closures are placed over the openings to prevent debris from entering the equipment. Prior to flushing or final closing of equipment, a visual inspection is made and foreign objects are removed from the equipment.

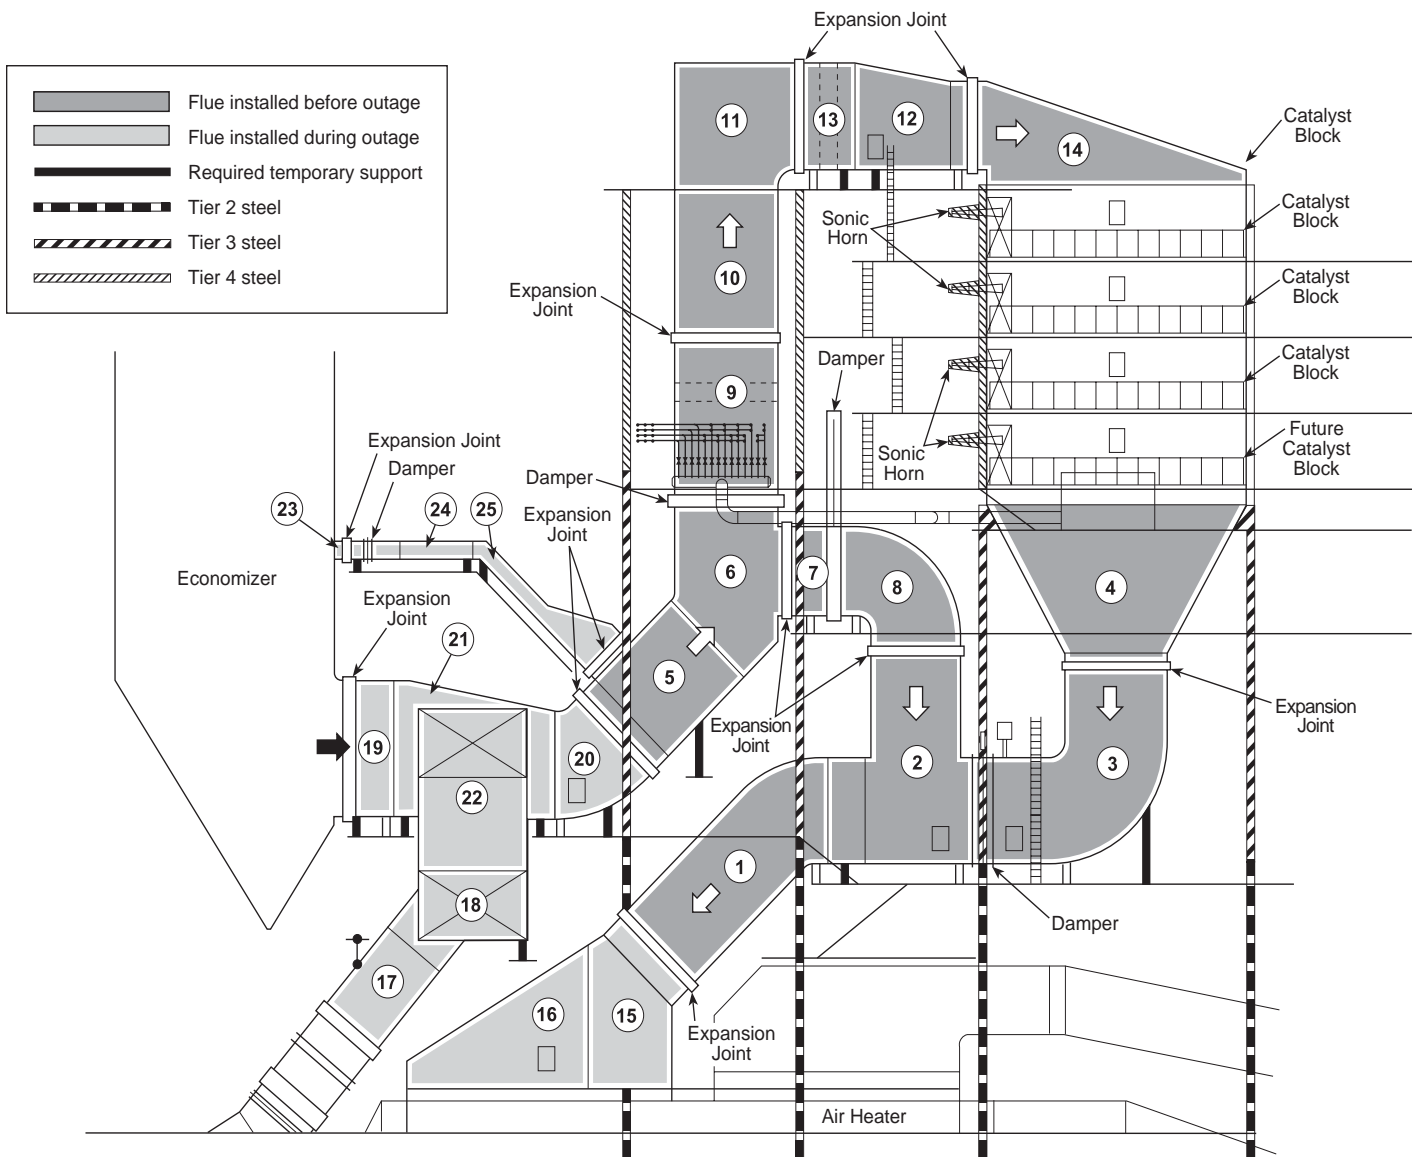

Fig. 23 Typical arrangement for an SCR retrofit project.

Removal of tube sections during repair or alteration must be performed in a manner that prevents foreign material from entering the tubes during the cutting operation. Ends of existing tubes are plugged before machining new weld preparations.

Post-construction testing

Hydrostatic testing

When all pressure part connections have been completed, the steam generating unit is tested at a pressure specified by the applicable code; this is usually 1.5 times the maximum allowable working pressure (MAWP). Before the test is applied, a final inspection is made of all welding. External connections, including all fittings, are completed within Code requirements. Connections for flange safety valves are usually blanked. Welded safety valves are closed with an internal plug.

Hydrostatic testing water must be clean and warm enough to bring pressure part metal temperatures to

at least 70F (21C). Nondrainable superheaters and reheaters are filled with demineralized water or condensate, if available. As a boiler is being filled, it is vented at every available connection to allow water to reach every circuit.

Hydrostatic pressure is applied after the boiler is filled. If a boiler feed pump or other high capacity pump is used, precautions must be taken to control the pressure at all times. While water is being pumped into the boiler, continuous inspection is made to detect any leakage. During hydrostatic testing, safety precautions must be observed, and nonessential personnel must be kept away from the test area.

The test pressure must be held long enough to allow minute leaks to be detected. Following this holding period, pressure is reduced to MAWP and retained for an inspection period. During final inspection, every area of the pressure system is viewed for leakage and repaired if necessary.

After inspection, the unit is drained and all nondrainable parts are protected from freezing, if nec-

essary. The refractory, insulation and casing work are then completed in areas left open for inspection.

Air testing

Gas-bearing components, such as the boiler, flues and ducts are field-tested for leakage and tightness. All boilers are tested by one of two procedures. Boilers designed to operate with a positive pressure, wherein furnace leaks would emit gases from the boiler setting, are tested following a pressure-fired procedure. Units designed for suction or balanced draft are tested following the balanced draft procedure.

The pressure-fired air test procedure is a pressure drop test. A test is considered satisfactory when the pressure is raised to 15 in. wg (3.74 kPa) maximum and does not drop more than 5 in. wg (1.25 kPa) in ten minutes. If pressure can not be maintained, leaks are sought and corrected and the test is rerun until satisfactory tightness is achieved. On large units, it is common to install temporary bulkheads in flue and duct runs for individual tests.

The balanced draft testing procedure is commonly performed by pressurizing the system with the forced draft fan while throttling the dampers at the downstream test terminal. With the system pressurized, all field welds are inspected by sight and sound to detect leaks.

Assembly of nonpressure parts and auxiliaries

While pressure parts are being assembled and tested, work is in progress on nonpressure parts and auxiliary equipment. These components, including air heaters, fuel equipment, fans, duct work, refractory, insulation and casing, require a large portion of the construction labor. They must be scheduled with consideration for items that must be assembled in a prescribed sequence. For example, air heaters are finished prior to erection of flues and ducts. Pulverizers are placed early enough for piping, drives and other auxiliaries to be completed.

Refractory materials

The furnace and other wall areas of modern fossil fuel boilers are made almost entirely of water-cooled tubes. The increased use of membrane walls has reduced the use of refractory in these areas. However, castable and plastic refractories may still be used to seal flat studded areas, wall penetrations, and door and wall box seals. (See Chapter 23.)

Other than membrane wall construction, when tubes are tangent or flat studded, several types of plastic refractory materials are applied to the outside of tubes for insulation or sealing purposes. When an inner casing is to be applied directly against the tubes, the refractory serves principally as an inert filler material for the lanes between tubes. It has a binder that cements it to the tubes and it is troweled flush with the surface of the wall.

Smaller boilers may have furnaces constructed of tubes on wide-spaced centers backed with a layer of brick or tile. Brickwork of this type is supported by the pressure parts and held in place by studs. The brick is insulated and made air-tight by various combinations of plastic refractory, plastic or block insulation and casing.

High quality workmanship is mandatory in the application of refractory material. Construction details are clearly outlined on drawings and instructions that also designate the materials to be used. These materials must be applied to correct contour and thickness without voids or excessive cracking. Skilled mechanics and close supervision are essential.

Casing

In general, inner or outer boiler casing is used in areas that are not membraned. Outer casing is applied outside of insulating materials and has, for the most part, been replaced by sheet metal lagging. Inner casing is positioned inside of insulation and may be pressure or nonpressure casing.

The primary purpose of pressure inner casing is to prevent air and gas leakage from a steam generating unit. The inner casing is seal welded to prevent leakage from the boiler setting and also serves as a base for the application of insulation and lagging.

In most cases, modern boiler casings feature welded construction. For pressure casing, it is essential that the strength of the weld equal the strength of the plate, that the welds be free of cracks and pinholes, and that they present a good appearance. For pressure casing, tightness is checked by a pressure drop air test. Nonpressure casings are given a thorough visual inspection.

Insulation

Selecting the type and thickness of insulation applied to boiler surfaces is an essential part of the design work. Specifications are written and drawings are made to indicate the applied materials and the method of attachment.

Typical standards specify insulation blocks or insulation blankets. Some plastic insulation is used for filling voids. The thickness of the insulation for all surfaces is selected to give a specific surface temperature, e.g., 130F (54C) with 80F (27C) ambient air temperature and 50 ft/s (15.2 m/s) surface velocity. The prime

requisites for installing boiler insulation are that the material be tight, free of voids, well anchored, and reinforced where necessary.

Ductwork with heavy stiffeners at frequent intervals presents a difficult insulating job. With the stiffeners outside the flue and duct plate, the insulation thickness is often increased over minimum requirements to assure adequate coverage of the stiffeners. If the stiffeners are placed in a manner where standard insulation coverage is too costly, the insulation may be placed over the stiffeners. As an alternative, inner lagging may be applied over the stiffeners and the minimum required insulation is placed over the lagging. When insulation is applied at an appreciable distance from a hot surface with a long vertical run, air may circulate in the void. This increases heat transfer into the insulation, which is undesirable. Where vertical runs exceed 10 ft (3 m), horizontal barriers are installed between the duct and/or tube wall and insulation.

Sheet metal lagging

Outdoor boilers require the use of a durable waterproof lagging. A light gauge metal lagging (galvanized steel or aluminum) or outer casing is used on walls, flues, ducts, air heaters, vestibules, windboxes, downcomers, steam/water lines and other exposed components. The metal covering does not seal against air infiltration but serves as a barrier to protect the insulation against water and physical damage. The cost

is reasonable and it is extensively used in both indoor and outdoor installations.

Pre-operational inspection

A final inspection is made after erection work is completed and the unit is ready for operation. This is the combined responsibility of the erection, service and operating organizations.

Externally, all components of the unit are checked for expansion clearances. Obscure corners are examined for any construction blocking or bracing that might have been left in place. Points reviewed for expansion clearances are platforms and walkways constructed adjacent to external members that move with the unit.

Of special importance in fossil fuel units is the removal of combustible materials that may present an explosion hazard during initial firing. Internal cavities are checked to ensure that all debris has been removed. Tubes are given a final inspection for alignment, particularly those that might interfere with sootblower operations. Movable connections between tubes are examined for expansion clearances and to see that all attachments are properly anchored.

On most units, construction schedules do not permit completion of insulation before the unit is fired. It is important that this work be completed in areas that will be inaccessible or cause a safety hazard when the unit is in operation.

Section VI

Operations

With proper design, manufacture and construction, modern steam generating systems are capable of operating efficiently for long periods of service. However, successful operation requires adherence to basic operating principles. These principles begin with the careful monitoring of operating conditions so that a system functions within design limits. Chapter 40 describes the instrumentation for monitoring pressures, temperatures and flows – the key process parameters. (Specialized instrumentation for environmental equipment is covered in Section IV, Chapter 36.) These operating parameters then serve as the inputs to the control system. The fundamentals of control theory and modern integrated control systems are reviewed in Chapter 41. These systems have advanced rapidly during the past few decades to provide greater operator knowledge and flexibility to optimize plant performance.

Successful long-term operation of steam producing systems requires careful attention to water treatment and water chemistry control. Chapter 42 provides a discussion of water treatment practices from startup through operation and chemical cleaning. Drum and once-through boilers have different requirements, and each boiler requires individual consideration.

General operating principles and guidelines outlined in Chapter 43 conclude this section. Each steam generating system is unique and requires specific operating guides. However, a number of general principles covering initial operations serve as a basis.

Chapter 40

Pressure, Temperature, Quality and Flow Measurement

Instruments for measuring pressure, temperature, fluid flow, and the quality and purity of steam are essential in the operation of a power plant. The measurements obtained permit safe, economical and reliable operation of the steam generating equipment. Instrumentation may range from a simple indicating device to a complex automatic measuring device. The fundamental purpose of the instrument is to convert some physical property of the material being measured into useful information. The methods used to obtain the measurement depend on available technology, economics, and the purpose for which the information is being obtained.

Test instrumentation, often portable, may be used to determine flow, pressures, and temperatures required to satisfy the user and the boiler equipment supplier that the design operating conditions have been achieved. Requirements for these instruments are summarized in the American Society of Mechanical Engineers (ASME) Performance Test Codes. Many test instruments require skilled technical operators, careful handling, and frequent calibration. Some instruments and measurement methods may not be suitable for long-term continuous operation because of a harsh environment, material limitations, or excessive cost. Instruments used for continuous measurement may require compromises in accuracy for long-term, dependable, reliable operation.

Pressure measurement

The pressure gauge is probably the earliest instrument used in boiler operation. Today, with complex control systems in operation and more than one hundred thirty years after the first water tube safety boiler, a pressure gauge is still used to determine steam drum pressure. The Bourdon tube pressure gauge is shown in Fig. 1. Although improvements have been made in construction and accuracy, its basic principle of operation remains unchanged. A closed end oval tube in a semicircular shape straightens with internal pressure. The movement of the closed end is converted to an indication (needle position).

Pressure measuring instruments take various forms, depending on the magnitude of the pressure, the accuracy desired and the application.

Fig. 1 Bourdon gauge.

Manometers are considered an accurate means of pressure or pressure differential measurement. These instruments, containing a wide variety of fluids depending on the pressure, are capable of high accuracy with careful use. The fluids used vary from those lighter than water for low pressures to mercury for relatively high pressures. Fig. 2 illustrates an inclined manometer used to measure low pressure differentials

Fig. 2 Inclined differential manometer (courtesy of Dwyer Instruments, Inc.).

at low static pressure. Differential diaphragm gauges with a magnetic linkage are also used for low pressure measurement. Fig. 3 shows a high pressure mercury manometer. For greater precision in measuring small pressure differentials, such as the measurement of flow orifice differentials, hook gauges or micromanometers may be used.

Bourdon tube pressure gauges are available for measuring a wide range of static pressures in varying degrees of precision and accuracy. Pressure gauges used as operating guides need not be of high precision and normally have scale subdivisions of about 1% of the full scale range. For certain tests, such as hydrostatic testing of pressure parts and boiler efficiency, more precision is required. Gauges with 0.1% full scale subdivisions are used. For performance calculations, high precision temperature and pressure measurements are required to accurately determine steam and water enthalpies. Dead weight gauges or calibrated pressure transmitters are preferable to Bourdon gauges for high precision pressure measurement.

Diaphragm type gauges are used for measuring differential pressures. A slack diaphragm pressure gauge can be used to measure small differentials where total pressure does not exceed about 1.0 psig (6.9 kPa). For high static pressures, opposed bellows gauges (Fig. 4) read a wide range of differential pressures. They are suitable for measuring differential pressure across boiler circuits and can be used to measure differentials from 2 to 100 psi (0.01 to 0.69 MPa) at static pressures up to 6000 psi (41.37 MPa).

Incorporated into many pressure measurement devices is the capability of producing an output signal proportional to the measurement. The output signal may be transmitted to a central measurement or control system. Pneumatic transmitted signals are

Fig. 3 High pressure mercury manometer (courtesy of Meriam Process Technologies).

Fig. 4 Opposed bellows gauge (courtesy of ITT Barton, a unit of ITT Industries, Inc.).

used in control systems, but the more common designs use electrical circuitry to sense the changing position of basic mechanical motion and to produce an electrical output signal to be transmitted. These are readily adaptable to computer based systems. Some transducers use a piezoelectric crystal which changes electrical resistance as the element is deformed under pressure. Other pressure transmitter designs use a diaphragm with strain gauges attached; minor changes in diaphragm strain are transferred to the strain gauges, which change resistance. Electrical circuits recognize the resistance change in the crystal or strain gauges and produce an indication of pressure. Advanced applications have used an optic glass fiber embedded in a metal diaphragm, with pressure measurement determined as a change in the light beam traversing the fiber. Pressure transducers incorporating electrical components have the advantage of fewer mechanical parts for improved durability. However, this may restrict the installation location due to temperature limitations of the electrical components. Instruments configured to generate electric signals have been adapted to incorporate computing capability to assist in calibration. Pressure transmitters and transducers have been readily adapted for power plant computer data acquisition and control systems.

Instrument corrections

In recording and reporting pressure readings, corrections may be necessary for water leg and for conversion to absolute pressure by adding atmospheric pressure. Effective water leg is the added pressure imposed on the gauge by the leg of water standing above the gauge. Fig. 5 illustrates a water leg correction to a pressure gauge reading. The density of the water in the leg may change with ambient temperature and, for precise measurement, the water leg temperature should be monitored. On some gauges it may be possible to zero the gauge at zero operating pressure with the water leg completely filled to compensate for the water leg static head. Care must be taken in performing water leg adjustments as this may affect the instrument calibration over the operating range. Differential pressure measurements require a water leg correction for both sides of the measuring instrument. For some liquid level devices, the differential pressure measurements from two water legs of different elevations are used to provide the indication of liquid level. Differential pressure measurements across orifices, nozzles or pitot tubes to measure flow are described below.

Location of pressure measurement connections

The criteria for selecting a connection location to the pressure source for the measuring device are the same regardless of the magnitude of the pressure, the type of measuring device or the fluid being measured. Pressure connections, or *taps*, in piping, flues or ducts should be located to avoid impacts or eddies; this assures an accurate static pressure measurement. Un-

der certain circumstances a through the wall pressure connection may not be representative. It may be necessary to use a probe incorporating a tip configuration that minimizes the effects of the flowing fluid to obtain a representative static pressure measurement.

Connecting lines to instruments should be as short and direct as possible and must be leak-free. For differential pressure readings, it is preferable to use a differential pressure measuring device rather than to calculate the difference between the readings on two instruments. Particular attention should be paid to the placement of the instrument, the potential for condensation in the impulse lines, and the accumulation of debris or non-condensable gases in the completed installation.

Temperature measurement

Today, the Fahrenheit and Celsius (formerly centigrade) scales are the most common and firmly established temperature scales.

The Fahrenheit scale is fixed at the freezing point (32F) and the boiling point (212F) of pure water at atmospheric pressure, with 180 equal degrees between the two points. The centigrade scale was originally based on the same freezing (0C) and boiling (100C) points of water at standard atmospheric pressure, using the convenient 100 degree interval of the decimal system.

In 1960, the General Conference of Weights and Measures changed the defining fixed point from the freezing point to the triple point (0.0C) of water. The triple point is the condition under which the three phases of matter (solid, liquid and vapor) coexist in equilibrium. This point is more easily and accurately reproduced than the freezing point. At standard atmospheric pressure the interval between the triple point for water and steam on the centigrade scale became 99.99C instead of 100C.

In 1990, temperature standards were further refined by the International Temperature Scale 1990

Fig. 5 Application of water leg correction to pressure gauge reading (Correction $\Delta P = g\rho L/g_c$).

(ITS-90). These changes, however small, reflect the continued review of temperature measurement. As measured by the current standard, water at standard conditions boils at 211.953F (99.974C).

In thermometer calibrations, the fusion and vaporization of various pure substances have been carefully determined and are known as fixed points. Two additional scales in scientific work use the absolute zero of temperature, i.e., -273.16C or -459.69R. The absolute scale using Celsius degrees as the temperature interval is called the Kelvin (K) scale; the absolute scale using Fahrenheit degrees is called the Rankine (R) scale.

Methods of measuring temperature

Heat affected properties of substances, such as thermal expansion, radiation and electrical effects, are incorporated into commercial temperature measuring instruments. These instruments vary in their precision depending on the property measured, the substance used and the design of the instrument. The care taken in selecting the correct instrument largely determines the accuracy of the results. It is the engineer's responsibility to make certain that the application is correct and that the results are not affected by extraneous factors.

Changes of state

Fusion For a pure chemical element or compound such as mercury or water, fusion, or change of state from solid to liquid, occurs at a fixed temperature. The melting points of these materials are suitable fixed reference points for temperature scales.

The fusion of pyrometric cones is widely used in the ceramic industry as a method of measuring high temperatures in refractory heating furnaces. These cones, small pyramids about 2 in. (50.8 mm) high, are made of oxide and glass mixtures that soften and melt at established temperatures. The pyrometric cone is suitable for temperatures ranging from 1100 to 3600F (593 to 1982C). Its use in the power industry is generally limited to the laboratory. An adaptation of this method of temperature determination is used when observing ash and slag accumulations soften and flow in a coal-fired furnace or superheater.

Fusion pyrometers are also made in the form of crayons, paint and pellets. The crayons and paint, applied to a metal surface, produce a flat-finish mark. A change in the finish from flat to glossy indicates that the surface temperature has reached or exceeded a selected value. The pellets melt at specified temperatures when in contact with a hot surface and may be seen more easily than crayon marks.

Vaporization The vapor pressure of a liquid depends on its temperature. When the liquid is heated to its boiling temperature, the vapor pressure is equal to the total pressure above the liquid surface. The boiling points of various pure chemical elements or compounds at standard atmospheric pressure [29.92 in. Hg (101.33 kPa)] can be used as thermometric fixed points. If the liquid and vapor are confined, the increase in vapor pressure may be used to measure temperature using a calibrated pressure gauge. (See Fig. 6.)

Expansion properties

Most substances expand when heated and, for many materials, the amount of expansion is almost directly proportional to the change in temperature. This effect is the basis of various thermometer types using gases, liquids or solids.

Gases The expansion of gases follows the relationship, in English units:

$$Pv_M = RT \quad (1)$$

where

P = absolute pressure, lb/ft²

v_M = volume, ft³/mole of gas

R = universal gas constant, 1545 ft lb/mole R

T = absolute temperature, R = F + 460

At high pressures or near the condensation point, gases deviate considerably from this relationship. Under other conditions, however, the deviation is small.

Two types of gas thermometers are based on this relationship. In one, a constant gas volume is maintained and pressure changes are used to measure changes in temperature. Very accurate instruments of this type have been developed for laboratory work. The constant volume type thermometer is widely used commercially.

Nitrogen is commonly used for the gas-filled thermometer in industrial applications. It is suitable for a temperature range of -200 to 1000F (-129 to 538C). The construction is similar to the vapor pressure thermometer with nitrogen gas replacing the liquid and vapor. Expansion of the heated nitrogen in the bulb increases the pressure in the system and actuates a temperature indicator.

Liquids Liquid expansion properties may be incorporated into a thermometer by using a bulb and capillary to confine the liquid. In this thermometer, the bulb and capillary tube are completely filled with liquid and a calibrated pressure gauge is used to measure temperature. Mercury has been used for a temperature range of -40 to 1000F (-40 to 538C). Instrument readings can be in error if the capillary tubing is subjected to temperature changes.

The liquid-in-glass thermometer is a simple, direct

Fig. 6 Schematic assembly of vapor pressure thermometer.

reading, portable instrument. Low precision thermometers are inexpensive and instruments of moderate precision are available for laboratory use. This thermometer features a reservoir of liquid in a glass bulb that is connected directly to a glass capillary tube with graduated markings. Mercury, the most common liquid, is satisfactory from -40°F (-40°C), just above its freezing point, to about 600°F (316°C) if the capillary space above the mercury is evacuated. The upper temperature limit may be 900°F (482°C) or higher if this space is filled with pressurized nitrogen or carbon dioxide (CO_2).

The use of unprotected glass thermometers is restricted to laboratory or research applications. For more severe service there are various designs of industrial thermometers with the bulb and stem protected by a metal casing and usually arranged in a thermometer well. Response to rapid temperature changes is slower than with the unprotected laboratory type instrument.

Solids The expansion of solids when heated is recognized in thermometers using a bimetallic strip. Flat ribbons of two metals with different coefficients of thermal expansion are joined face to face by riveting or welding to form a bimetallic strip. When the strip is heated, the expansion is greater for one metal than for the other. A flat strip bends, or changes curvature if it was initially in a spiral form. Bimetallic strips are seldom used in power plant thermometers but are widely used in inexpensive thermometers, household thermostats and other temperature control and regulating equipment. They are particularly useful for automatic temperature compensation in other instrument mechanisms.

Radiation properties

All solid bodies emit radiation. The amount is very small at low temperatures and larger at high temperatures. The quantity of radiation may be calculated by the Stefan-Boltzman formula:

$$q/S = \sigma \epsilon T^4 \quad (2)$$

where

- q = radiant energy per unit time, Btu/h
- S = surface area, ft^2
- σ = Stefan-Boltzman constant, 1.71×10^{-9} Btu/h $\text{ft}^2 \text{R}^4$
- ϵ = emissivity of the surface, dimensionless (usually between 0.80 and 0.95 for boiler materials)
- T = absolute temperature, $\text{R} = \text{F} + 460$

At low temperatures the radiation is primarily in the invisible infrared range. As the temperature rises, an increasing proportion of the radiation is in shorter wavelengths, becoming visible as a dull red glow at about 1000°F (538°C) and passing through yellow toward white at higher temperatures. The temperature of hot metals [above 1000°F (538°C)] can be estimated by color. For iron or steel, the approximate color scale is:

dark red	1000F (538C)
medium cherry red	1250F (677C)
orange	1650F (899C)
yellow	1850F (1010C)
white	2200F (1204C)

Within the visible range, two types of temperature measuring instruments, the optical pyrometer and the radiation pyrometer, sense the emitted radiation to indicate temperature.

Optical pyrometers The optical pyrometer visually compares the brightness of an object to a reference source of radiation. The typical internal calibration source is an electrically heated tungsten filament. A red filter may also be used to restrict this visual comparison to a particular wavelength. This instrument measures the temperature of surfaces with an emissivity of 1.0, which is equivalent to that of a blackbody. By definition, a blackbody absorbs all radiation incident upon it, reflecting and transmitting none. When calibrated and used properly, the pyrometer yields excellent results above 1500°F (816°C). Temperature measurement of the interior surface of a uniformly heated enclosure, such as a muffle furnace, is a typical application. When used to measure the temperature of an object outside a furnace, the optical pyrometer always reads low. The error is small [20°F (11°C)] for high emissivity bodies, such as steel ingots, and large [200 to 300°F (111 to 167°C)] for unoxidized liquid steel or iron surfaces.

The optical pyrometer is widely used for measuring objects in furnaces at steel mills and iron foundries. It is not applicable for measuring gas temperature because clean gases do not radiate in the visible range.

Radiation pyrometers In one type of radiation pyrometer, all radiation from the hot body, regardless of wavelength, is absorbed by the instrument. The heat absorption is measured by the temperature rise of a delicate thermocouple (TC) within the instrument. The thermocouple is calibrated to indicate the temperature of the hot surface at which the pyrometer is sighted, on the assumption that the surface emissivity equals 1.0. The hot surface must fill the instrument's entire field of view.

This type of radiation pyrometer has high sensitivity and precision over a wide range of temperatures. The instrument gives good results above 1000°F (538°C) when used to measure temperatures of high emissivity bodies, such as the interiors of uniformly heated enclosures. Because operation of the instrument does not require visual comparison, radiation pyrometers may be used as remotely operated temperature indicators. Errors in temperature measurements of hot bodies with emissivities of less than 1.0, especially if they are in the open, are extremely large.

Radiation pyrometers sensitive to selective wavelengths in the infrared band give good results when measuring temperatures of bodies or flames. One design uses a system of lenses, a lead sulfide cell and electronic circuitry to produce a measurement.

An advancement of the single band pyrometer is the two color pyrometer, which measures the intensities of two selected wave bands of the visible spectrum emitted by a heated object. This unit computes the total of the emitted energies and converts it into a temperature indication. As with the optical pyrometer, indications depend on sighting visible rays and therefore its minimum temperature measurement is 1000°F (538°C).

Infrared radiation is produced by all matter at temperatures above absolute zero and detectors sensitive to the infrared band may be used to measure objects at low temperatures where the radiation is not in the visible band. The development of metal-silicide detectors permits sensitivities in the 1 to 5 μm band. Metal-silicides are formed by the reaction of metals, such as platinum or palladium, with p-type silicon. When coupled with electronic circuitry for producing an image, the detectors are sophisticated devices for low temperature measurement.¹

Infrared thermal imaging equipment is available for quantitative measurement or qualitative imaging. The instruments for making quantitative measurements and providing target temperature indications are called *thermographic imagers* or *imaging radiometers*. Qualitative imaging instruments are called *thermal viewers*. These viewers are mechanically or electronically scanned; the electronically scanned units are called *pyroelectric vidicons* or *pyrovidicons*.²

Infrared temperature measurement is applicable to surveys of surfaces, such as boiler casings and insulated steam pipes, for locating temperature variations. These instruments may also assist in determining electrical component temperatures in operating circuits. Radiation pyrometers are not capable of determining gas temperatures.

Optical properties

Optical fibers have been used in fixed (end) and distributed (average temperature along length) temperature measurement. Development is continuing in the application of this method to temperatures above 450F (232C).³

Electrical properties

Two classes of widely used temperature measuring instruments, the thermocouple and the electrical resistance thermometer, are based on the relation of temperature to the electrical properties of metals.

Because of its versatility, convenience and durability, the thermocouple is of particular importance in power plant temperature measurements. A separate section later in this chapter is devoted to the thermocouple and its applications.

Resistance thermometer The electrical resistance thermometer, used over a temperature range of -400 to 1800F (-240 to 982C), depends on the increase in electrical resistance of metals with increasing temperature; this relationship is nearly directly proportional. If the electrical resistance of a calibrated wire material is measured (by a Wheatstone bridge or other device), the temperature of the wire can be determined.

In the simplest form of the Wheatstone bridge system, shown in Fig. 7a, the reading would be the sum of the resistances of the calibrated wire and the leads connecting this wire to the Wheatstone bridge. However, this value would be subject to error from temperature changes in the leads. By using a more refined circuit shown in Fig. 7b, the resistance of the leads can be eliminated from the instrument reading. To localize the point of temperature measurement, the resistance wire may be made in the form of a small

Fig. 7 Diagrams of electrical circuits for resistance thermometers (courtesy of Leeds and Northrup Company).

coil. From room temperature to 250F (121C), commercial instruments usually have resistance coils of nickel or copper. Platinum is used for higher temperatures and in many high precision laboratory instruments to cover a wide range of temperatures.

The electrical resistance thermometer can be used for the remote operations of indicating, recording or automatic controlling. If proper precautions are taken, it is stable and accurate, but it is less rugged and less versatile than a thermocouple.

Acoustic properties

Acoustic properties of gases vary with temperature and are used as the basis for temperature measuring instruments. The velocity of sound in a gas varies directly with the square root of its absolute temperature, as indicated in the following formula:

$$c = \sqrt{g_c kRT/M} \quad (3)$$

where

- c = speed of sound, ft/s
- g_c = proportionality constant, 32.17 lbm ft/lbf s²
- k = specific heat ratio, dimensionless
- R = universal gas constant, 1545 ft lb/mole R
- T = absolute temperature, R = F + 460
- M = molecular weight, lb/mole

By measuring the time required for sound to traverse a specific distance, the average gas temperature can be calculated. This phenomenon has been commercially applied to measuring furnace gas temperatures. By developing a number of independent temperature paths a thermal contour may be developed.

Other properties

Other material properties that vary with temperature are also used as the basis for temperature measuring instruments. By flowing gas through two orifices in series, a method has been developed for measuring gas temperatures up to 2000F (1093C) commercially and up to 4500F (2482C) in the laboratory. Temperatures ranging from absolute zero to 5000F (2760C) have been accurately determined by using a laboratory instrument that measures electron motions. High temperature research has been stimulated by gas turbine and jet propulsion applications, and further development of new and improved temperature measuring instruments is expected.

Thermocouples

A thermocouple consists of two electrical conductors of dissimilar materials joined at the ends to form a circuit. If one of the junctions is maintained at a temperature higher than the other, an electromotive force (emf) is generated, producing current flow through the circuit, as shown in Fig. 8.

The magnitude of the net emf depends on the temperature difference between the two junctions and the materials used for the conductors. No unbalance, or net emf, is generated if the two junctions are at the same temperature or if the conductors are of the same material at different temperatures. If one junction of a calibrated thermocouple is maintained at a known temperature, the temperature of the other junction can be determined by measuring the net emf produced; this emf is almost directly proportional to the temperature difference of the two junctions. The relationship between emf and the corresponding temperature difference has been established by laboratory tests throughout the temperature ranges for common thermocouple materials. These values are plotted in Fig. 9. The thermocouple is a low cost, versatile, durable, simple device providing fast response for accurate temperature measurement. It also allows convenient centralized reading.

In the potentiometer circuit, copper leads may connect the reference junction terminals to the measuring instrument without affecting the net emf of the thermocouple. If the instrument is at a uniform temperature, no emf is set up between the copper conductors and slide wire materials within the potentiometer. However, if temperature differences exist within the instrument, there will be disturbing emf values in the circuit and the readings will be affected.

Multiple circuits

If two or more thermocouples are connected in series, the net emf at the outside terminals is equal to the sum of the emf values developed by the individual thermocouples. When all of the individual hot and cold junctions are maintained at the same respective temperatures, as in the device known as the thermopile, this multiplied emf value makes it possible to detect and measure extremely small temperature variations.

Two or more thermocouples may be connected in

Fig. 8 Principle of the thermocouple illustrated.

parallel to obtain a single reading of average temperature. In this case, the resistance of each thermocouple must be the same. The emf across the terminals of such a circuit is the average of all the individual emf values and may be read on a potentiometer normally used for a single thermocouple.

Practical application and multiple circuits

The limitation of the potentiometer circuitry to measure small emf values has led to various circuits of multiple thermocouples connected in series or parallel. These circuits make it possible to measure extremely small temperature variations or average temperatures. Thermocouple circuit considerations of wire diameter and length, while less important for steady-

Fig. 9 Relation of temperature to electromotive force produced by several commonly used thermocouples.

state measurement, will affect thermocouple readings during dynamic temperature conditions. These applications require detailed circuit design investigation.

The application of thermocouples requires attention to the insulation of the lead wire to prevent erroneous circuits. Parasitic couples may be introduced by mechanical, soldered, or brazed connections if temperature variations exist within different metals of the connections.

Selection of materials The combinations of metals and alloys most frequently used for thermocouples are listed in Table 1 with their general characteristics and useful temperature ranges. Selection depends largely on the ability to withstand oxidation attack at the maximum expected service temperature. Durability depends on wire size, use or omission of protection tubes, and nature of the surrounding atmosphere.

All thermocouple materials deteriorate when exposed at the upper portion of their temperature range to air or flue gases and when in contact with other materials. Platinum in particular is affected by metallic oxides and by carbon and hydrocarbon gases when used at temperatures above 1000F (538C) and is subject to calibration drift. The upper temperature limits shown in Table 1 are well below the temperatures at which rapid deterioration occurs.

For high temperature duty in a permanent installation or where destructive contact is likely, service life may be extended, at some sacrifice in response speed, by using closed-end protection tubes of alloy or ceramic material. The arrangement should permit removal of the thermocouple element from the protection tube for calibration or replacement. Omission of the protection tube may require frequent calibration and corrections for calibration drift. For short periods of service within the useful range of the thermocouple selected, the correction for calibration change is usually negligible.

Sheathed-type thermocouple Sheathed-type magnesium oxide insulated thermocouples have been in use for some time. The thermocouple wires are insulated with inert magnesium oxide insulation that protects the wires from the deteriorating effects of the environment. Sheaths can be made of stainless steel and other resistant materials, ensuring relatively long life

Fig. 10 Sheathed-type thermocouple.

and resistance to oxidizing, reducing, or otherwise corrosive atmospheres. Sheathed thermocouples are available as grounded or nongrounded types, as illustrated in Fig. 10. The grounded type has a more rapid response to temperature change but can not be used for connection in series or parallel, because it is grounded to the sheath. For these applications, the nongrounded type should be used. The grounded type is susceptible to separation or parting of the thermocouple wire where long leads at high temperatures are used, whereas the nongrounded type appears satisfactory for this service.

Sheathed thermocouples may be equipped with pads for welding to tubes, as illustrated in Fig. 11. Pad-type thermocouples should not be used when the pad is exposed to temperatures that are markedly different from that of the body being measured, because this added metal surface can radiate or absorb heat. Typical applications of pad-type thermocouples are drum, superheater header, or tube surface temperature measurements. (See Fig. 12.)

Thermocouple and lead wire There are two classes of wire for thermocouples, the closely standardized and matched thermocouple wire and the less accurate

Table 1
Types of Thermocouples in General Use

Type of Thermocouple (Note 1)	Useful Temperature Range, F (C)		Maximum Temperature, F (C)	Millivolts at 500F (260C) (Note 2)	Magnetic Wire
(+) Copper to constantan (-)	-300 to 650	(-184 to 343)	1100 (593)	13.24	-
(+) Iron to constantan (-)	0 to 1400	(-18 to 760)	1800 (982)	15.01	Iron (+)
(+) Chromel to constantan (-)	-300 to 1600	(-184 to 871)	1800 (982)	17.94	-
(+) Chromel to alumel (-)	0 to 2300	(-18 to 1260)	2500 (1371)	11.24	Alumel (-)
(+) 90% Pt — 10% Rh to platinum (-)	900 to 2600	(482 to 1427)	3190 (1754) (Note 3)	2.048	-

Notes:

1. Nominal composition: constantan, 55% Cu, 45% Ni; chromel, 90% Ni, 10% Cr; alumel, 95% Ni, 5% Al, Si and Mn combined.
2. Reference junction 0F (-18.0C).
3. Melting point.

compensating lead wire. For thermocouples of noble metal, extension leads of copper and copper-nickel alloy, which have an emf characteristic approximating the noble metal pair, are used to reduce cost. For thermocouples of base metal, the extension lead wire is the same composition as the thermocouple wires, but it is less expensive because the control in manufacture and calibration is less rigorous.

For accuracy, the matched thermocouple wire should be used at the hot junction and continued through the zone of greatest temperature gradient to a point close to room temperature, where a compensating lead wire may be spliced in for connection to the reference junction. The reference junction is usually located at the recorder or central observation point. Where a number of thermocouples are used, it may be economical to establish a zone box (see Fig. 13) from which copper conductors are extended to the measuring instrument.

Splicing of extension lead wires may be done by twisting the wire ends together, by using screw clamp connectors, or by fusion welding, soldering or brazing.

Care should be taken to maintain correct polarity

Fig. 12 Application of pad-type thermocouple.

Fig. 13 Thermocouple and lead wire arrangement to measuring instrument through selector switch.

by joining wires of the same composition. Polarity is usually identified by color code or tracers in the wire covering.

Hot junction Wire and pipe-type elements for hot junctions may be purchased or may be made from stock thermocouple wire, as shown in Fig. 14. These types are useful for direct immersion in a gas stream, for insertion into thermometer wells, or for thermal contact with solid surfaces.

Where the temperature of a metallic surface is to be measured, a versatile hot junction may be formed by peening the wires separately into holes drilled in the surface of the metal. Steps for making this type of junction are illustrated in Fig. 15.

The peened junction has the advantage of being completely mechanical, with a tight and remarkably strong attachment and minimum interference with the temperature of the object. The temperature indicated is essentially that of the metallic surface, which is the first point of contact with the conductors. The depth of the drilled hole has no temperature effect; it only provides mechanical strength. However, the junc-

Fig. 14 Thermocouple elements and hot junctions.

Fig. 15 Procedure for installing a peened-junction thermocouple to measure surface temperature of metal.

tion contact points are subject to thermal conduction in the wires. Where this type of error is significant, precautions should be taken to prevent temperature gradients in the wires. Drilled holes for the wire ends should allow a snug fit before peening. For installations requiring a significant number of thermocouples, there are portable spot welding machines available to join the ends of the wire directly to a steel surface.

Millivolt potentiometer

The temperature-emf relationships of standardized thermocouple wires, as established and published by the manufacturer, should be used to convert the potentiometer readings to equivalent temperature values. These tabulated values represent the net emf impressed in the potentiometer terminals when the reference junction is at 0°F (−18°C) and the measuring junction is at the temperature listed. The millivolt potentiometer may be used with any type of thermocouple. It is frequently used when several different thermocouple types are installed.

It is usually impractical to maintain the reference junction at 0°F (−18°C) while taking readings. Correction for any reference junction temperature can be made by adding to each observed emf reading the emf value corresponding to the reference junction temperature. The temperature of the measuring junction can then be determined. Most millivolt potentiometers are equipped with a compensator, which should be used to correct for the reference junction temperature. Direct millivolt readings then correspond to the actual thermocouple temperature.

Direct reading potentiometer

A potentiometer may be graduated to read the hot junction temperature directly instead of in millivolts. When calibrated for use with a specific type of ther-

mocouple, the reference junction temperature is usually automatically compensated for by an internal resistor circuit. This circuit compensates for deviations from standard room temperature. The resistor circuit characteristics are specific to the type of thermocouple material for which the potentiometer is calibrated. Some potentiometers provide a selector switch to directly read different types of thermocouples.

Temperature recorders

In temperature recorders, a power operated mechanism automatically adjusts the slide wire of a potentiometer circuit to balance the emf received from the thermocouple. The action of the slide wire is coordinated with the movement of a recording pen or print wheel that is drawn over, or impressed on, a moving temperature graduated chart.

As a result, an essentially continuous record may be traced for one thermocouple, or a rapid scanning of many thermocouples may be recorded.

Checking recorder calibration Compared with the manually operated potentiometer, all recorders are inherently less accurate because of wear and lost motion in the actuating mechanism, shrinkage, or printing inaccuracies of paper and chart scales.

Temperature of fluids inside pipes

The temperature of a fluid (liquid, gas or vapor) flowing under pressure through a pipe is usually measured by a glass thermometer, an electrical resistance thermometer, or a thermocouple. Each thermometer is inserted into a well, or thermowell, projecting into the fluid. The thermowell is preferred but a thermocouple properly attached to the outside of a pipe wall can provide good results. The thermowell provides

Fig. 16 Thermocouple well installation.

an average temperature if temperature stratification exists in the fluid, because thermal conduction along the well equalizes the temperature.

A metal tube closed at one end, screwed into or welded to a pipe wall, and projecting into the fluid, serves as a thermowell (Fig. 16). It must have strength and rigidity to withstand hydrostatic pressure, resistance to bending and vibration caused by its resistance to fluid flow, and material compatibility for a welded attachment. To minimize heat conduction to the surroundings and to give rapid response to temperature changes, the well should be as small as possible. The portion outside the pipe should also be small. The material of the well must resist the erosive or corrosive action of the fluid. Because the temperature may be locally depressed by acceleration of a compressible fluid through a constriction in a pipe, the well should be carefully positioned, taking these factors into account. Care should also be observed when locating the well for measuring steam temperature downstream of spray water attemperator injection points, as inadequate mixing of the steam and spray water may result in fluid temperature measurement errors. Projecting parts of the thermowell and the pipe wall should be thoroughly insulated to prevent heat loss. Substantial error can result from air circulation within the thermowell and should be minimized by packing with insulating material.

Thermowell designs vary. If the fluid is a liquid or a saturated vapor, good heat transfer is assured and a plain well is satisfactory. If the fluid is a gas or superheated vapor, a finned well is sometimes used. The method of attachment, a mechanical thread or welded attachment to the pipe wall, is optional provided safety code requirements are met (see Fig. 16).

Tube temperature measurement

It is frequently desirable to know the metal temperature of tubes in different classes of service. These classes include furnace wall or boiler bank tubes that are cooled by water and steam at saturation temperature, economizer tubes cooled by water below the temperature of saturation, and superheater and reheater tubes cooled by steam above saturation temperature. These temperature measurements may be used to determine the safety of pressure parts, the uniformity among tubes in parallel flow circuits, or the fluid temperature increase between inlet and outlet conditions. The peened-type hot junction, illustrated in Fig. 17, is satisfactory in many cases and is probably the simplest form of thermocouple application. Sheathed-type thermocouples with pads are generally used to permanently monitor temperatures of tubes not exposed to external heat. (See Fig. 11.) Properly applied insulation of sufficient thickness in the vicinity of the thermocouple attachment will reduce the effects of thermal conduction along the tube. The thermocouple wire wrapped around the tube will minimize the conduction along the thermocouple wire. These techniques are illustrated in Fig. 17. When properly installed the surface thermocouple may be used to measure both metal and fluid temperatures.

Fig. 17 Thermocouple wires extending from hot junction disposed on pipe wall before leading outside.

Furnace wall tubes

In measuring water-cooled furnace wall tube temperatures, special protection for the thermocouple and its lead wires must be provided because of the destructive high temperature furnace atmosphere and, in some cases, the accumulation and shedding of ash and slag deposits. If a simple peened thermocouple is used, the results may lack accuracy because of errors from conduction; in most cases, the service life would be short because of physical damage or wire deterioration from overheating. Cover plates welded to the tubes have been used to protect the wires, but these plates interfere with the normal heat transfer and cause local ash deposits to create abnormal conditions at the temperature measurement point.

The use of chord-drilled holes through which the thermocouple wires are laced (Fig. 18) was developed by The Babcock & Wilcox Company (B&W); this is a satisfactory temperature measurement method for furnace wall tubes. The tube surface is free of projections, the wires are protected, and the thermal conduction effect at the hot junction is minimized because the wires pass through an essentially isothermal zone before emerging into cooler surroundings at the rear of the tube. To minimize the effect on the heat flow pattern within the tube metal, the chord-drilled holes should

Fig. 18 Chordal thermocouple.

be as small as possible. The effect of these holes on the strength of the tube is small. This effect is minimal in the critical direction of hoop stress and is readily tolerated in the direction of longitudinal stress. The use of chord-drilled holes in the thicker, high pressure wall tubes is a practical method of obtaining surface metal temperatures.

Gradient thermocouple

Measuring the temperature gradient through a tube wall is a means of determining the heat flow rate through the wall and of detecting the accumulation of certain types of internal deposits.

To obtain the best results, a large temperature gradient through the wall is desirable. However, ideal conditions may be compromised to permit an arrangement that provides measurable metal temperatures and is practical to fabricate. Fig. 18 shows a section through a tube which illustrates the drilling and installation of typical surface and depth thermocouples.

Calibration Sheathed thermocouples are suitable for this temperature gradient application. For greater accuracy the thermocouples may be laboratory calibrated. No procedure is available to accurately or economically calibrate the thermocouple tube assembly in the field. The most satisfactory method is as follows.

Following installation, obtain a series of temperature readings on all thermocouples at two or three different ratings on the boiler, from a low rate to maximum rate, while the tube is known to be internally clean; read all temperatures as simultaneously as possible. Several series of readings should be taken on the thermocouples at each rating. An average should be calculated for each thermocouple to correct for minor differences in temperatures resulting from heat input variations. This also compensates for the

time lag between surface and depth thermocouples. By using the surface and depth dimensions, the equivalent lengths can be determined and the temperature gradients can be plotted. In practice, the heat flows through a tube wall in a path of decreasing sectional area and the temperature gradient through the metal is not linear with respect to thickness. The gradient, however, may be drawn as a straight line if temperatures are plotted against an equivalent length of flow path (l_e). This represents an equivalent flat plate having a uniform flow path with an equivalent but greater thickness. This is illustrated in Fig. 19.

The equivalent plate thickness is calculated in the following manner:

$$l_e = R \ln (R/r) \quad (4)$$

where

R = outside radius of tube, in.

r = inside radius of tube, in.

l_e = equivalent flat plate thickness, in.

In many cases, thermocouple error may represent a significant portion of the gradient being measured. Ideally, lines drawn through the surface and depth temperature (Fig. 20) should intersect the inner surface equivalent thickness line slightly above the fluid temperature as measured by a thermocouple peened on the outside surface of the tube opposite the furnace. The amount above the fluid temperature represents the temperature drop across the fluid film and this drop increases with increased heat input. It is difficult to obtain consistently drilled thermocouple holes that reflect the pattern shown in Fig. 20. If, at low inputs, the line drawn through the surface and depth temperature intersects the inner surface equivalent thickness line at fluid temperature or slightly above, it may be considered as satisfactory. If it falls below or well above this point, a correction or calibration may be made by ignoring the measured equivalent depth dimension, plotting a line through the outer and inner surface temperatures, then adjusting the equivalent depth to a value represented by the intersection of the adjusted gradient and depth thermocouple temperature (Fig. 21).

Heat flux measurement Once a series of temperature plots shows consistent results, heat inputs may be calculated:

$$q'' = \frac{k (T_1 - T_2)}{l_e} \quad (5)$$

where

q'' = heat flux, Btu/h ft²

k = thermal conductivity, Btu/h ft F

T_1 = outside surface thermocouple temperature, F

T_2 = depth thermocouple temperature, F

l_e = equivalent plate thickness (surface to depth), ft (Fig. 19)

Scale detection If the temperature gradients are to be used as a scale detector, then thermocouples should be read periodically, plotted, and checked for a change in the temperature above saturation.

Fig. 19 Thermocouple installation.

To assure a close comparison, the thermocouple temperatures should always be read with the calibrated equipment and under operating conditions close to those existing during the original setup. An accumulation of internal deposits in the thermocouple zone is marked by an increased temperature difference from inner surface to saturation.

When the average of the surface and depth temperatures approaches the limit for the tube metal, the boiler should be shut down and the inside tube surfaces inspected. Sufficient allowance should be made for tube to tube temperature variations.

Fig. 20 Sample plot of temperature gradients for low, medium and high heat rates.

Limitations of gradient thermocouples The gradient thermocouple method of measuring heat flow through tube walls is a guide rather than an absolute measure. Relatively small dimensions and small differential temperatures exist between surface thermocouple and depth thermocouple locations. Also, any small error in determining temperatures or in metal thickness between thermocouples usually represents a large percentage of this small difference.

The effectiveness of the gradient temperature plot as an internal scale detector is also dependent on the nature of the scale. Certain types of scale, such as carbonate or silica deposits, accumulate uniformly, while iron oxide deposits can accumulate irregularly. The location of nonuniform deposits is uncertain and the gradient thermocouple method is not reliable for detecting such accumulations.

For a quick determination of internal tube deposit changes, the difference between surface and depth temperature readings can be plotted against the difference between surface and fluid temperature readings. With a clean tube, points should fall along a straight line over a range of inputs. As deposits form, the difference between surface and fluid temperature increases for an unchanging surface and depth temperature difference. Fig. 22 shows a typical plot of such conditions.

Fig. 21 Adjustment of temperature gradient.

Fig. 22 Plot of chordal thermocouple temperatures showing effect of internal deposits.

Superheater and reheater applications

Chordal surface thermocouples can be used to measure metal temperatures of superheater or reheater tubes in the gas stream, using the principles previously described. However, special provision must be made to protect the wires between the point of measurement and the exit from the boiler setting. This can be done by containing the sheathed thermocouple in stainless steel tubing that is welded to the superheater or reheater tube. This maintains the sheath and protection tubing at a temperature which is approximately that of the superheater or reheater tube. Additional cooling of the stainless steel protection tube is frequently required.

Gas temperature measurement

Temperature measurement of combustion gas at different locations within the boiler is important to the boiler design engineer and the operating plant engineer. Accurate temperature measurements of gas entering and leaving the heat absorbing components can confirm design predictions and operating performance.

In all cases of gas temperature measurement, the temperature sensitive element approaches a temperature that is in equilibrium with the conditions of its environment. While it receives heat primarily by con-

vection transfer from the hot gases in which it is immersed, it is also subject to heat exchange by radiation to and from the surrounding surfaces and by conduction through the instrument itself. If the temperature of the surrounding surfaces does not differ from that of the gas (gas flowing through an insulated duct), the temperature indicated by the instrument should accurately represent the gas temperature. If the temperature of the surrounding surfaces is higher or lower than that of the gas, the indicated temperature will be correspondingly higher or lower than the gas temperature.

The variation from the true gas temperature depends on the temperature and velocity of the gas, the temperature of the surroundings, the size of the temperature measuring element, and the construction of the element and its supports. To correct for the errors in temperature measurement caused by the surroundings, it is best to calibrate the instrument to a known and reliable source.

As an example, consider a 22 gauge (0.7112 mm) bare thermocouple. When it is used to measure the gas temperature in boiler, economizer, or air heater cavities with surrounding walls cooler than the gas, the error in the observed readings may be found from Fig. 23 (line for bare TC).

High velocity thermocouple

The design and operation of steam generating units depend on the evaluation of gas temperatures in the furnace and superheater sections of the equipment. Boiler design to achieve successful thermal performance must take into account the limitations imposed by the allowable metal temperatures of superheater

Fig. 23 General magnitude of error in observed readings when measuring temperature in boiler cavities with thermocouples.

tubes and by the fusing characteristics of ash and slag from the current or expected fuel. The overall complexity of combustion and heat transfer relationships prevents exact calculation and accurate measurement of the gas temperatures provides information to confirm calculation methods.

The optical pyrometer and radiation pyrometer are not designed to measure gas temperature. Excessive error is also encountered when gas temperatures in the furnace and superheater areas are measured with a bare thermocouple.

The high velocity and multiple-shield high velocity thermocouples (HVT and MHVT), developed to correct for radiation effects, are the best instruments available for measuring high gas temperatures in cooler surroundings or low gas temperatures in hotter surroundings. Cross-sections through single and multiple-shield high velocity thermocouples developed for use in boiler testing are shown in Fig. 24.

The surfaces (water-cooled walls, or superheater or boiler tube banks) surrounding the usual location of a gas traverse are cooler than the gases. Consequently, the readings from a bare unshielded thermocouple indicate lower temperatures than those obtained with an HVT. For the same reason, an HVT generally indicates lower values than an MHVT. A comparison between bare thermocouple, HVT and MHVT results in typical boiler furnaces and cavities is given in Fig. 23.

MHVT measurements closely approach true gas temperatures. In this design, the thermocouple junction is surrounded by multiple shields, all of which receive heat by convection induced by the high gas flow rate. In this manner, the heat transfer by radiation is so reduced that there is virtually no heat exchange between the junction and the innermost shield. Because of the small flow areas that rapidly become clogged by ash, use of the MHVT is limited to clean gas conditions. Where traverses are taken in dust- or slag-laden gases, it is usually necessary to use the HVT. The readings are corrected by comparison with results obtained under clean gas conditions from an MHVT.

For temperatures exceeding 2200F (1204C), noble metal thermocouples are required and it is important to protect the thermocouple from contamination by the gases or entrained ash. Various coverings, shown in Fig. 24, provide some protection for the wires, especially when fouling occurs from molten slag at temperatures above 2400F (1316C). When platinum thermocouples are used in gas above 2600F (1427C), appreciable calibration drift may occur even while taking measurements requiring only several minutes of exposure time. The thermocouple elements should be checked before and after use with corrections applied to the observed readings. When the error (ΔT) reaches 40 to 60F (22 to 33C), the contaminated end of the thermocouple should be removed and a new hot junction should be made using the sound portion of the wire.

Because heat transfer by radiation is proportional to the surface area, emissivity, and difference of the source and receiver absolute temperatures, the effects of radiation increase as the temperature difference between the thermocouple hot junction and the surrounding surfaces increases. Also, because heat trans-

fer to the thermocouple by convection is proportional to the gas mass velocity and the temperature difference between gas and thermocouple, the junction temperature may be brought closer to the true temperature of the gas by increasing the rate of mass velocity and convection heat transfer at the thermocouple while shielding the junction from radiation.

A special high velocity thermocouple probe for measuring high gas temperatures in boilers is illustrated in Fig. 25. This portable assembly is primarily used for making test traverses in high duty zones by insertion through inspection doors or other test openings in the setting.

This thermocouple is supported by a water-cooled probe. The measuring junction is surrounded by a tubular porcelain radiation shield through which gas flow is induced at high velocity by an attached aspirator. The gas aspiration rate over the thermocouple can be checked by an orifice incorporated with the aspirator and connected to the probe by a flexible hose. The gas mass velocity (or mass flux) over the thermocouple junction should be at least 15,000 lb/h ft² (20.34 kg/m² s). Convection heat transfer to the junction and shield is simultaneous and both approach the temperature of the gas stream. Radiation transfer at the junction is diminished by the shield. Because the shield is exposed to the radiation effect of the surroundings, it may gain or lose heat and its temperature may be slightly different from the junction temperature.

With the increasing size of steam generators, handling long HVT probes has become more difficult but,

Fig. 24 Shield assemblies for high velocity thermocouple (HVT) and multiple-shield, high velocity thermocouple (MHVT).

Fig. 25 Rugged, water-cooled, high velocity thermocouple (HVT) for determining high gas temperatures.

to date, no acceptable point by point measurement of high temperature gases has been fully developed.

Measurement evaluations

Large boilers may have significant variation in actual measurements at a particular measurement plane. Where significant data variation exists, data reduction may require mathematical methods to weight-average individual measured values during the data reduction process.

Flue gas temperature measurements at the economizer outlet during performance tests are an example of a large number of data points which require reduction to a single representative temperature.

A weighted average temperature becomes time consuming and the need for such accuracy must be justified. An average of the individual temperature measurements is usually acceptable if a sufficient number of points are obtained. The average gas temperature may be approached by increasing the number of points or by instrument design to satisfy a particular requirement. For example, in a heat loss efficiency test, multiple measuring locations are used to indicate flue gas exit temperatures for determining dry gas loss. The number of points required by the ASME Performance Test Code permits efficiency accuracies within 0.05%.

Under certain circumstances, the maximum, rather than average, gas temperature may be required for equipment protection. A moveable probe with one or two thermocouples may be used to determine the location of this high temperature. For instance, during boiler pressurization and before steam is flowing through the superheater or reheater tubes, a bare thermocouple temporarily installed in the gas stream immediately before the tubes may be used to indicate the highest temperature to prevent tube overheating. These thermocouples are normally removed after steam flow is adequate for cooling. On units designed for remote operation, it is possible to remotely retract

and insert these thermocouples using a sootblower carriage. The remotely insertable thermocouple is called a thermoprobe.

Insulation and casing temperature

Outer surfaces

The measurement method should be carefully selected to avoid significant errors in measuring uncased insulation surface temperature. Portable contact thermocouple instruments designed to be pressed against a surface are unsatisfactory on insulated surfaces because the instrument cools the surface at the point of contact, and the low rate of heat transfer through the insulating material prevents adequate heat flow from surrounding areas to the contact point.

Thermocouple attachment to the insulation surface must not appreciably alter the normal rate of heat transmission through the insulation and from the surface to the surroundings. Fine wires can be attached and maintained at the surface temperature more easily than heavy wires. If the insulation is plastic at the time of application, press the thermocouple junction and several feet of lead wire into the surface of the insulation; the thermocouple will adhere when the insulation hardens. If the insulation is hard and dry, the junction and lead wires may be cemented to the surface using a minimum of cement. Fastening the wires to the surface with staples introduces conduction errors. Covering the wires with tape changes the heat transfer characteristics of the surface and imposes an undesirable insulation layer between the wire and the ambient air.

Steel casings

The temperature of steel boiler casings may be accurately measured with portable contact thermocouple instruments, because lateral heat flow from adjoining metal areas quickly compensates for the small quan-

tity of heat drawn by the instrument at the contact point. Thermocouple wires may be peened into or fused onto the metal surface to form the hot junction. Thermal contact between the lead wires and the surface should be maintained for several feet. The wire installation should minimize any disturbance of heat transfer from the surface to the surrounding air. Approximate surface temperatures may be conveniently measured with fusion paints or crayons.

Thermometers are sometimes fastened to metal surfaces with putty. This method gives an approximate surface temperature indication if the metal is massive and near ambient temperature. It is not recommended for boiler casing temperature measurement and is completely unsatisfactory for measuring insulation surface temperature.

Through-steel components, such as metal ribs imbedded in insulation and studs or door frames extending through insulation, cause considerable local upsets in surface temperatures and their influence may spread laterally along a metal casing. These effects must be considered in planning and interpreting surface temperature measurement.

Infrared cameras may be used to measure surface temperatures. These instruments can minimize the need for complex thermocouple installations, especially if large surface areas are to be measured. Improved equipment permits recording for further review.

Measurement of steam quality and purity

The most common methods of field testing for steam quality or purity are:

1. sodium tracer (flame photometry),
2. electrical conductivity (for dissolved solids),
3. throttling calorimeter (for direct determination of steam quality), and
4. gravimetric (for total solids).

Each of these methods is described in ASME Performance Test Code 19.11, *Water and Steam in the Power Cycle*. The throttling calorimeter determines steam quality directly, whereas the other methods determine the steam solids content.

Most of the solids content of steam comes from the boiler water, largely in the carryover of water droplets. (See also Chapter 5.) It is customary to relate steam quality and solids content of steam by the following equation:

$$x = 100 - \left[\frac{\text{solids in steam} \times 100}{\text{solids in boiler water}} \right] \quad (6)$$

where x equals % steam quality in percent by weight and solids are expressed as equivalent parts per million (ppm) (by weight) of steam or water.

By the use of Equation 6, steam quality can be determined if the solids content is known. This relationship is subject to error resulting from carryover of solids in solution in the steam or in vaporized form. This effect occurs principally with silica at pressures above 2000 psi (13.79 MPa).

The four steam quality measurement methods may be summarized as follows:

1. The sodium tracer method, with continuous recording of total dissolved solids in steam, is used for the highest accuracy.
2. The conductivity method is useful within certain limitations but is less accurate.
3. The calorimeter method is not suitable for measuring extremely small quantities of carryover and at pressures exceeding 600 psi (4.14 MPa).
4. Gravimetric analyses require large samples and do not detect carryover peaks.

Obtaining the steam sample

If the steam quality results are to be accurate, the instruments must be supplied with a representative steam sample. The method of obtaining a steam sample and the operation of the boiler during testing are fundamentally the same for each testing method.

The sampling nozzle design should be as recommended by ASME Performance Test Code 19.11. It should be located after a run of straight pipe equal to at least ten diameters. Locations in the order of preference are:

1. vertical pipe, downward flow,
2. vertical pipe, upward flow,
3. horizontal pipe, vertical insertion, and
4. horizontal pipe, horizontal insertion.

The nozzle should be installed in the saturated steam pipe in the plane of a preceding bend and in a position that ensures the sampling ports directly face the steam flow. On boilers with multiple superheater supply tubes, sampling nozzles should be located in tubes spaced across the width of the drum. These sampling points should be at no greater than 5 ft (1.52 m) intervals.

When a calorimeter is used the connection from the sampling nozzle to the calorimeter must be short and well insulated to minimize radiation losses. Connections must be steam-tight so the insulation remains dry.

When steam purity is tested by conductivity or sodium tracer methods, the tubing from the sampling nozzles to the condenser should be steel (preferably stainless), with an inside diameter not exceeding 0.25 in. (6.4 mm). It should be of minimal length to reduce the storage capacity of the line. Multiple connections can be run to a common line and then to the condenser. However, these connections should be valved so that each one can be sampled individually to isolate possible selective carryover. Cooling coils, or condensers, should be located close to the sampling nozzles to minimize settling of solids in the sample line.

Sodium tracer method

The sodium tracer technique permits measuring dissolved solids impurities (carryover) in steam condensate to as low as 0.001 ppm.

Sodium is present in all boiler water where chemical treatment is in the form of solids. The ratio of the total dissolved solids in the steam condensate to the total dissolved solids in the boiler water is proportional

to the ratio of the sodium in the steam condensate to the sodium in the boiler water. By determining the sodium content of the steam condensate and boiler water and the total dissolved solids in the boiler water, the solids content of the steam and the percent moisture carryover may be calculated. The sodium content of steam condensate and water is usually determined by using a flame photometer. The effect of any change in boiler operating conditions on carryover is promptly indicated, facilitating problem analysis.

The operation of a flame photometer is illustrated in Fig. 26. The condensed steam sample is aspirated through a small tube in the burner into the oxygen-hydrogen flame. The flame, at 3000 to 3500F (1649 to 1927C), vaporizes the water and excites the sodium atoms, which emit a characteristic yellow light having a definite wavelength. The intensity of the emitted yellow light is a measure of the sodium in the sample. The intensity of the light is measured with a spectrophotometer equipped with a photomultiplier attachment.

The light from the flame is focused by the condensing mirror and is directed to the diagonal entrance mirror. The entrance mirror deflects the light through the entrance slit and into the monochromator to the plane mirror. Light striking the plane mirror is reflected to the fiery prism where it is dispersed into its component wavelengths. The desired light wavelength is obtained by rotating a wavelength selector which

adjusts the position of the prism. The selected wavelength is directed back to the plane mirror where it is reflected through the adjustable exit slit and lens. The light impinges on the photomultiplier tube, causing a current gain which registers on the meter. The amount of sodium in the sample is obtained by comparing the emission from the water sample to emissions obtained from solutions of known sodium concentration.

Conductivity method

Electric conductivity can be used to determine steam purity in certain boilers. This method is applicable to units operating with significant solids concentration in the boiler water and with a total steam solids content in excess of 0.5 ppm.

The conductivity method is based on the fact that dissolved solids, whether acids, bases or salts, are completely ionized in dilute solution and, therefore, conduct electricity in proportion to the total solids dissolved. On the basis of solids normally present in boiler water, the solids content in parts per million equals the electrical conductivity of the sample in micromho per mm times 0.055.

The condensed sample should ideally be free from dissolved gases, especially ammonia (NH_3) and CO_2 , which contribute nothing to the solids content of the steam but have a significant effect on conductivity.

Fig. 26 Schematic arrangement of flame photometer.

Throttling calorimeter

When steam expands adiabatically without doing work, as through an orifice, the enthalpies of the high and low pressure steam are equal, provided there is no net change in steam velocity. Such an expansion is termed throttling. As can be seen from a Mollier chart (see Chapter 2), wet steam with an enthalpy exceeding 1150 Btu/lb (2675 kJ/kg) becomes superheated when throttled to atmospheric pressure. The temperature of the expanded steam determines the enthalpy, which may be used with the pressure of the wet steam to determine the percent moisture in the wet steam sample.

The foregoing principle is used in various forms of throttling calorimeters. Each incorporates a small orifice for expansion of the steam sample into an exhaust chamber, where the temperature of the expanded steam is measured at atmospheric pressure. Velocity changes in properly designed calorimeters are negligible. The variations in the different designs are chiefly in the means of shielding the unit from external temperature influences. At pressures below 600 psi (4.14 MPa), the calorimeter shown in Fig. 27 is used. This is a small, low cost, simple, accurate instrument which gives good results for steam having appreciable quantities of moisture: up to 4.3% at 100 psi (0.69 MPa), 5.6% at 200 psi (1.38 MPa) and 7.0% at 400 psi (2.76 MPa).

Fig. 27 shows the calorimeter installed and ready for use. The connection should be short; the connection and the calorimeter should be well insulated. It is essential that the calorimeter discharge be completely unobstructed, so no backpressure can build in the exhaust chamber. The orifices must be clear, full opening and of the correct diameter: 0.125 in. (3.175 mm) for pressures from atmospheric to 450 psi (3.10 MPa) and 0.0625 in. (1.588 mm) from 451 to 600 psi (3.11 to 4.14 MPa). The thermometer should be immersed in oil of suitably high flashpoint. The calorimeter is operated by fully opening the shutoff valve and letting the steam discharge through the unit to the atmosphere. The calorimeter must be thoroughly warmed up and in temperature equilibrium before normal temperature or test readings are taken.

Fig. 27 Throttling calorimeter showing sampling tube in steam pipe.

In obtaining calorimeter readings, the temperature of the expanded and superheated steam is measured by a thermometer inserted in the thermometer well. Due to radiation from the calorimeter installation, thermometer corrections and orifice irregularities, the observed temperature is generally lower than the actual temperature. To determine a suitable correction, the as-installed temperature of the calorimeter should be determined. This can be done by taking readings when the boiler is known to be delivering dry saturated steam. This is the case when the boiler output is steady at about 20% of rated capacity with low water concentration and steady water level. The normal correction is obtained by subtracting the as-installed temperature from the theoretical temperature, read from the zero moisture curve of Fig. 28. The normal correction should not exceed 5F (2.8C). If it does, the calorimeter orifice is clogged, the insulation is faulty, or some other test feature is incorrect. When the unit is used to determine the quality of a wet steam sample, the percent moisture can be found from the curves of Fig. 28 using measured drum pressure and corrected calorimeter temperature. When properly installed, insulated and operated, the calorimeter can give accurate results for steam moisture contents as low as 0.25% for low pressure boilers. For pressures above 600 psi (4.14 MPa) and for greater accuracy of steam purity measurement in the low ppm range, other methods of measurement should be used.

Gravimetric analysis

Gravimetric analysis is used to determine solids levels, particularly total solids, in a condensed steam sample. It consists of evaporating a known quantity

Fig. 28 Percent moisture in steam versus calorimeter temperature.

of condensed steam to complete dryness and weighing the residual. This can be done on a batch basis or by a continuous sample system.

While a gravimetric analysis provides an accurate measure of total solids in water, its main disadvantage is that it requires a relatively large quantity of water obtained over an extended period of time. It therefore does not localize carryover peaks when they occur. Time lag in other methods of steam purity measurement is usually small enough to permit attributing peaks of carryover to periods of high water level, high boiler water solids, or other operating upsets.

Flow measurement

Fluid flow includes water, steam, air and gas flow. While there are many means of measuring flow, the basic methods for the accuracy required by the ASME Performance Test Code use the orifice, flow nozzle (flow tube), or venturi tubes as primary elements. The pressure drop or differential pressure created by these restrictions can be converted into a flow rate.

The flow of any fluid through an orifice, nozzle or venturi tube may be determined by the equation:

$$\dot{m} = C_q YA \sqrt{\frac{2g_c \rho_1 (P_1 - P_2)}{1 - \beta^4}} \quad (7)$$

where

\dot{m} = flow rate, lb/s

C_q = coefficient of discharge, dimensionless, dependent on the device used, its dimensions and installation

Y = compressibility factor, dimensionless, equals 1.0 for most liquids and for gases where the pressure drop across the device is less than 20% of the initial pressure

A = cross-sectional area of throat, ft²

g_c = proportionality constant, 32.17 lbm ft/lbf s²

P_1 = upstream static pressure, lb/ft²

P_2 = downstream static pressure, lb/ft²

β = ratio of throat diameter to pipe diameter, dimensionless

ρ_1 = density at upstream temperature and pressure, lb/ft³

Details of primary element sizing, fabrication and flow calculations can be obtained from the ASME publication *Fluid Meters, Their Theory and Application*.

Table 2 is extracted from the ASME Performance Test Code 19.5, Section 4, *Flow Measurement*, to show the advantages and disadvantages of the three primary element types. The throat tap nozzle has the highest accuracy of the primary flow measuring devices.

The primary elements listed should be fabricated of erosion and corrosion resistant materials. The orifice and flow nozzles are shown in Fig. 29; the venturi tube is shown in Fig. 30.

Even though these elements can be sized with considerable accuracy by calculation, they should be laboratory calibrated prior to precision testing. Calibration is usually by weighed water tests using scales. For commercial use, calculated flow rates or rates based on prototype testing or calibration are adequate.

Certain important factors of the primary element installation should be considered for accurate measurement. These include:

Table 2
Advantages and Disadvantages of Various Types of Primary Elements

Advantages	Disadvantages
Orifice	
<ol style="list-style-type: none"> 1. Lowest cost 2. Easily installed and/or replaced 3. Well established coefficient of discharge 4. Will not wiredraw or wear in service during test period 5. Sharp edge will not foul with scale or other suspended matter 	<ol style="list-style-type: none"> 1. High nonrecoverable head loss 2. Suspended matter may build up at the inlet side of horizontally installed pipe unless eccentric or segmental types of orifices are used with the hole flush with the bottom of the pipe 3. Low capacity 4. Requires pipeline flanges, unless of special construction
Flow Nozzle	
<ol style="list-style-type: none"> 1. Can be used where no pipeline flanges exist 2. Costs less than venturi tubes and capable of handling same capacities 	<ol style="list-style-type: none"> 1. Higher cost than orifice 2. Same head loss as orifice for same capacity 3. Inlet pressure connections and throat taps when used must be made very carefully
Venturi Tube	
<ol style="list-style-type: none"> 1. Lowest head loss 2. Has integral pressure connections 3. Requires shortest length of straight pipe on inlet side 4. Will not obstruct flow of suspended matter 5. Can be used where no pipeline flanges exist 6. Coefficient of discharge well established 	<ol style="list-style-type: none"> 1. Highest cost 2. Greatest weight and largest size for a given size line

Fig. 29 Orifice and flow nozzles.

1. location in the piping in relation to bends or changes in cross-section,
2. possible need for approach straightening vanes,
3. location and type of pressure taps,
4. dimensions and condition of surface or piping before and after the element,
5. position of the element relative to direction of fluid flow, and
6. type and arrangement of piping from primary element to differential pressure measuring instrument.

Details of these requirements for precision testing are also covered in the ASME publication *Fluid Meters, Their Theory and Application*. These devices produce a differential pressure across the element and a differential pressure gauge should be used for the flow measurement.

Flow measurement of combustion air or flue gas generally does not require a high degree of precision. Orifices, flow nozzles, or venturis are also used, but the rigid requirements of construction and location are usually not possible because of space limitations. As a substitute, a component of the steam generator, located in the flow path, can create a suitable pressure differential, which is used to obtain a flow measurement.

For example, the draft loss across the gas side of an air heater may be used as an index of the flue gas flow. Because pressure differentials vary with a change in surface cleanliness, these are not highly reliable methods. The use of orifices, flow nozzles, venturi air foils, or impact suction tubes in areas free of entrained dust and at relatively stable temperatures prove more satisfactory. Fig. 31 illustrates two types of venturi sections used in air ducts for measuring combustion air flow. Fig. 32 illustrates an impact suction pitot tube arrangement for metering primary air flow to a pulverizer. For a dependable determination of air flow, the primary element should be calibrated at normal operating pressure and temperature. Test connections, or sampling points, for this purpose are located at a zone in the duct or pipe where good flow characteristics are obtainable, and the calibrating flow measurements are made using a hand held pitot tube or equivalent probe. The pitot tube, when inserted facing the air or gas flow stream, measures velocity pressure, that is, the difference between total and static pressure. The velocity pressure measurement can be converted into a velocity reading for English units only by:

Fig. 30 Dimensional proportions of classical (Herschel) venturi tubes with a rough-cast, convergent inlet cone. (Source: ASME, *Fluid Meters, Their Theory and Application*, Sixth Edition, 1971.)

$$V = 1097 \sqrt{\frac{h_V}{\rho}} \quad (8)$$

where

V = velocity, ft/min

h_V = velocity head as indicated by pitot tube differential, in. wg

ρ = density at the temperature of the sampling location, lb/ft³

A typical pitot tube and measuring manometer are illustrated in Fig. 33. The pitot tube has a coefficient of 1.0, which is applied to velocity head readings, eliminating the need for corrections. Fig. 34 shows a method of traversing a round duct using a pitot tube.

An additional portable flow measuring device that can be used for calibration purposes is the Fechheimer

probe. It also has a coefficient of 1.0 and incorporates a null balance feature that permits determining when the probe faces the direction of gas flow. This probe is illustrated in Fig. 35. In this schematic, the outer holes in the probe are each at exactly 39.25 deg from the centerline hole, placing them at a point of zero impact pressure and providing a reading of true static pres-

Fig. 31 Venturi sections for air ducts.

Fig. 32 Averaging pitot tubes.

Fig. 33 Arrangement of pitot tube and manometer.

sure. When the probe faces the gas flow, a manometer connected across the two outer holes shows a zero, or null, balance. Because the centerline hole receives full impact or total pressure when facing into the gas stream, a manometer connected across one outer hole and the centerline hole gives true velocity pressure, that is, impact pressure less static pressure.

The impact suction or reversed type pitot tube, illustrated in Fig. 36, produces a differential pressure greater than one velocity head, which gives a magnified reading. This type of pitot tube measures flow in either direction. To use the reversed type pitot tube for flow measurement, calibration is required for the Reynolds number range as well as for the geometry of the flow channel and its orientation in the stream.

Permanently installed pitot tubes are used where relatively high pressure losses due to the primary measuring element are undesirable. Flow tubes are also used in these cases. These tubes differ from most other primary elements in that the flow channel cross-section varies symmetrically in the inlet and exit directions from the contoured throat section.

The throat section is equipped with two sets of pressure taps, one set pointing upstream and one downstream, similar to impact suction pitot tubes. Each set of taps is interconnected and the two sets in turn are connected to a differential pressure gauge. The pressure taps are located at cross-sections of equal area so that the differential developed is a result of impact and suction pressure differences only and is, therefore, a function of the velocity head alone.

Many other types of flow measuring devices exist. The pitot tube grid incorporates an array of pitot tubes in a flow path. The primary signal is a pressure differential. The array of pitot tubes measures a number of flows and minimizes measurement errors caused by flow unbalance and upstream conditions. The hot wire anemometer measures flow using a probe with a small wire at the tip. Flow over the wire removes heat, and flow may be measured when the hot wire is in equilibrium with electrical power input and heat lost. Doppler phenomena may be applied to flow measure-

Fig. 34 Pitot tube traverse.

Fig. 35 Fechheimer probe.

Fig. 36 Combined-type pitot tube with reversed static tube. (Source: ASME, *Fluid Meters, Their Theory and Application*, Sixth Edition, 1971.)

ment with laser or acoustic transmissions. The transmission signal and type of fluid make these methods very application specific.

Computer application to measurement

The application of computer technology to instrumentation provides the capability to further understand the operating characteristics of many interrelated power plant components and processes at a much faster rate than was previously possible. Measurements have progressed from readings recorded at local gauges, strip charts, or manually recorded test gauges to significant quantities of information acquired in seconds.

The instrument readings are not made directly at the instrument, but rather transmitted signals from the instrument are entered into a data acquisition system and the reading is indicated at a computer. The computer gathers, stores, interprets and displays the information. The display appears as an extension of the instrument. The information gathered may be further manipulated for process control or equipment performance computations.

Performance computation

Computer computation permits calculations in near real time for boiler efficiency and other plant performance indicators. These performance indicators provide

rapid updates to operating information and provide a check on measurement errors. Measurements of temperature, pressure and flow that might be in error because of instrument calibration are identified rapidly.

Process control

A computer based control system receives its basic information from a data acquisition system which accumulates information from the plant instrumentation. Process control is achieved according to specific mathematical algorithms. The control system, updated by current data or operator interface, produces output signals to modulate components based on these algorithms.

Data acquisition system

A typical data acquisition system consists of computer hardware and related software. The basic hardware components are the computer, a signal multiplexer and the measuring instrument. The computer program (software) controls the hardware operation and data recording. In operation, the program causes the signal multiplexer to read a specific instrument analog output signal. The signal is converted from an analog to a digital signal, which is conveyed to the computer and stored in memory. The first processing of the data is the storage of the digitized signal in a data array. Data acquisition, incorporating many instruments, other computer outputs and manual inputs, requires that each of the signals be assigned a specific location in the array. The stored signal may be converted to engineering units and stored in another array. Furthermore, the data may be averaged over time and then stored. Performance calculations are generally performed using data converted to engineering units and averaged over time. Portable data acquisition systems are generally used for specific test purposes and may use high precision transmitters and thermocouples.

Signal multiplexer

The signal multiplexer in a data acquisition system provides an interface between the transmitted instrument signal and the computer. The typical multiplexer provides signal conditioning, analog to digital signal conversion and switching capability for multiple inputs. It produces a digital output signal for computer processing and assignment to a position in the data array. Significant engineering design is required to accommodate the variety of signals entering the multiplexer.

Data acquisition computer program

The data acquisition software may be program oriented or menu oriented but should readily permit changes to the quantity of signals, the rate at which the computer reads each signal and the computations performed with each signal. Data storage and retrieval are but two of many design considerations for computer program configurations.

Chapter 41

Controls for Fossil Fuel-Fired Steam Generating Plants

Instruments and controls are essential to all steam generating installations, promoting safe, economic and reliable operation of the equipment. They range from the simplest manual devices to complete systems that automatically control the boiler and all associated equipment.

Boiler control systems, particularly those applied to boiler turbine-generator units, are of several types that perform varied control functions. In the past, the accepted practice has often been to identify these functions as separate and independent systems, often applied to the boiler by different suppliers. Today, a power plant control system is most often an integrated package with demand requirements applied simultaneously to the boiler, turbine and major auxiliary equipment. This minimizes the number of complex interactions between subsystems.

Various types of boiler control systems for fossil fuel boilers include:

1. combustion (fuel and air) control,
2. steam temperature control for superheater and reheater outlet,
3. drum level and feedwater flow control,
4. burner sequence control and management systems,
5. bypass and startup,
6. systems to integrate all of the above with the turbine and electric generator control,
7. data processing, event recording, trend recording and display,
8. performance calculation and analysis,
9. alarm annunciation system,
10. management information system, and
11. unit trip system.

An overall integrated control system for a fossil fuel-fired drum boiler is described later in this chapter.

Basic control theory

Boiler control is the regulation of the boiler outlet conditions of steam flow, pressure and temperature to their desired values. In control terminology, the boiler outlet steam conditions are called the outputs or controlled variables. The desired values of the outlet conditions are the set points or input demand signals. The quantities of fuel, air, and water are adjusted to obtain the desired outlet steam conditions and are called the manipulated or controlled variables.

Disruptive influences on the boiler, both internal and external, such as fuel heating value variations, unit load change or change in cycle efficiency, are called disturbance inputs. The controller or control system looks at the desired (set points) and actual (output variables) values of the outlet steam conditions and adjusts the amounts of fuel, air and water (manipulated variables) to make the outlet conditions match their desired values. The controller can be manual, with an operator making the adjustments, or automatic, with a pneumatic system, electronic analog computer, or a digital computer making the adjustments. A block diagram of a conceptual boiler control system is shown in Fig. 1.

While it is theoretically possible to operate a boiler with manual control, the operator must maintain a constant watch for a disturbance. Time is needed for the boiler to respond to a correction and this can lead to overcorrection with further upset to the boiler. An automatic controller, on the other hand, once properly

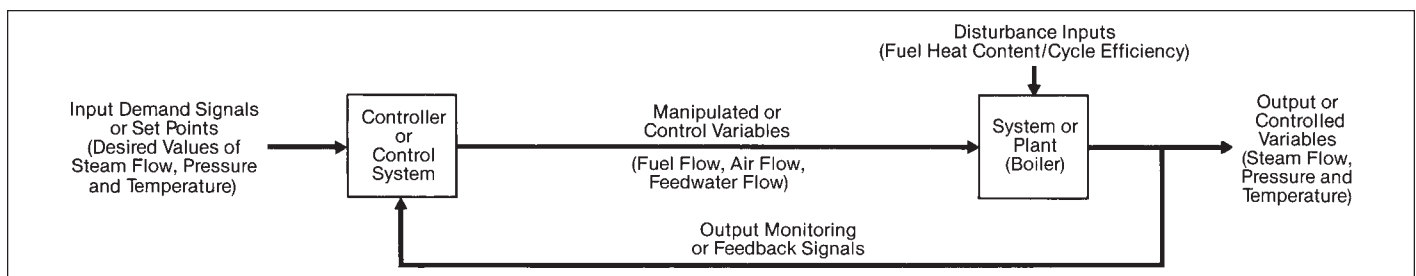

Fig. 1 Block diagram of conceptual boiler control system.

tuned will make the proper adjustment quickly to minimize upsets and will control the system more accurately and reliably.

The various types of automatic control can be illustrated by Fig. 2, which represents the control of one output variable, steam pressure, in a hypothetical boiler. The set points for steam pressure and steam flow will be used as reference values, and the manipulated variable is the fuel valve position. Disturbance inputs act on the boiler, which is the system to be controlled.

Open loop control

The simplest control mode is an open loop, feedforward, or non-feedback control. The manipulated variables of fuel, air and water are adjusted only from the input demand signals without monitoring the outlet conditions or output variables. As an example, Fig. 3 illustrates an open loop control system used to accomplish the control function illustrated by Fig. 2. Fig. 3a is a block diagram representing the action to be taken, which is feedforward only. Fig. 3b is a calibration curve expressing fuel valve position as $f(x)$, a function of steam flow demand. This curve, established by calibrating or programming the fuel valve position required to maintain the desired steam flow with a constant steam pressure, is entered into the controller. The response of this open loop control is fast and depends only on the accuracy of the calibration curve.

One difficulty with open loop control is that the calibration curve is accurate only as long as the boiler conditions are the same as when the calibration was set. Another problem is that the output changes as the load changes on the output signal (the fuel valve in Fig. 3). For example, a change in friction on the valve stem will cause a variation in valve position in response to a given input demand signal. This introduces an error into the performance of the open loop control. Such disadvantages normally outweigh the open loop advantages of stability and simplicity.

Closed loop control

Usually the process requirements can not be met by an open loop control, and a closed loop or feedback control must be used. In closed loop control, the actual output of the system is measured and compared to the input demand signal with the difference between the two signals (the error signal) used to eliminate this difference.

The open loop system of Fig. 3 could be closed by having an operator observe the measured steam pres-

Fig. 3 Open loop mode using steam flow demand to vary fuel input.

sure and then manually adjust the fuel valve position to obtain the fuel flow necessary to maintain the desired steam pressure and flow. To avoid the disadvantages of manual control, an automatic controller can be provided in a closed loop or feedback system.

Proportional control

The simplest type of closed loop system is proportional control. The manipulated variable or controller output is proportional to the deviation of the controlled variable from its desired value. The deviation is called the error signal. Depending upon controller arrangement, the output signal of a proportional control system will always be either directly or inversely proportional to the controlled variable.

Fig. 4 illustrates the application of proportional control to the control function of Fig. 2. Table 1 explains symbols in Fig. 4 and subsequent figures. In this system, for every deviation of steam pressure from its set point, the fuel valve will be moved to a specific position, as shown in Fig. 5, for three values of relative

Fig. 2 Simplified block diagram of a boiler control function.

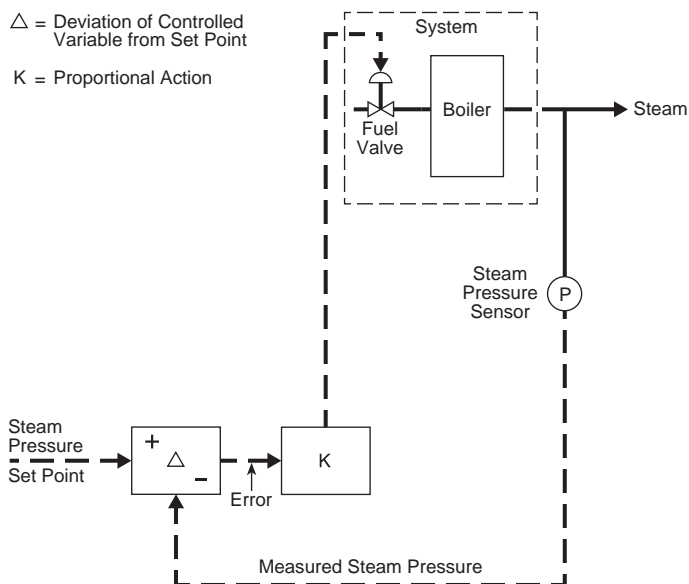

Fig. 4 Proportional control.

proportional gain. In Fig. 5, the relative proportional gain could be set so that a pressure error of 10 psi (68 kPa) initiates a 50% change in position of the fuel valve which in the system calibration would be called a gain of 1.0. If the control were set to be two or four times as sensitive, the relative proportional gain would be said to be 2.0 or 4.0 respectively. In the latter case, a change of 2.5 psi (17.2 kPa) in steam pressure initiates a 50% change in fuel valve opening.

The response of steam pressure to step increases in load on the boiler is shown in Fig. 6 for two values of

Fig. 5 Fuel valve opening for various pressure deviations in proportional control system.

proportional gain on the controller. A step increase in load or steam flow immediately decreases the steam pressure which, through the proportional controller, causes the fuel valve to open by a proportional amount. The additional heat input due to the increased fuel flow causes the steam pressure to return toward its set point, which in turn reduces the fuel valve opening.

There may be a certain amount of cycling or searching, depending on the proportional gain of the controller, before the steam pressure stabilizes. It is noted in Fig. 6 that the steam pressure does not stabilize at its set point, but is offset to a lower value. A characteristic of proportional only control is that an error or

offset is necessary to provide a steady-state fuel valve opening which will support the desired load, except for a single load condition.

An increase in the relative proportional gain or sensitivity will reduce the final offset in the steam pressure as shown in Fig. 6. An increase in proportional gain may increase the time required for the system to reach a steady-state condition. This offset is always present with proportional control and, if the gain is increased even more to reduce the offset, undamped oscillations will result.

Proportional plus integral control

The offset may be eliminated by adding integral or reset control to the proportional control system (Fig. 7). The response of the boiler to a step increase in load, when using a proportional plus integral control system, is shown in Fig. 8. The steam pressure is returned to its set point without the offset. However, the system may be less stable as it takes a longer period of time for the steam pressure to stabilize with the offset completely eliminated.

Integral control, as its name implies, is based on the repetitive integration of the difference between the controlled variable and its set point over the time the deviation occurs. Integral control is also referred to as reset control because the band of proportional action is shifted or reset so that the manipulated variable operates about a new base point.

Proportional plus integral plus derivative control

The stability and response of the system can be improved further by adding a third mode of action called derivative or rate control. Derivative control action is a function of the rate of the controlled variable change from its set point, as shown in Fig. 9. The addition of this control function is shown in Fig. 10. As soon as the step change is made, the pressure starts to drop and the proportional mode begins to open the fuel valve. The derivative mode will also open the fuel

Fig. 8 Response of steam pressure to step increase of load in proportional plus integral control system.

valve further, as a function of the rate at which the pressure is changing, anticipating where the valve should be positioned. When the rate of steam pressure change decreases, the derivative control has less effect and the proportional and integral action do the final valve positioning.

Feedforward/feedback control

In a closed loop system, the controlled variable must deviate from its set point before the controller initiates a corrective action. The open loop system therefore has a faster response because it takes corrective action before the controlled variable starts to change. When the open loop or feedforward system is combined with the closed loop or feedback system, the result is a fast response system that can compensate for changes in the calibration curve. Fig. 11 represents a feedforward/feed-back control system for the control function of Fig. 2.

As the step change in load occurs, the feedforward signal immediately positions the fuel valve to meet the calibration curve requirements. If this curve is exact, no error develops and the feedback loop has no work to do. If the calibration curve is in error, the feedback loop readjusts the fuel valve position to eliminate any pressure error which may develop due to shifts in the calibration. However, the response will be faster and the magnitude of the system upset will be smaller because the feedforward signal moves the valve near its final steady-state position leaving a smaller range of action for the feedback loop.

Control system design philosophy for a utility boiler

The effectiveness of a boiler turbine-generator unit, as a power producing system, depends on how well it can respond to demands. To achieve optimum response from the unit while maintaining stable pressure and temperature, the control system must coordinate the boiler and turbine. Because the boiler can not produce rapid changes in steam generation by changes in throttle pressure, the turbine valves open and close for initial load response. This initial change permits the new steam flow requirements to be met at the existing throttle pressure. The control system then acts to restore the proper amount of stored energy to the boiler by coordinating the boiler and turbine. This

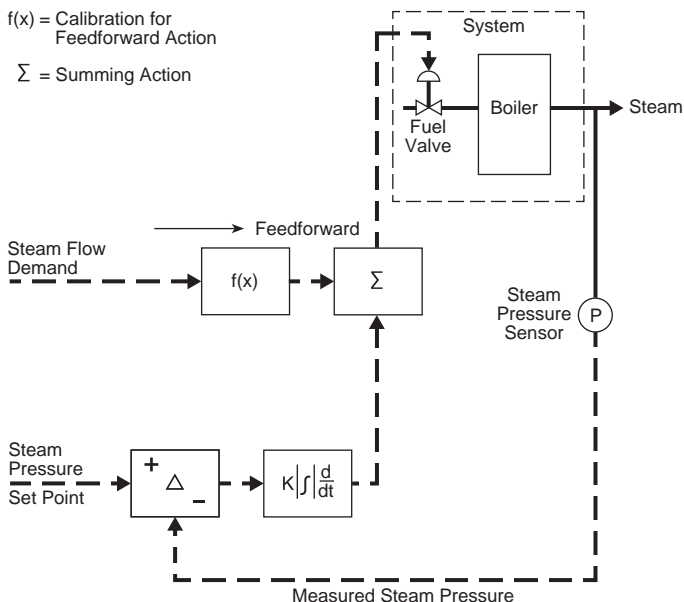

Fig. 11 Feedforward/feedback control.

must be done without exceeding the operating limits of the boiler or turbine-generator.

Characteristics of different control modes

Boiler-following control This mode of operation is designed for the boiler response to follow turbine response. Megawatt load control is the responsibility of the turbine-generator. The boiler is assigned secondary responsibility for throttle pressure control. The demand for a load change repositions the turbine control valves. Following a load change, the boiler control modifies the firing rate to reach the new load level and to restore throttle pressure to its normal operating value.

Load response with this type of system is rapid because the stored energy in the boiler provides the initial change in load. The fast load response is obtained at the expense of less stable throttle pressure control. A boiler-following control system is illustrated in Fig. 12.

Turbine-following control In this operating mode, turbine response follows boiler response. Megawatt load control is the responsibility of the boiler while the turbine-generator is assigned secondary responsibility for throttle pressure control. With increased load demand, the boiler control increases the firing rate which, in turn, raises throttle pressure. To maintain a constant throttle pressure, the turbine control valves open, increasing megawatt output. When a decrease in load is demanded, this process is reversed. Load response with this type of system is rather slow because the turbine-generator must wait for the boiler to change its energy output before repositioning the turbine control valves to change load. However, this mode of operation will provide minimal steam pressure and temperature fluctuation during load change. A conventional turbine-following control system is shown in Fig. 13.

Coordinated boiler turbine control While both of the above systems can provide satisfactory control, each

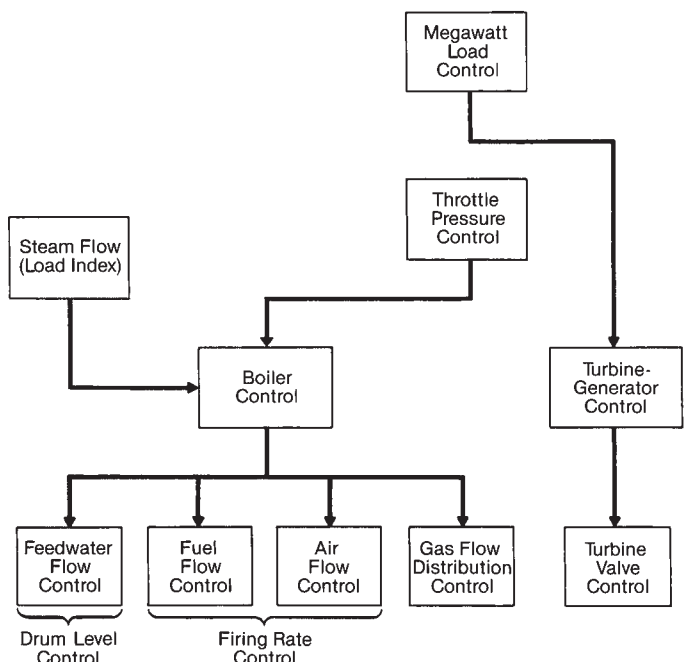

Fig. 12 Boiler-following control system.

has inherent disadvantages and neither fully exploits the capabilities of both the boiler and turbine-generator. The turbine-following and boiler-following systems may be combined into a coordinated control system giving the advantages of both systems and minimizing the disadvantages. The coordinated boiler turbine-generator control system is shown in Fig. 14. Megawatt load control and throttle pressure control are the responsibility of both the boiler and the turbine-generator. One type of a coordinated system assigns the responsibility of throttle pressure control to the turbine-generator, taking advantage of the stability of a turbine-following system. In addition, the system uses the stored energy in the boiler, taking advantage of the fast load response of a boiler-following system.

Because the boiler is not capable of producing rapid changes in steam generation at constant pressure, the turbine is used to provide the initial load response. When a change in load is demanded, the throttle pressure set point is modified using megawatt error (the difference between the actual load and the load demand), and the turbine control valves respond to the change in set point to give the new load level quickly. As the boiler modifies the firing rate to reach the new load and restore throttle pressure, the throttle pressure set point returns to its normal value. The result is a fast and efficient production of electric power through proper coordination of the boiler and turbine-generator. The response is much faster than the turbine-following system, (Fig. 13). However, it is not as fast as the boiler-following system because the effect of megawatt error is limited to maintain a balance between boiler response and stability. Wider limits would provide more rapid response while narrower limits would provide more stability.

A comparison of response characteristics of various arrangements of a boiler turbine-generator control system for a large change in load demand is shown in Fig. 15.

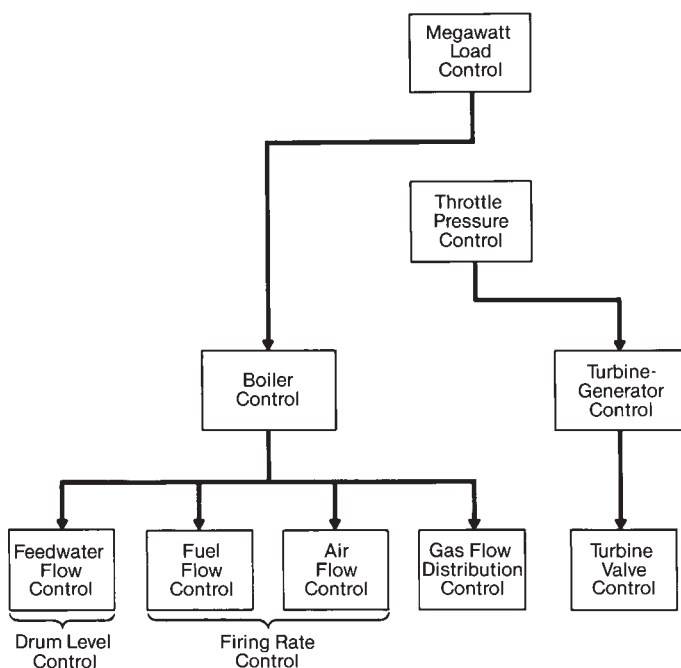

Fig. 13 Turbine-following control system.

Development of the coordinated control system received added impetus when electric power generating companies introduced the wide area economic load dispatch system. This system requires precise load control. Each controlled unit must produce a specific level of megawatts and the area load control system adjusts the turbine control valves until this level is reached. Even relatively minor interactions between steam flow and throttle pressure can create a continuous interaction between the boiler, the turbine-generator, and the area load control. The conventional boiler-following system, which is subject to such interactions between steam flow and throttle pressure, does not lend itself to area load control because two highly responsive systems would be adversely interacting with each other.

Wide area economic load dispatch systems require controlling the boiler and turbine-generator together in a coordinated system. This achieves automatic control over a wide operating load range.

Integrated boiler turbine-generator control The integrated control system, in its basic form, consists of ratio controls that monitor pairs of controlled inputs, including:

1. boiler energy input to generator energy output,
2. superheater spray water flow to feedwater flow,
3. fuel flow to feedwater flow,
4. fuel flow to air flow,
5. recirculated gas to air flow; this, in effect, is a ratio of reheater absorption to absorption in primary water and steam, and
6. fuel to primary air flow for pulverized coal-fired units.

Fig. 16 is a simplified diagram showing all system inputs controlled in a parallel relationship by ratio controls.

The integrated control system, shown in Fig. 17, coordinates the boiler and turbine-generator for fast

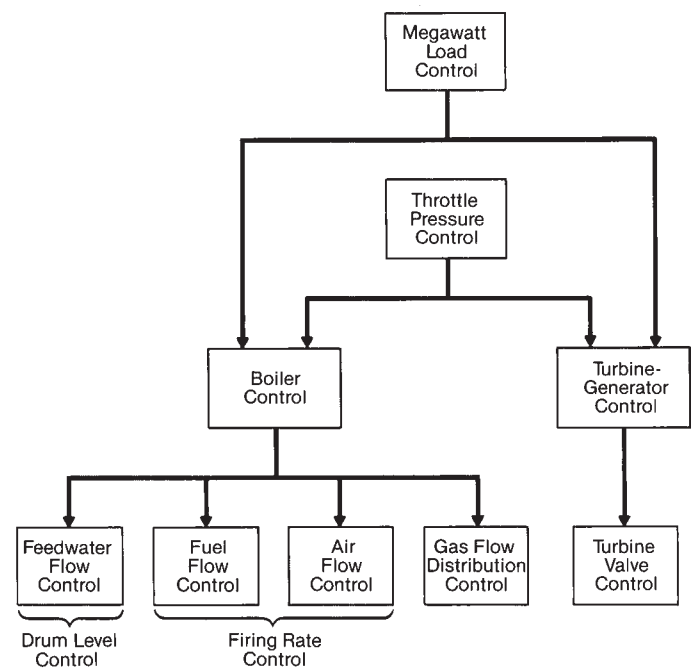

Fig. 14 Coordinated boiler turbine-generator control system.

Fig. 15 Megawatt load change and throttle pressure deviation.

and efficient response to load demand initiated by the automatic load dispatch system. See Table 1 for control symbols.

Variable pressure operation

A variable pressure boiler operates with the throttle pressure varying with load. In its purest form, the throttle valves on the turbine are left wide open and throttle pressure varies directly with load. There are recognized advantages of variable pressure operation at lower loads. These include minimum change in turbine metal temperature due to the elimination of the adiabatic throttling effect of turbine valves. Improved cycle efficiency at reduced loads results from reduced boiler feed pump power and higher turbine inlet steam temperatures. However, there are disadvantages including sluggish response to load change demand because of little energy storage during operation. Typically, the load demand change response rate for variable pressure operation is approximately 50% of the response rate for constant pressure operation.

The Babcock & Wilcox Company (B&W) drum boiler bypass and startup system adds another dimension

to variable pressure operation. The system, shown in Fig. 18, can generate and deliver steam to the turbine with a wide range of controlled throttle pressure and temperature to assure the least thermal stress to the turbine and consequently the most rapid startups.

This system combines the advantages of constant pressure operation of the boiler with variable pressure operation of the superheater and turbine. The throttle pressure is controlled by modulating the superheater division valves with the drum pressure held at or near full load pressure. The control strategy and operating procedure are equivalent to variable throttle pressure operation with load or steam flow controlled by the turbine control valves.

Cycling operation

Most of the fossil fuel-fired drum boilers being installed today will encounter cycling operation. Cycling involves taking a unit off-line on nights and weekends and reloading it on weekday mornings.

This analysis of cycling units assumes that the daily load cycle starts at full load, full temperature operation and passes successively through a load reduction, an off period and an idle period. This is followed by a restart and a reloading back to full load, full temperature. The basic difficulty is that steam temperatures must be controlled to limit cyclic thermal stresses on the turbine. The boiler lacks capability for temperature control during startup and low load. Therefore, the turbine requirements and the boiler capability are not compatible unless an interfacing system is provided. The startup system described above (Fig. 18) provides this interface.

A more aggressive integrated control strategy is needed to take full advantage of the boiler turbine system capabilities while recognizing the limitations of each. The principles applied to such a control system include:

1. The fuel heat content effectively released in the boiler furnace will establish and maintain the megawatt output from the unit on a steady-state basis. Therefore, the only valid boiler load index for fuel and air input is megawatt demand and/or generation.

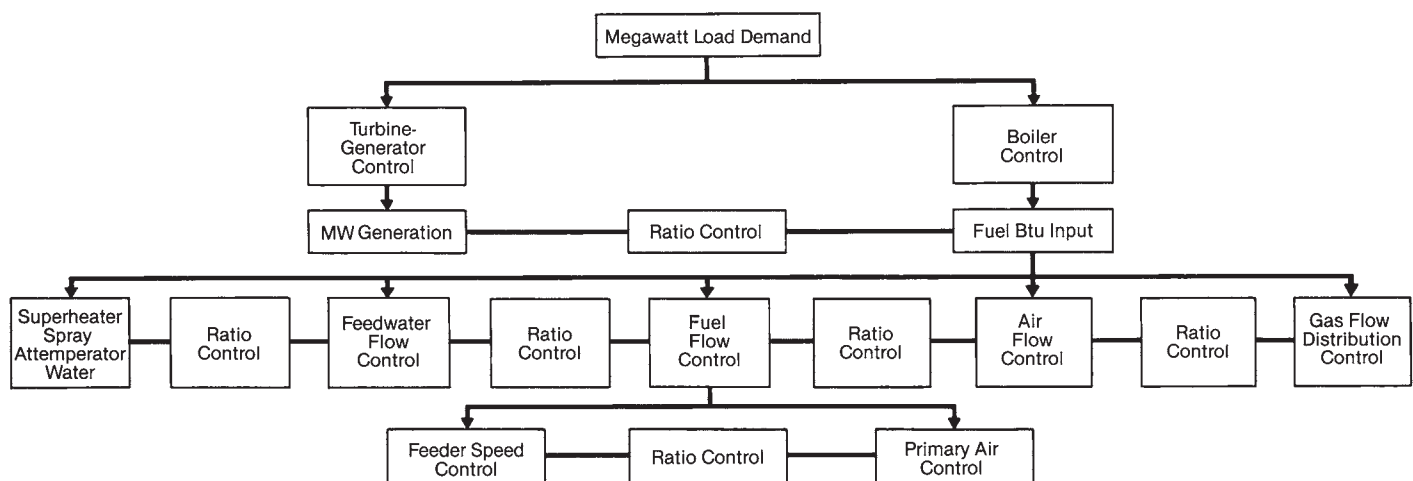

Fig. 16 Simplified diagram of ratio control.

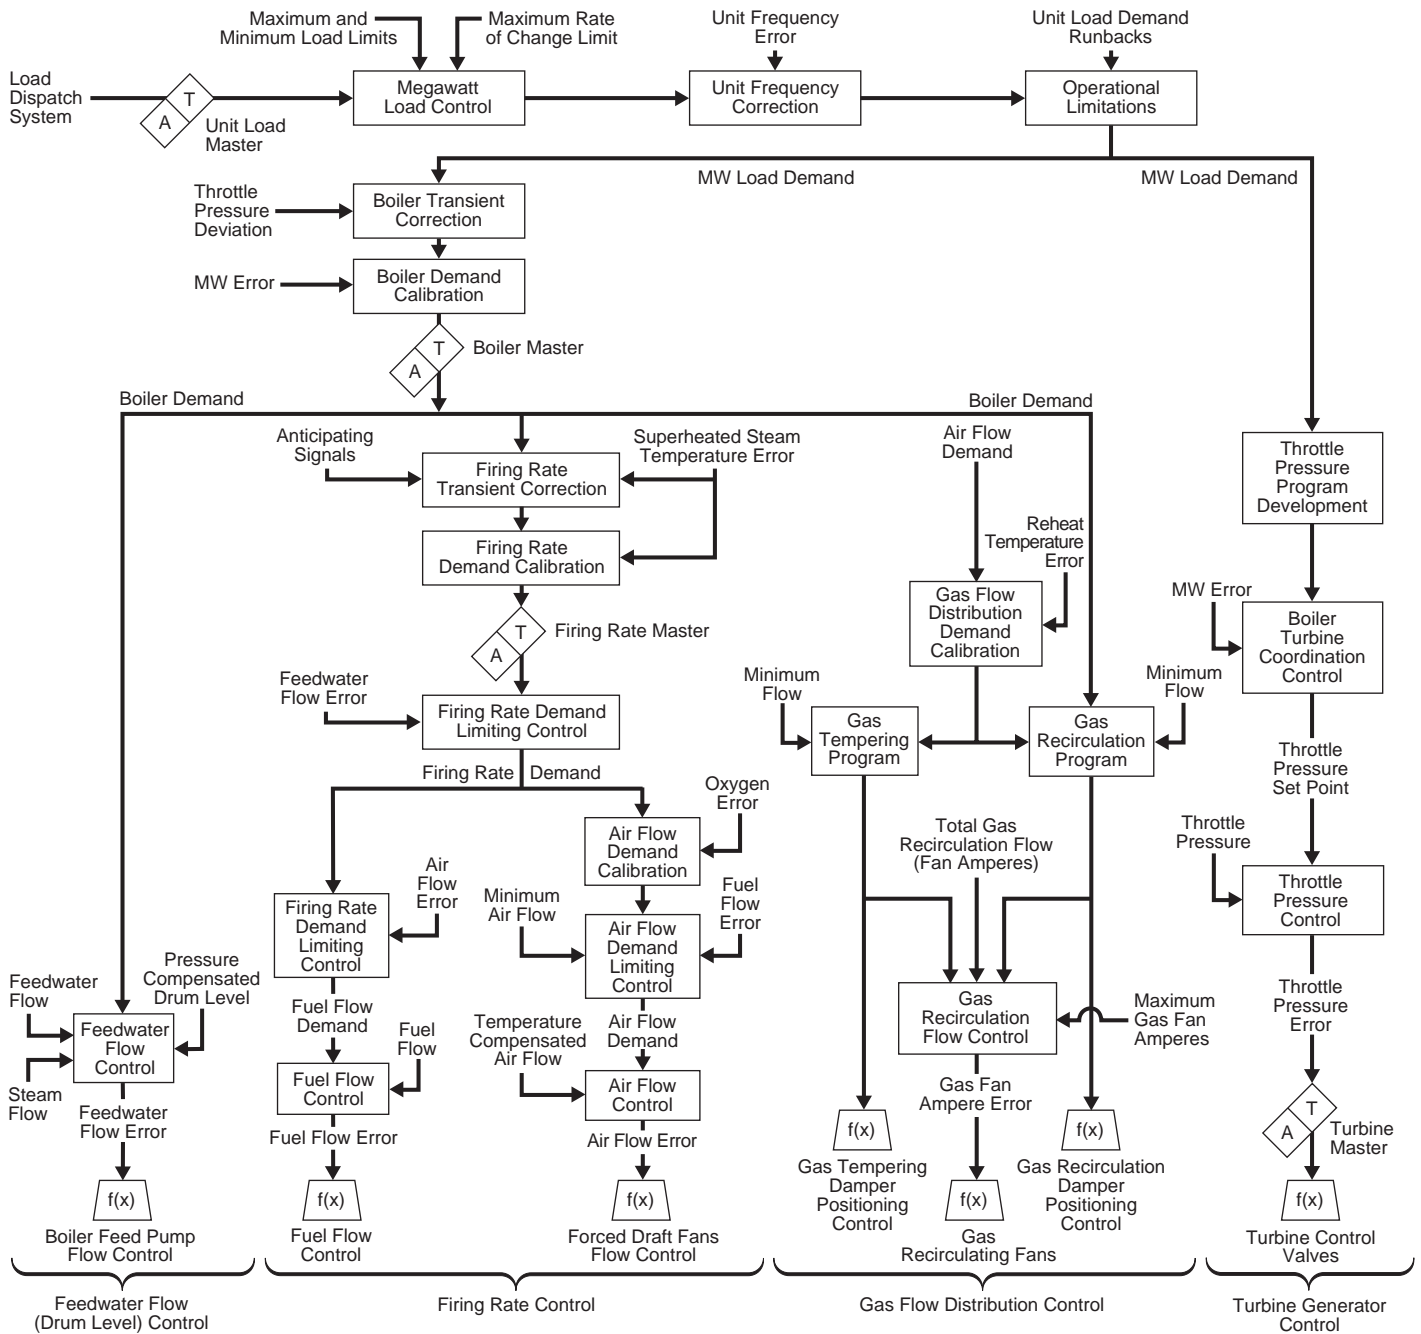

Fig. 17 Integrated boiler turbine-generator control system.

2. The turbine valve control will control steam flow and megawatt generation but only on a short term transient basis.
3. The relationship between steam flow and megawatt generation is not dependent on the turbine valve position.

Feedwater control systems

Feedwater control regulates the flow of water to a drum-type boiler to maintain the level in the drum within the desired limits. The control system will vary with the type and capacity of the boiler as well as with load characteristics.

The control strategy of the feedwater control sys-

tem can be one of three types. They are classified as one-, two- or three-element feedwater control systems.

In single element feedwater control (Fig. 19) the water in the drum is at the desired level when the signal from the level transmitter equals its set point. If a deviation of water level exists, the controller applies proportional plus integral action to the difference between the drum level and set point signals to change the position of the regulating valve. A hand-automatic station gives the operator complete control over the valve. A valve positioner can be included in the control valve assembly to match the valve characteristics to the individual requirements of the system.

Single element control will maintain a constant drum level for slow changes in load, steam pressure

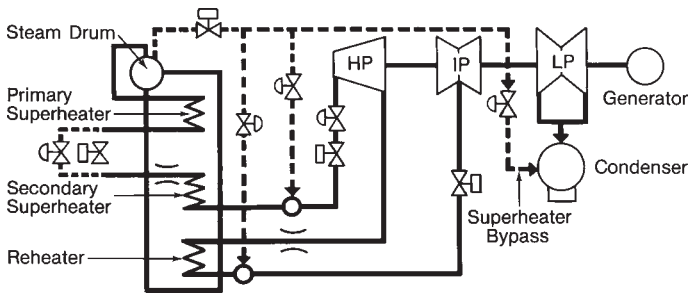

Fig. 18 Superheater bypass and startup system for drum boiler.

or feedwater pressure. However, because the control signal satisfies the requirements of drum level only, excessive swell (increase in steam bubble volume due to an increase in load) or shrink (decrease in steam bubble volume due to a decrease in load) effects will result in wider drum level variations and a longer time for restoring drum level to set points following a load change with single element control than with two- or three-element control.

Two-element control comprises a feedforward control loop which utilizes steam-flow measurement to control feedwater input, with level measurement assuring correct drum level. This control strategy is primarily used in industrial applications and seldom used in power generating plants.

The most widely used feedwater control system, especially in the utility industry, is the three-element feedwater control.

Three-element control is a cascaded-feedforward control loop which maintains water flow input equal to feedwater demand. Drum level measurement keeps the level from changing due to flow meter errors, blowdown, or other causes.

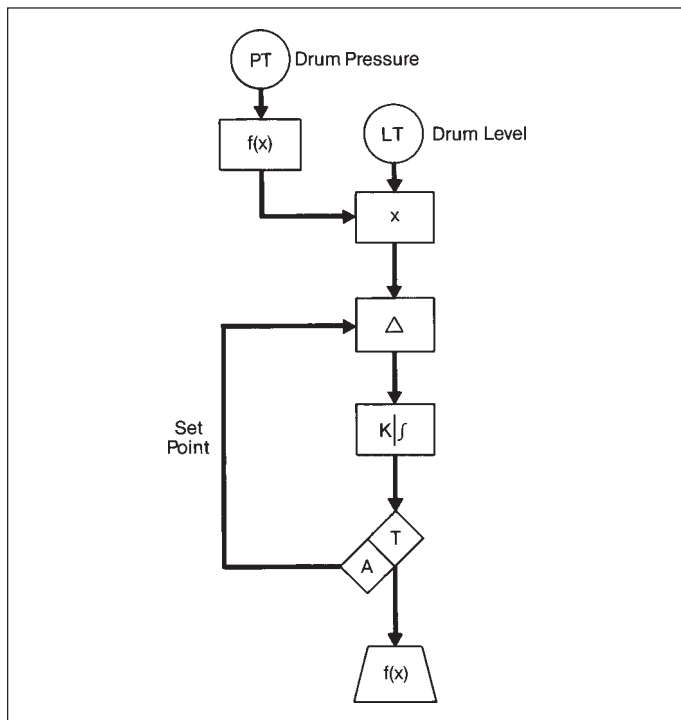

Fig. 19 Single element feedwater control.

The control applies proportional action to the error between the drum level signal and its set point. The sum of the drum level error signal and the steam flow signal is the feedwater demand signal. This is the output of the summer. The feedwater demand signal is compared with the water flow input and the difference is the combined output of the controller. Proportional plus integral action is added to provide a feedwater correction signal for valve regulation or pump speed control. A hand-automatic station gives the operator complete control over the valve. In single boiler turbine units, the turbine first stage shell pressure can be used as a measure of steam flow. The details of this system are illustrated in Fig. 20, using the symbols given in Table 1.

Three-element feedwater control systems can be adjusted to restore a predetermined drum level at different loads. In boilers with severely fluctuating loads, the system can be modified to permit drum water level to vary with boiler load to compensate for swell and shrink effects. If the drum level is allowed to vary in this manner, a nearly constant inventory of water, as opposed to a constant level, is maintained.

During low load operation (0 to 20%), it is difficult to obtain steam and water flows accurately because flow transmitters are usually calibrated for high load operation. It is advisable to transfer the feedwater control system to single element control. Drum level is the only variable used in the control scheme. Automatic transfer as a function of load between three element and single element control is often provided.

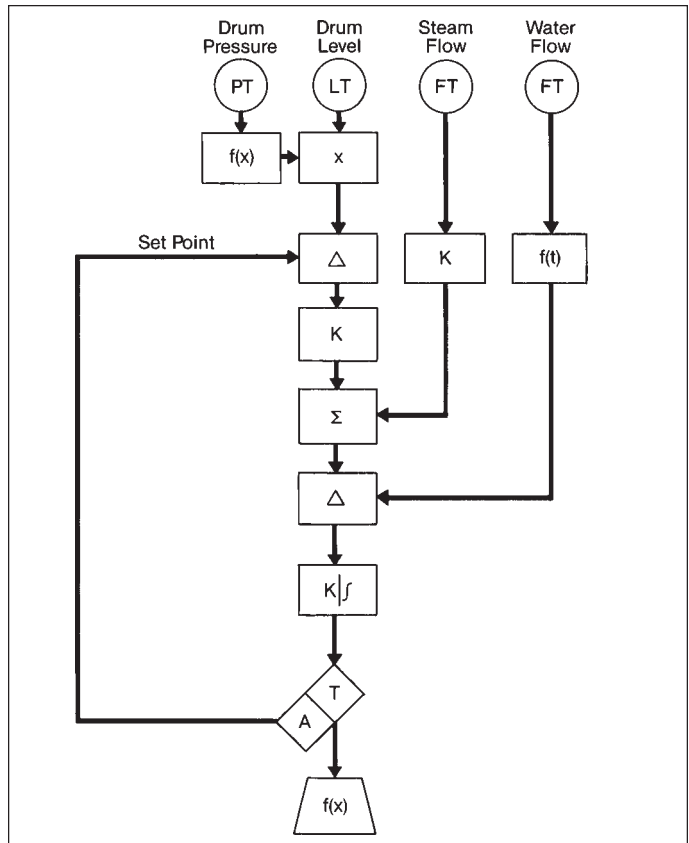

Fig. 20 Three-element cascade feedforward control loop for feedwater flow control.

Drum water level is one of the most important measurements for safe and reliable boiler operation. If the level is too high, water can flow into the superheater with droplets carried into the turbine. This will leave deposits in the superheater and turbine, and in the extreme, cause superheater tube failure and turbine water damage. Consequences of low water level are even more severe. An insufficient head of water may cause a reduction in furnace circulation, causing tube overheating and failure. To provide a more reliable system B&W recommends the use of three independent drum level transmitters as inputs to an auctioneered remote level signal system for control, interlocking, alarming and tripping functions. To provide an additional safeguard, the control logic for drum level should be independent of the boiler tripping logic. It is also important to install and calibrate drum level instrumentation with care. Instrumentation to be provided must be in accordance with The American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code. Minimum drum water level instrumentation used on utility size power boilers should be one water gauge glass and two indirect water level indicators with alarm and trip points clearly marked.

Furnace draft control

The furnace draft control regulates the induced draft (ID) fans to provide the proper exhausting force for flue gas flow through the boiler. When the ID fans are properly balanced with the forced draft (FD) fans, the furnace pressure will be at the desired operating level. To improve reliability and meet National Fire Protection Association NFPA 85 requirements, furnace pressure is measured with three independent transmitters connected to independent connections. A median select auctioneering system selects the median or middle of the three transmitter signals for control. The ID fans are regulated by a feedforward program based on air flow demand which is then corrected by any deviation of furnace pressure from its desired set point. This control strategy must also include furnace overpressure and implosion protection overrides. The most common and most dangerous disturbance is furnace implosion.

Furnace implosion is usually the result of a combination of a master fuel trip (flame collapse) and an equipment malfunction resulting in a vacuum condition in the furnace. The control system must include two furnace override circuits to minimize any negative pressure excursions. The first is a low furnace pressure override which will proportionally drive the inlet dampers or vanes closed when the median furnace pressure signal shows a large negative furnace pressure excursion. The second is a master fuel trip (MFT) kicker (or rundown) circuit which will temporarily start driving the ID fan inlet damper or vanes in the closed direction as soon as a MFT occurs without waiting for a negative furnace excursion to develop. The magnitude of the closing of the ID fan inlet dampers or vanes is dependent on the existing unit load, as represented by steam flow. These override circuits are required by NFPA 85 to be downstream of

the hand/automatic control stations of the ID fans so that operator action is not permitted. Fig. 21 illustrates the furnace draft control strategy.

Superheat and reheat temperature control

From the viewpoint of control system designers, there are inherent advantages to considering boiler outlet steam temperature control as an independent temperature control system. A greater understanding is gained if the temperature control systems are recognized as a system for distributing the boiler heat input between steam generation, steam superheating and steam reheating. Starting from that viewpoint, some of the inherent limitations of boilers to control temperatures and the difficulties in reaching design solutions can be identified. For the various methods of steam temperature control, refer to Chapter 19.

Combustion control systems (air and fuel flow control)

A combustion control system regulates the fuel and air input, or firing rate, to the furnace in response to a load index. The demand for firing rate is, therefore, a demand for energy input into the system to match a withdrawal of energy at some point in the cycle. For boiler operation and control systems, variations in the boiler outlet steam pressure are often used as an index of an unbalance between fuel-energy input and energy withdrawal in the output steam.

A great variety of combustion control systems have been developed over the years to fit the needs of particular applications. Load demands, operating philosophy, plant layout, and types of firing must be considered. The following examples show some of the systems for various types of fuel firing. The control symbols shown in these figures are listed in Table 1.

Oil- and gas-fired boilers Fig. 22 illustrates a system for burning oil and gas, separately or together. The fuel and air flows are controlled from steam pressure through the boiler master with the fuel readjusted from fuel flow and air flow. The oil or gas header pressure may be used as an index of fuel flow and the windbox to furnace differential as an index of air flow on a per burner basis. Such indices are common for single burner boilers. For multiple burner boilers, a pitot tube or other flow measuring instrument is used to provide more accurate air flow measurement.

Pulverized coal-fired boilers Fig. 23 illustrates a more sophisticated combustion control that would be used on larger boilers having several pulverizers. Each pulverizer supplies a group of burners that are located in an open or compartmented windbox. Primary and secondary air are admitted and controlled on a per-pulverizer basis.

To compensate for boiler and pulverizer response characteristics, a firing rate kicker (derivative action) is usually required on the pulverizer system. The boiler firing rate demand is then compared to the total measured fuel flow (summation of all feeders in service delivering coal) to develop the demand to the fuel-air master. The fuel-air master demand signal is then applied in parallel to all operating pulverizers.

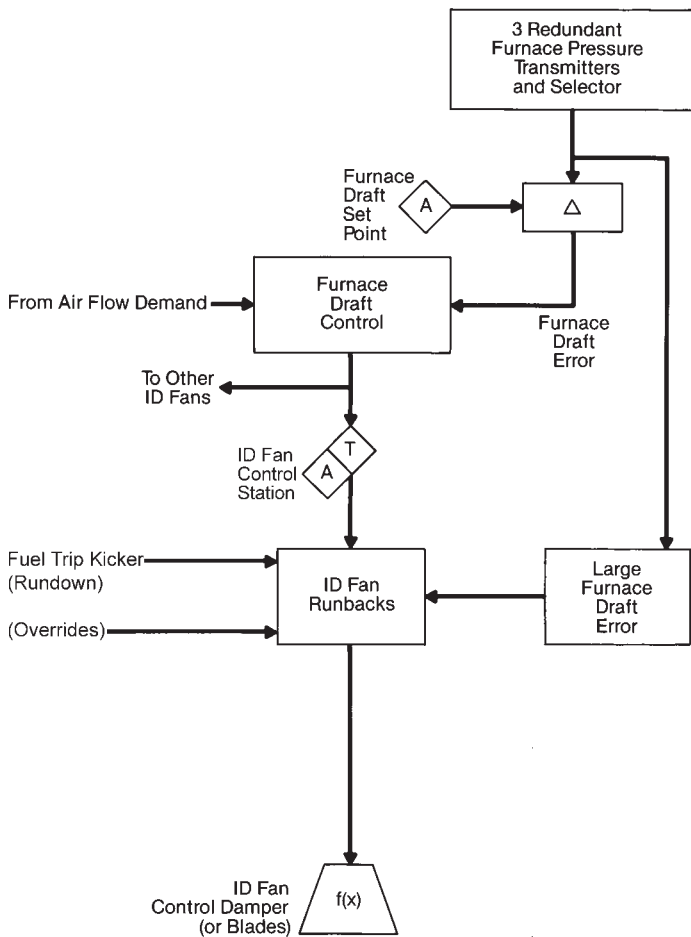

Fig. 21 Furnace draft control.

The individually biased pulverizer demand signal is then applied in parallel to meet demands for coal flow, primary air flow, and total pulverizer group air flow (primary and secondary air flows). When an error develops between demanded and measured primary air flow or total air flow, proportional plus integral action will be applied, adjusting the primary or secondary air dampers to reduce the error to zero. A low primary air flow or total air flow cross-limit is applied in the individual pulverizer control. If either measured primary air flow or total air flow is low relative to coal rate demand, this condition is recognized in the air flow cross limits in the coal feeder demand to reduce the demand to that equivalent to the measured air flows. A minimum pulverizer loading limit, a minimum primary air flow limit, and a minimum total air flow limit are applied to the respective demands to keep the pulverizers above their minimum safe operating load. (See Chapter 13.) A minimum load limit maintains sufficient burner nozzle velocities at all times, and maintains primary air/fuel and total air/fuel ratios above prescribed levels.

High capacity vertical shaft pulverizers, such as the B&W Roll Wheel™ pulverizer (Chapter 13), are being supplied on most large boilers today to achieve the required steam flow capacities with coal having low heating values. Pulverizer response can be improved by overshooting both primary air flow and feeder

speed. This overfeed is obtained with present control systems by the use of kickers on primary air flow and coal flow developed from a change in pulverizer demand.

Cyclone-fired boilers The Cyclone™ boiler (see Chapter 15) controls shown in Fig. 24 are similar to those described for pulverized coal-fired units. Although the Cyclone furnace functions as an individual furnace, the principles of combustion control are the same.

On multiple Cyclone installations, the feeder drives are calibrated so that all feeders run at the same speed for the same master signal. The total air flow is controlled by the velocity damper in each Cyclone furnace to maintain the proper air/fuel relationship. This air flow is automatically temperature compensated to provide the correct amount of air under all boiler loads. The total air flow to the Cyclone furnace is controlled by the windbox to furnace differential pressure, which varies with load to increase or decrease the forced draft fan output.

Automatic compensation for the number of Cyclone furnaces in service has been incorporated, along with an oxygen analyzer. This gas analyzer helps the operator monitor excess air for optimum firing conditions.

Atmospheric pressure fluidized-bed boilers The circulating fluidized bed thermal performance (load, power consumption, furnace temperature, combustion efficiency, gaseous emissions) is strongly dependent on the solids mass or inventory distribution within the system, solids size, and solids flow within and through the system. (See Chapter 17.) Specific examples of the special role of solids in a circulating fluidized-bed process include the following:

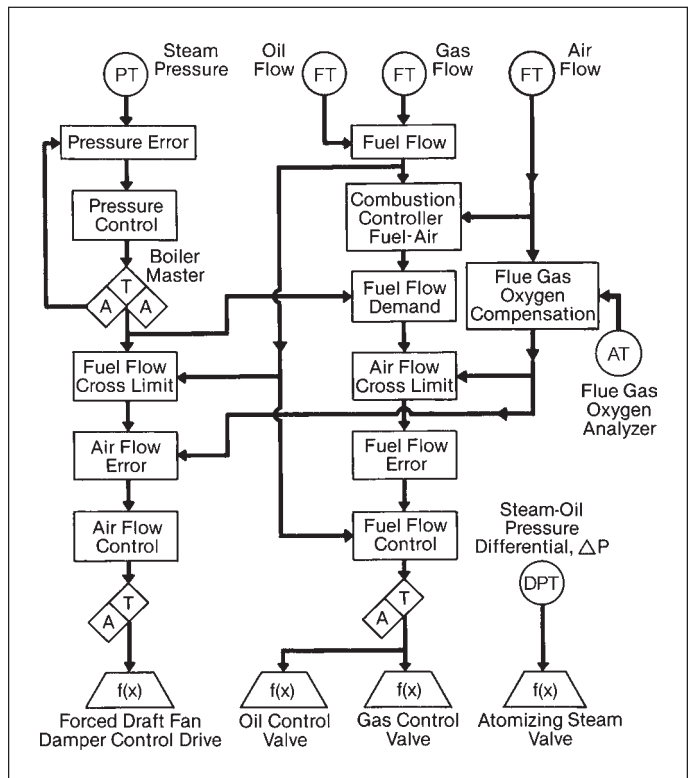

Fig. 22 Diagram of combustion control for an oil- and gas-fired boiler.

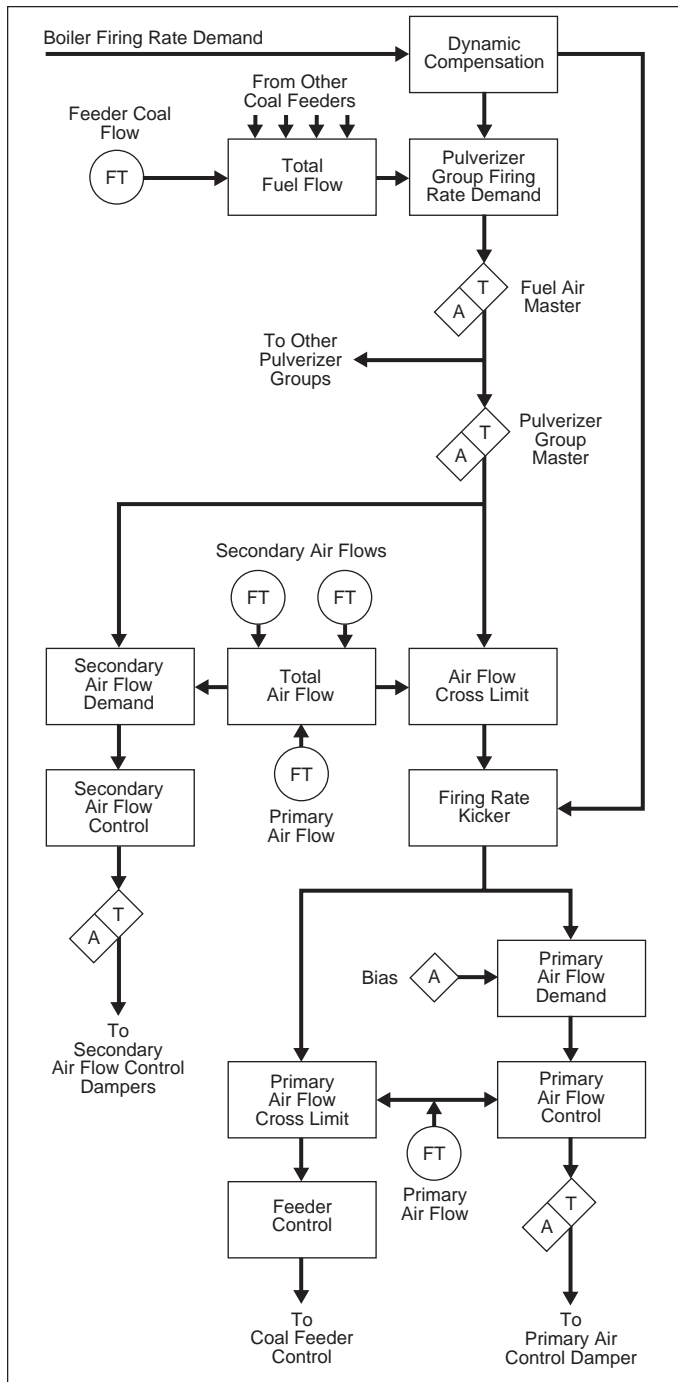

Fig. 23 Diagram of combustion control for a pulverized coal-fired boiler.

1. furnace heat absorption is controlled through changes in solids inventory,
2. fuel combustion is affected by the solids inventory distribution in the furnace,
3. solids size strongly affects furnace heat transfer and inventory distribution, U-beam and multiclone dust collector efficiencies, solids flow in the system, and solids losses,
4. carbon conversion efficiency and sorbent consumption depend on amount and distribution of solid effluents,
5. U-beam collection efficiency depends on the solids level in the particle storage hopper, and

6. forced draft fan operating point, power consumption and air flow depend on the furnace solids inventory.

Different areas of circulating fluidized-bed process control are interrelated, with the solids inventory control function playing a central role. The complexity of process control makes it difficult to analyze and predict system performance for multiple combinations of the process variables. Additional problems have been caused by continuous variation of material and energy inputs and widely different speeds of the system dynamic responses to these variations. Much is to be learned from operation of commercial and laboratory circulating fluidized-bed units to define more exactly the optimal control strategy.

Control system design philosophy for Universal Pressure (UP®) once-through boilers

The use of the once-through boiler design in the United States (U.S.) stems from continuing efforts to reduce electric power generating costs. The once-through boiler can operate at full steam temperature over a wider load range, and can operate at supercritical pressures to increase cycle efficiency. The B&W Universal Pressure UP® boiler is one type of a once-through boiler.

The once-through concept can best be visualized as a single tube as discussed in Chapters 1 and 26. Feed-

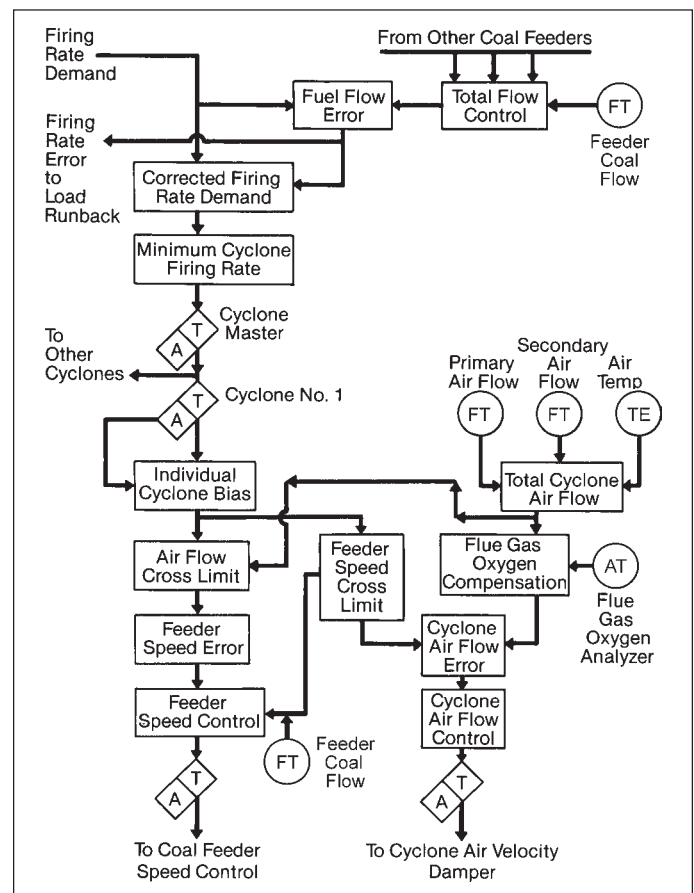

Fig. 24 Diagram of combustion control for a Cyclone-fired boiler.

water is pumped into one end, heat is applied along the length of the tube, and steam flows out of the other end. The output is a function of the feedwater flow and the amount of heat supplied. The outlet fluid enthalpy, or heat content, depends only on the ratio of heat input to feedwater flow. A valve at the outlet provides a means of varying the pressure level. When the pressure level is maintained constant, the outlet steam temperature is also dependent only on the ratio of heat input to feedwater flow.

At steady-state conditions, feedwater flow equals steam flow. The pressure level will be influenced by the valve restriction at the outlet and by the density of the fluid throughout the system. Therefore, a change in heat input will influence both pressure and temperature. It is possible to vary the flow and pressure at the outlet by changing the amount of valve restriction, or at the inlet by changing both the feedwater flow and the heat input. It is important to note that a change in feedwater flow without a corresponding change in the heat input will result in a change in the outlet steam temperature. During transient conditions, other factors, such as the fluid and energy storage requirements which change with load, must be considered because they influence the feedwater flow and heat inputs.

Combustion guides

With the increase in complexity and automation of steam generating plants, it is necessary to provide the operating personnel with information about significant operating events to assist the operator to make rapid evaluations of the operating situation. The NFPA 85 Boiler and Combustion Systems Hazards Code requires that the following information, at a minimum, be provided to the operating personnel in a continuous trend display:

1. Steam flow
2. Feedwater flow rate
3. Total fuel flow rate (% of maximum unit load)
4. Total air flow rate (% of maximum unit load)
5. Drum level
6. Final steam temperature
7. Main steam pressure
8. Furnace pressure/draft

Excess Air

The level of excess air is one index commonly used to determine the performance of the unit and to guide its operation. Excess air is the amount of air supplied above the theoretical air needed for combustion. (See Chapter 10.) It is always necessary to supply some excess air to assure complete combustion of the fuel. Any excess air not used constitutes a loss in boiler efficiency by exhausting excess heat up the stack.

Steam flow-air flow

The comparison of steam flow to air flow can give an immediate indication of fuel consumption efficiency. Because boiler efficiency at a specific load remains

essentially constant for a given amount of excess air, fuel consumption can be determined from steam flow, which is established by standard flow measuring devices. Steam flow is used as an index of heat absorption. The air flow indication or index can be established by primary elements located on either the air side or the flue gas side of the unit.

Air flow measurement

From a control standpoint, the preferred location for air flow measurement is in the clean air duct between the air heater and the burners. Available air measuring devices are discussed in Chapter 40.

The alternate location for air flow measurement is on the flue gas side, with connections to measure pressure differences resulting from the flow of combustion products through a section of the main boiler or air heater. The products of combustion at a given flue gas temperature are proportional to the amount of air supplied; therefore, the flue gas flow can be an index of air flow.

The measurement of combustion air supplied to a boiler is made difficult by several factors:

1. The air measuring device is typically of the restrictive type, similar to the primary elements used in other flow measurements. The resulting unrestored head loss means added fan power.
2. On large and complicated units it is usually impossible to find one duct through which all of the combustion air passes. Metering equipment capable of accurately totaling several flows must then be used.
3. Air density must be considered in both the calibration and operation of any air flow meter. Either manual or automatic temperature compensation must be applied to the air flow indication for it to reflect the mass rate of air flow.

Fuel flow-air flow

The rates of admission of fuel and air flow before combustion provide an important indication of the fuel flow to air flow ratio. With reference to NFPA 85, under no circumstances is the air flow demand to be less than the boiler purge rate and shall not be reduced below the amount required by the actual fuel inputs. It is important that the fuel and air flow control subsystem be designed to keep the fuel and air in proper calibration and enable the operator to adjust the fuel-air ratio within a span consistent with the fuel being fired.

Fuel flow measurement

The measurement of gaseous fuels must consider the physical properties of the gas, particularly temperature, pressure and specific gravity. Where widely changing properties are encountered, automatic compensation should be used. A primary element installed in the main header will produce a differential pressure to actuate the recording. On less complex installations, particularly those with single burners, the pressure at the burner can be used to indicate flow.

With liquid fuels, various types of flow meters can be installed directly in the supply header to indicate

and record fuel flow. As with gaseous fuels, oil-header pressure can be used to indicate flow.

The measurement of solid fuel flow can be accomplished through weight scales or feeder speeds. The use of mass flow, however, is more accurate. The feeder can be calibrated in units of fuel flow per feeder revolution to produce a continuous flow rate. Gravimetric feeders (see Chapter 12) provide controlled weight flow rates to the pulverizers.

Gas analysis

Gas analyzers are used to determine correct fuel-air relationships. Representative flue gas samples are continuously analyzed either chemically or electronically to record the oxygen and combustibles present in the products of combustion. Because there is direct correlation between oxygen content in the flue gas and the quantity of excess air supplied to the combustion zone, the operator receives a continuous and direct reading of combustion efficiency. The indicated or recorded oxygen signal is used in adjusting the total air flow.

Comparison of combustion guides

Each combustion guide has its particular merits; none is infallible. The advantages of one may be used to overcome the disadvantages of another.

The fuel flow to air flow ratio index will illustrate how the control system proportions fuel and air continuously during severe load swings. Because coal has wide variations in fuel heating value and moisture content, the coal flow as measured by the feeders only provides an approximation of the fuel flow to the boiler. When the fuel heating value changes, the calibration of the correct fuel-air relationship also changes. Therefore, to maintain a given excess air, the proportions of air and fuel must be corrected. To compensate for this, the energy per unit mass can be calculated using the boiler as a calorimeter.

On major load changes, the steam flow to air flow is temporarily unbalanced because of the overfiring and underfiring necessary for responsive load change. The fuel consumption is normally higher or lower than indicated by the steam flow load index. This guide is also affected by changing feedwater or steam temperatures, because a variation of either temperature demands more or less transfer of heat per unit of steam produced at the specified pressure and temperature. These deviations are inherently minimized where megawatt generation is used as the index of heat absorption. It is necessary, when substantial changes may occur in steam or feedwater temperature, to provide manual or automatic compensation to the steam flow-air flow circulation.

A gas analyzer gives true excess air determinations. There is some delay because combustion must be completed before a representative sample can be obtained. If the sample is taken near the combustion zone, this delay is not usually significant. Considerable study may be needed to locate sample points that will give correct average excess air values. The dirty, hot, and corrosive conditions of the flue gases at these points make periodic maintenance necessary for continuous,

dependable sampling. The gas analyzer is an accurate index for feedback control.

Burner management systems

Burner management systems (BMS) are applied to all boilers to prevent continued operation during hazardous furnace conditions, and to assist the operator in starting and stopping burners and fuel equipment.

The most important burner control function is to prevent furnace or pulverizer explosions which could threaten the safety of operating personnel and damage the boiler and auxiliary equipment. The control system must also prevent damage to burners and fuel equipment from maloperation while avoiding false trips of fuel equipment when a truly unsafe condition does not exist.

Other important factors in the design of the burner management system are the method and location to be used in the startup, shutdown, operation and control of the fuel equipment. These factors must be understood before purchase, design, or application of a burner control system. The minimum requirements for a burner management system are specified in NFPA 85, Boiler and Combustion Systems Hazard Code.

The different categories of burner control are summarized below.

Supervised manual control

Supervised manual control (Fig. 25) is a system in which a trained operator has primary responsibility to operate the burner equipment at the burner platform. Checks on the existing conditions are dependent on observation and evaluation by the local operator. However, this system must include certain interlocks for preventing improper operator action, certain safety trips and flame detection. Good communication between the local operator and the control room is needed to coordinate the startup and shutdown of burner equipment. Supervised manual controls may be found on older boilers but are not permitted by NFPA 85 to be used on new boilers.

Remote manual sequence control

Illustrated in Fig. 26, this system represents a major improvement over manual control, permitting remote manual operation using instrumentation systems and position indications in the control room for intelligence. This system requires various burner permissives (prequalifying conditions), interlocks, and trips to account for the position of fuel valves and air registers in addition to main flame detection. With this system, the operator participates in the operation of the fuel equipment. Each sequence of the burner operating procedure is controlled from the control room and no steps are taken except by operator command.

Automatic sequence control

The next logical step (Fig. 27) is to automate the sequence control to permit startup of burner equipment from a single pushbutton or switch control. Automation, then, replaces the operator in controlling the operating sequences. Because the operator initiates

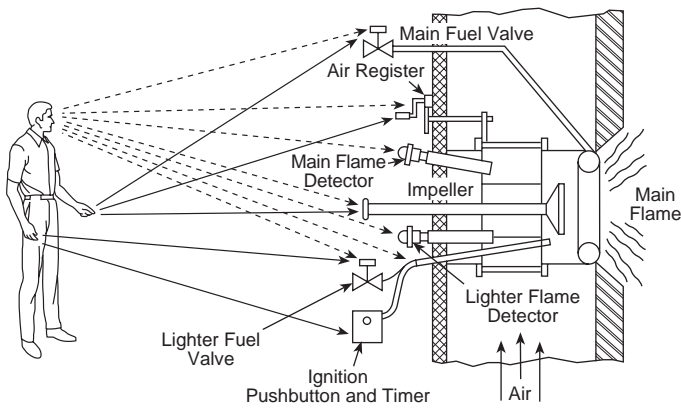

Fig. 25 Fuel burner supervised manual control.

the start command, it is expected that the operator participates in, or at least monitors each step of the operating sequence as indicated by signal lights and instrumentation signals, as the startup process proceeds to completion with the fuel utilization unit in service on automatic control. This type of system is the most common system applied to gas, oil, and coal burning systems.

Fuel management

A degree of fuel system automation can be achieved that will permit fuel equipment to be placed in service without operator supervision (Fig. 28). A fuel management system can be applied that will recognize the level of fuel demand to the boiler. This system will know the operating range of the fuel equipment in service, will reach a decision concerning the need for starting up or shutting down the next increment of fuel equipment, and will select the next increment based on the firing pattern of burners in service. Such demands for the startup or shutdown of fuel preparation and burning equipment can be initiated by the management system without the immediate knowledge of the operator.

The degree of operating flexibility allowed with a burner control system is closely related to the degree of operator participation. A higher level of automation reduces the flexibility of the operator in handling situations where a piece of equipment fails to perform as expected. One method used to provide more operat-

Fig. 26 Remote manual sequence control.

Fig. 27 Automatic sequence control.

ing flexibility is to allow operator participation at two or more levels. Increased flexibility is also obtained by the careful grouping of equipment so that a fault anywhere in the system will affect a limited amount of equipment. An example of this is the grouping of burners on a pulverizer so that the failure of a piece of hardware on a burner will only affect the failed burner, and not the pulverizer and its remaining burners.

Fig. 29 illustrates the provision for manual intervention in a fuel management type system. In this figure, functions are detailed at four levels of a pulverizer/burner group control. Manual intervention is provided at level 2 to permit remote manual operation with interlock protection features.

Flame detection

One of the most important items required for a burner management system is individual burner flame detection, regardless of fuel.

Ultraviolet (UV) flame detectors have been successfully applied to natural gas-fired burners due to the abundance of ultraviolet radiation produced by the combustion of the hydrogen in natural gas. Flicker or infrared detectors are better suited for coal- or oil-fired burners. A flicker detector uses the high frequency dynamic flickering of the primary combustion process. An infrared detector uses the infrared radiation produced in the primary combustion of the flame.

The proper location of the flame detectors on a burner is dependent on many factors, including

Fig. 28 Fuel management.

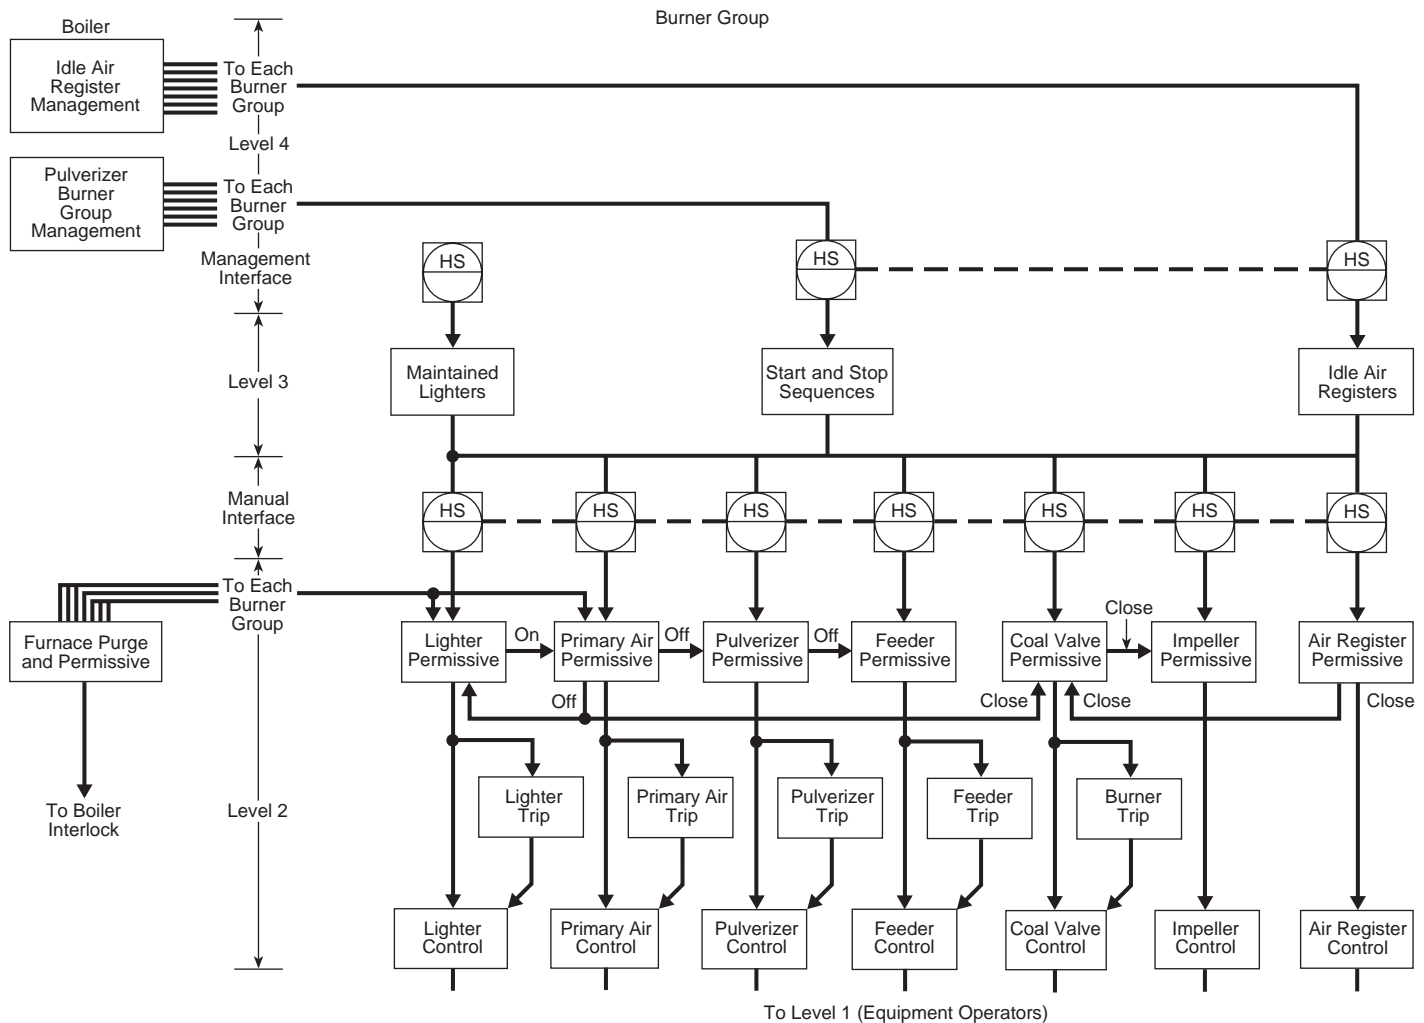

Fig. 29 Pulverizer/burner group control.

burner management system design. It should, therefore, be determined by the boiler manufacturer in conjunction with the BMS manufacturer as an integral part of the control system design.

Flame monitoring devices in current use are designed for on/off operation based on the presence or absence of flame. Although the basic detector units provide a variable analog output signal which can be read on a meter, there is no direct claim to an established relationship between this relative output signal and the flame quality. Therefore, the analog signals should never be relied upon as flame quality indicators. They should be used only to provide helpful information for initial setup adjustments and continuous on-line observance.

Some power plants use closed circuit television for continuous furnace observation by the operator from the control room.

Classification of lighters/igniters

The combustion of solid, liquid and gaseous fuels is hazardous because upset conditions may lead to an air-fuel mixture that could cause furnace explosion. These hazardous conditions are especially prevalent during startup and shutdown of the boiler. Therefore, it is important to have reliable instrumentation, well

designed safety interlocks, and clear understanding of operating sequences by the operator. However, a reliable and noninterruptible ignition source is probably the single most important factor. The National Fire Protection Association (NFPA) provides guidelines on the application of igniters. The following definitions are extracted from the NFPA 85 Boiler and Combustion Systems Hazards Code.

Class 1 Igniter. An igniter that is applied to ignite the fuel input through the burner and to support ignition under any burner lightoff or operating conditions. Its location and capacity are such that it will provide sufficient ignition energy, generally in excess of 10% of full load burner input, at its associated burner to raise any credible combination of burner inputs of both fuel and air above the minimum ignition temperature.

Class 2 Igniter. An igniter that is applied to ignite the fuel input through the burner under prescribed lightoff conditions. It is also used to support ignition under low load or certain adverse operating conditions. The range of capacity of such igniters is generally 4 to 10% of full load burner fuel input.

Class 3 Igniter. A small igniter applied particularly to gas and oil burners to ignite the fuel input to the burner under prescribed lightoff conditions. The ca-

capacity of such igniters generally does not exceed 4% of the full load burner fuel input.

Class 3 Special Igniter. A special Class 3 high energy electrical igniter capable of directly igniting the main burner fuel.

Failure mode analysis

NFPA 85 states that the burner management system must be totally independent of all other control systems. Therefore, the control system designer must consider carefully every aspect of the operation and equipment limitations. A great number of failure modes must be analyzed and addressed. Due to space limitation, the following are only a few of the issues:

1. The typical safe way to implement the master fuel trip (MFT) in the burner management system is *de-energize to trip* the equipment. As the description indicates, a circuit should be energized continuously. De-energizing of the circuit represents an abnormal condition. Therefore, the equipment must be removed from service. For an *energize to trip* system, in the event of specific power failure, the equipment can not be stopped.
2. Redundancy of control hardware may be necessary or desirable in many areas. However, too many backups may render the system too cumbersome for practical use.
3. System design must not prevent the operator from shutting down any equipment desired. The system will function to complement the operator's action so that he or she will not generate a hazardous operating condition.

Post-combustion NO_x emissions control

Various nitrogen oxides (NO_x) control technologies are discussed in Chapters 32 and 34. The following focuses on the control strategy associated with post-combustion selective catalytic reduction (SCR) technology. The B&W SCR NO_x removal system is a dry process in which ammonia (NH₃) is used as a reducing agent, and the NO_x contained in the flue gas is reduced to N₂ and H₂O.

As explained in Chapter 34, ammonia (anhydrous or aqueous) is injected into the flue gas upstream of the SCR reactor, through an injection grid. The grid is designed to ensure an even NH₃ distribution and allow for fine tuning of ammonia distribution. The flue gas then passes to the reactor and through the catalyst layers. As this occurs the inlet flue gas is constantly monitored to ensure that the NO_x is being reduced to an acceptable level without overspraying ammonia.

There are two primary control loops for an SCR system: ammonia flow and flue gas inlet temperature.

Ammonia flow control

Ammonia flow demand is calculated based primarily on flue gas flow and the outlet NO_x deviation from set point. This demand signal is limited on anhydrous systems to ensure that the ammonia to dilution air ratio is always below the hazardous buildup limit of ammonia in the system. If this ratio exceeds the limit, the ammonia block valve is interlocked to close (Fig. 30).

Flue gas inlet temperature

Economizer outlet and bypass dampers are modulated to maintain a minimum allowable flue gas temperature at the SCR inlet. This prevents the formation of ammonium bisulfate upstream of the catalyst. This salt can mask the catalyst pores and cause a loss of activity. The gas temperature demand is developed as a function of boiler load. This gas temperature demand signal is compared to a measured SCR system inlet temperature. The resulting error signal is conditioned by the firing rate demand to generate the demand for the economizer flue gas dampers (Fig. 31).

SO₂ emissions control

Various sulfur dioxide (SO₂) control strategies and technologies are discussed in Chapters 32 and 35. The following focuses on the main control loops associated with wet and dry scrubbing technologies.

Wet scrubbers

The wet scrubbing process typically includes reagent preparation, absorber area, primary dewatering, and secondary dewatering systems. Sulfur dioxide laden flue gas is contacted with a sorbent liquid which saturates the flue gas and produces a wet byproduct.

Sulfur dioxide removal is accomplished by a countercurrent spray absorption process within the absorber. By spraying limestone slurry into the flue gas, the sul-

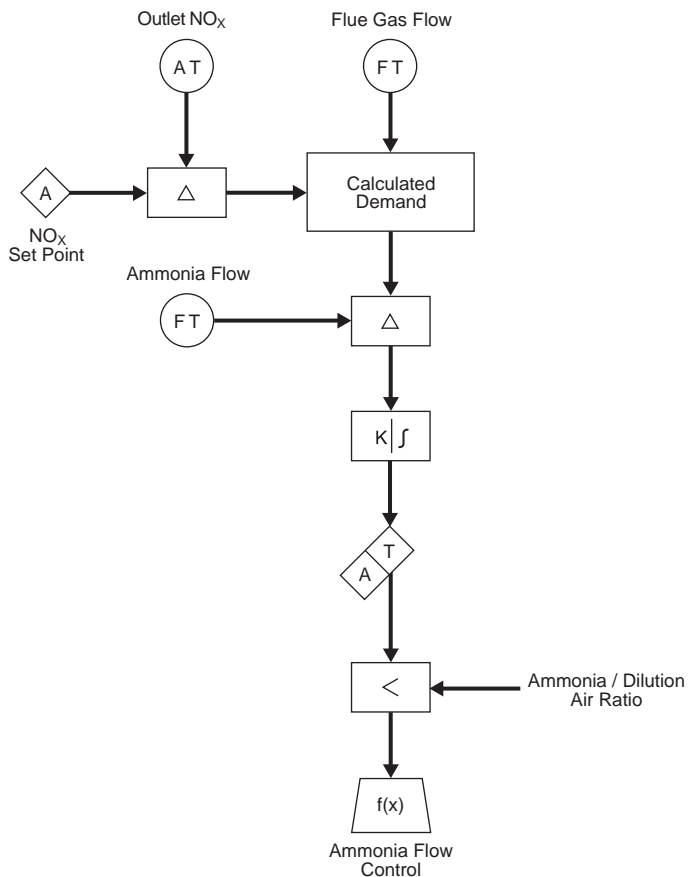

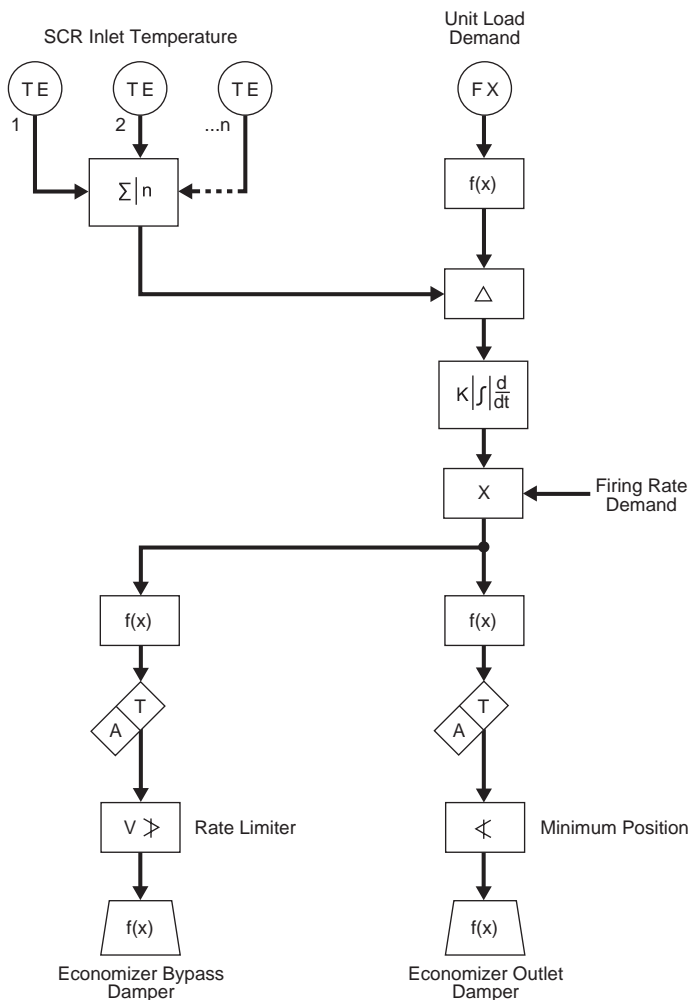

Fig. 30 SCR ammonia flow control.

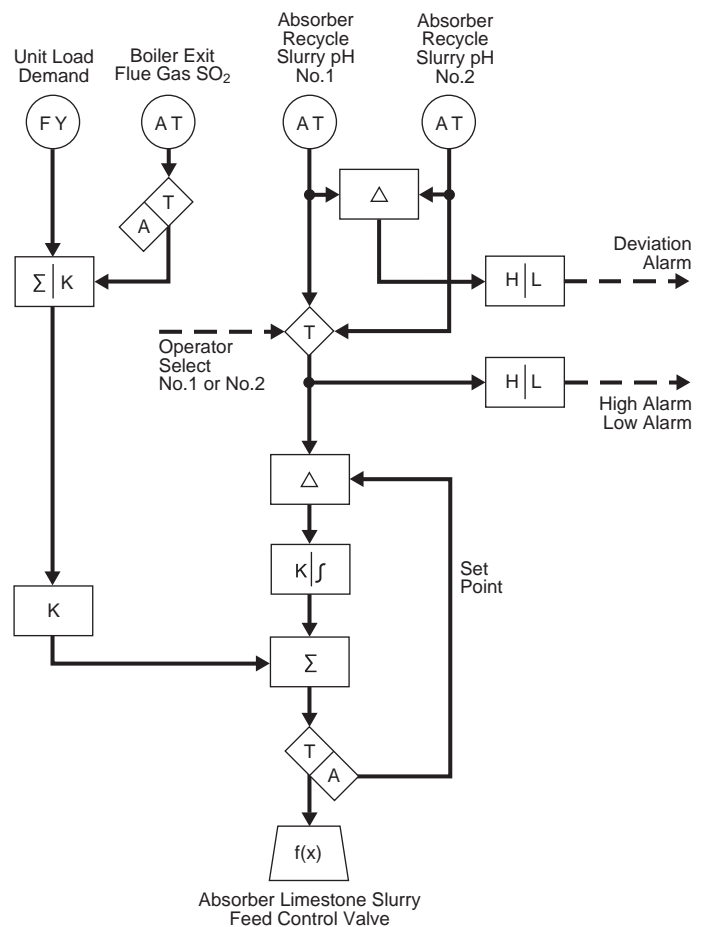

The recycle slurry and the mist eliminator wash water pass down through the absorber and are collected in the lower section of the absorber module, referred to as the absorber reaction tank. Fresh limestone slurry is added to control the pH, and reclaim water is added to control the recycle slurry density. Side agitators keep the recycle slurry solids in suspension.

There are three critical control loops associated with the wet scrubber: pH, density, and reaction tank level.

pH control The recycle slurry pH is controlled by adding fresh limestone slurry to the absorber. The amount added is a function of expected boiler load and SO_2 loading as shown in Fig. 32. Due to the large volume of slurry in the reaction tank, a change in flue gas flow or flue gas SO_2 concentration will not show up as a change in recycle slurry pH until after a relatively long delay. To compensate for this delay, feedforward signals from flue gas SO_2 concentration and boiler load are used to adjust the demand for fresh limestone slurry feed (Fig. 32).

Level control Absorber level control compares the level measurement of the absorber reaction tank to an operator-adjusted set point. Proportional plus integral action is applied to any error signal. The resultant demand signal positions the reclaim water control valve (Fig. 33). A level measurement greater than the set point will decrease reclaim water flow, while a level measurement less than set point will increase reclaim water flow.

Density control The absorber reaction tank density

is affected by the balance between water addition (fresh limestone slurry, mist eliminator wash, level control) and water removal (evaporation by the flue gas, slurry removal during dewatering). The balance between water removal and water addition, in conjunction with the increase in the density of the solids (as the fresh limestone reacts with absorbed SO_2), causes the absorber reaction tank density to rise. When the density reaches a high set point, the density control loop begins the dewatering process (removing solids). Once the density has reached a low set point, the slurry is recirculated back to the absorber reaction tank, thus completing the density control cycle.

Dry scrubbers

A dry scrubber is commonly referred to as a spray dryer absorber (SDA) module. Boiler flue gas exiting the air heater is directed to the SDA module which includes a rotary atomizer unit. Atomizer feed slurry, a mixture of hydrated lime slurry and recycle ash slurry, is supplied to the atomizer at a controlled rate and atomized within the SDA module into a cloud of extremely fine mist. Heat from the flue gas evaporates the moisture in the slurry cloud while the alkaline slurry simultaneously absorbs the SO_2 contained in the flue gas. The result is the conversion of the calcium hydroxide slurry component into a fine powder of calcium/sulfur compounds, and the lowering of flue gas temperature. The ratio of fresh lime slurry to recycle ash slurry is controlled to maintain the required alkalinity in the atomizer feed slurry, to achieve the desired level of SO_2 removal. The feed slurry to the atomizer is controlled to maintain the desired degree of evaporative cooling in the module. Module outlet flue gas temperature is regulated by the atomizer feed slurry control valve to be above the adiabatic saturation

temperature (dew point), to ensure the spray-dried calcium/sulfur product remains dry and free flowing.

SO_2 control The reagent preparation system provides a mixture of hydrated lime slurry and recycle ash slurry to the atomizer head tank to obtain the desired feed slurry blend for proper SO_2 absorption. The atomizer head tank lime slurry feed flow control valve regulates the flow of lime slurry to the atomizer head tank to maintain the required percent SO_2 removal and/or stack SO_2 concentration. The basic design of this control loop is illustrated in Fig. 34.

Developments in instrumentation and controls

Power plant automation

Many power plants today are essentially automatic when operating between one third and full load using the conventional systems discussed earlier in this chapter. To achieve complete automation of a plant, it is first necessary to add control subloops for the auxiliaries which were previously considered to be the exclusive responsibility of the operator. All of these subloops must then be integrated through unit management control to provide complete plant automation. Fig. 35 shows the arrangement of such a control system.

The basic concept of full automation is to provide the maximum amount of control and monitoring at the lowest possible level. The organization of the different levels, as shown in Fig. 36 for a fossil fuel plant, is summarized as follows:

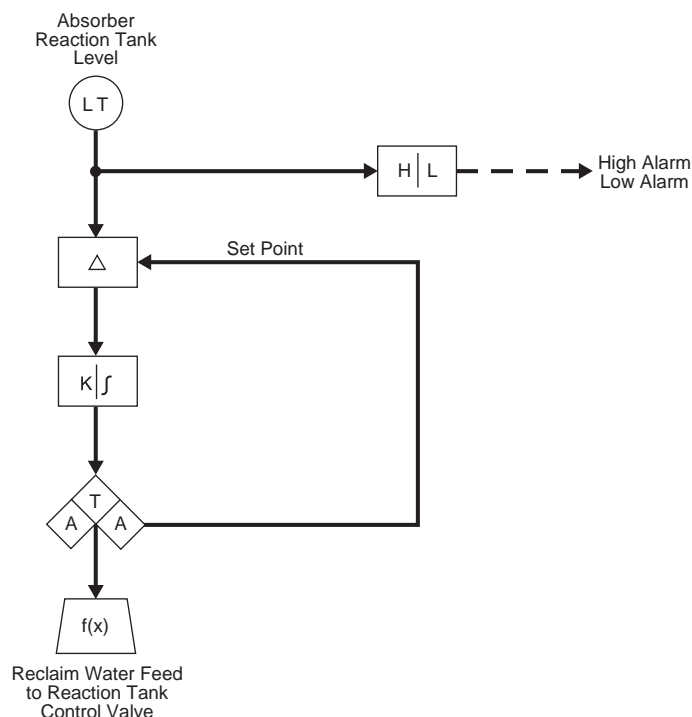

Fig. 33 Absorber reaction tank level control.

Fig. 34 Spray dryer absorber control loop.

- Level 1 – equipment hardware being controlled
- Level 2 – internal control of the individual equipment items or group of functionally identical items of equipment always operated in parallel
- Level 3 – coordination of the sequence of actions and interlocking with respect to more than one equipment group
- Level 4 – modulation and sequencing of major cycle components involving the entire unit
- Level 5 – generation of the major load demand signals to coordinate the operation of the overall plant

Advantages obtained with the hierarchical control concept include self-regulation of equipment groups. This allows the equipment group to protect itself through low level interlocking, which provides greater reliability and control decentralization and permits continued plant operation with some portions of the control system out of service.

Some of the advantages of overall unit automation are:

1. Improved protection of personnel and equipment through more complete instrumentation, simplified information display, and more extensive and thorough supervisory control.
2. Reduced outages, reduced maintenance, and longer equipment life through more uniform and complete control procedures of startup, on-line operation, and shutdown.
3. Better plant efficiency through continuous and automatic adjustments to the controls to optimize plant operation.
4. More efficient use of personnel during startup and on-line operation.

The trend of boiler automation is clear and its future scope can be predicted with considerable confidence. The achievement of some goals will be difficult. There are operating problems to be solved, traditions to be overcome, and new philosophies and approaches to be accepted. Reliable and adequate equipment is

already available and its application, through the cooperation of manufacturers and users, will make the automatic power plant a reality.

Human factor engineering

Until the 1990s, most control rooms were designed with only one thing in mind, i.e., how to group the indicators, recorders, and operator stations within reach and sight of an operator who stands in front of the panel and operates the unit. With a state-of-the-art control room, the operators are surrounded by display screens and keyboards, which make human factor engineering a very important part of the design. (See chapter frontispiece.) It will affect the physical well being of operators as well as his or her ability to operate the unit effectively. The following are just a few examples of why human factor engineering is important.

1. With microprocessor and computer based distributed control systems, the amount of information available to the operator has increased dramatically. The system has to be designed so that important information is presented and instantly understood by the operator. For example, an alarm list that is not recognized properly will cause a great deal of confusion. On the other hand, several levels of alarms using different color codes will help the operator make correct decisions.
2. To be able to read display screens for long periods of time, lighting in the control room must be designed to avoid eye strain of the operators.
3. Furnishings to accommodate display screens and keyboards to maximize operator alertness must be provided.

Smart transmitters

In the past, a transmitter was used to measure pressure, temperature, and flow (differential pressure) from remote locations. A signal representing the calibrated value of that measurement was sent to the control system located in or near the central control room. The signal was then conditioned to provide a usable

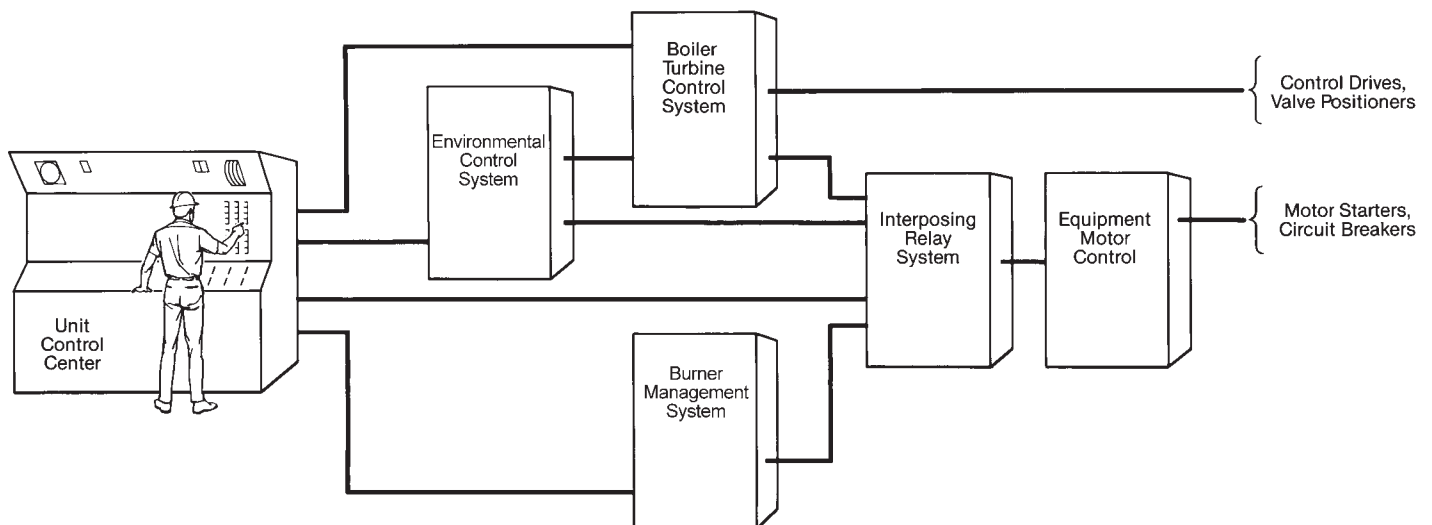

Fig. 35 Composite of automation components.

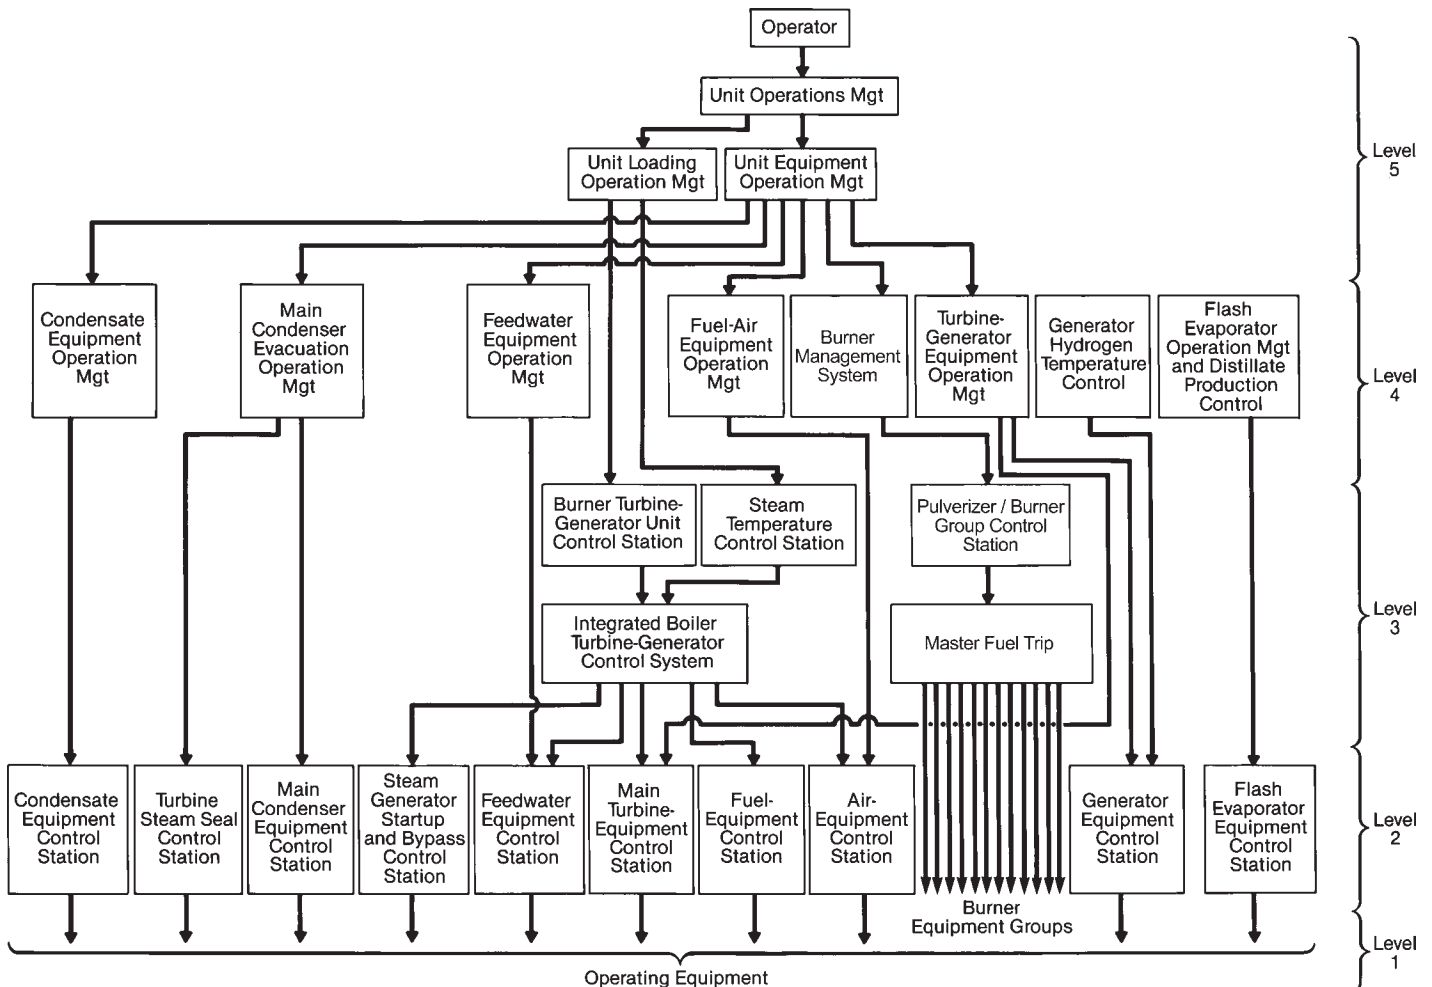

Fig. 36 Multi-level approach to power plant operation.

signal to the control system, indicator, or recorder. The smart transmitters available today can condition the signal locally – for example, square root extraction to convert differential pressure to flow and temperature compensation for flow measurements. The smart transmitter can also provide remote configuration, reranging, rezeroing, calibration and diagnostics features to provide direct access to the field device from the control room, virtually eliminating periodic maintenance visits to the instruments.

Installation and service requirements

It is important to make certain that instrumentation and control equipment are properly installed and serviced. Supervision of installation and the required calibration adjustments should be performed by qualified and experienced personnel. Adequate time to tune the controls should be provided during initial boiler operation.

Maintenance can be performed by trained plant personnel. The personnel who will be responsible for this maintenance should be available to observe and assist the control manufacturer's representatives in the installation and calibration of the control system. Most control manufacturers offer training programs to fa-

miliarize customer personnel with the control equipment. A planned program of preventive maintenance should be developed for the control system.

Performance monitoring

The continuing growth in size and complexity of units has added importance to the frequent analysis of performance. Many operating companies are analyzing their performance evaluation programs and developing monitoring techniques that make possible the detection of malfunctions before substantial losses have occurred.

A number of performance evaluation procedures are practiced today. In some power companies, the performance of each unit is checked periodically by extensive heat rate tests. Techniques and procedures for performing such evaluations are covered under the ASME Performance Test Codes.

The computer is also being used to conduct on-line performance calculations periodically, hourly and daily in most systems. This information can be compared with expected performance data stored in the computer and any deviation recorded for future correction. This could be especially useful for monitoring and controlling emissions.

Typical utility power plant control console.

Chapter 42

Water and Steam Chemistry, Deposits and Corrosion

Steam generation and use involve thermal and physical processes of heat transfer, fluid flow, evaporation, and condensation. However, steam and water are not chemically inert physical media. Pure water dissociates to form low concentrations of hydrogen and hydroxide ions, H^+ and OH^- , and both water and steam dissolve some amount of each material that they contact. They also chemically react with materials to form oxides, hydroxides, hydrates, and hydrogen. As temperatures and velocities of water and steam vary, materials may dissolve in some areas and redeposit in others. Such changes are especially prevalent where water evaporates to form steam or steam condenses back to water, but they also occur where the only change is temperature, pressure, or velocity. In addition, chemical impurities in water and steam can form harmful deposits and facilitate dissolution (corrosion) of boiler structural materials. Therefore, to protect vessels, tubing, and other components used to contain and control these working fluids, water and steam chemistry must be controlled.

Water used in boilers must be purified and treated to inhibit scale formation, corrosion, and impurity contamination of steam. Two general approaches are used to optimize boiler water chemistry. First, impurities in the water are minimized by purification of makeup water, condensate polishing, deaeration and blowdown. Second, chemicals are added to control pH, electrochemical potential, and oxygen concentration. Chemicals may also be added to otherwise inhibit scale formation and corrosion. Proper water chemistry control improves boiler efficiency and reduces maintenance and component replacement costs. It also improves performance and life of heat exchangers, pumps, turbines, and piping throughout the steam generation, use, and condensation cycle.

The primary goals of boiler water chemistry treatment and control are acceptable steam purity and acceptably low corrosion and deposition rates. In addition to customized boiler-specific guidelines and procedures, qualified operators are essential to achieving

these goals, and vigilance is required to detect early signs of chemistry upsets. Operators responsible for plant cycle chemistry must understand boiler water chemistry guidelines and how they are derived and customized. They must also understand how water impurities, treatment chemicals, and boiler components interact. Training must therefore be an integral, ongoing part of operations and should include management, control room operators, chemists, and laboratory staff.

General water chemistry control limits and guidelines have been developed and issued by various groups of boiler owners and operators (e.g., ASME,^{1,2,3} EPRI⁴ and VGB⁵), water treatment specialists^{6,7,8} utilities and industries. Also, manufacturers provide recommended chemistry control limits for each boiler and for other major cycle components. However, optimum water and steam chemistry limits for specific boilers, turbines, and other cycle components depend on equipment design and materials of construction for the combination of equipment employed. Hence, for each boiler system, boiler-specific water chemistry limits and treatment practices must be developed and tailored to changing conditions by competent specialists familiar with the specific boiler and its operating environment.

Chemistry-boiler interactions

To understand how water impurities, treatment chemicals and boiler components interact, one must first understand boiler circuitry, and steam generation and separation processes.

Boiler feed pumps provide feedwater pressure and flow for the boiler. From the pumps, feedwater often passes through external heaters and then through an economizer where it is further heated before entering the boiler. In a natural circulation drum-type unit, boiling occurs within steel tubes through which a water-steam mixture rises to a steam drum. Devices in the drum separate steam from water, and steam leaves through connections at the top of the drum. This steam is replaced by feedwater which is supplied

by the feedwater pumps and injected into the drum just above the downcomers through a feedwater pipe where it mixes with recirculating boiler water which has been separated from steam. By way of downcomers, the water then flows back through the furnace and boiler tubes. *Boiler water* refers to the concentrated water circulating within the drum and steam generation circuits. Chapters 1 and 5 provide detailed descriptions of steam generation and boiler circulation.

Boiler feedwater always contains some dissolved solids, and evaporation of water leaves these dissolved impurities behind to concentrate in the steam generation circuits. If the concentration process is not limited, these solids can cause excessive deposition and corrosion within the boiler and excessive impurity carryover with the steam. To avoid this, some concentrated boiler water is discarded to drain by way of a blowdown line. Because the boiler water is concentrated, a little blowdown eliminates a large amount of the dissolved solids. Since steam carries very little dissolved solids from the boiler, dissolved and suspended solids entering in the feedwater concentrate in the boiler water until the solids removed in the blowdown (boiler water concentration times the blowdown rate lb/h or kg/s) equal the solids carried in with the feedwater (lb/h or kg/s).

A small amount of dissolved solids is carried from the drum by moisture (water) droplets with the steam. Because moisture separation from steam depends on the difference between their densities, moisture separation is less efficient at high pressures where there is less difference between the densities. Therefore, to attain the same steam purity at a higher pressure, the dissolved solids concentration in boiler water must generally be lower.

In a drum boiler, the amount of steam generated is small compared to the amount of water circulating through the boiler. However, circulation is also largely driven by the difference in densities between the two fluids, so as pressure increases the ratio of water flow to steam flow decreases. At 200 psi (1379 kPa), water flow through the boiler must be on the order of 25,000 pph (3 kg/s) to produce just 1000 pounds per hour of steam. Even at 2700 psi (18.6 MPa), 2500 to 4000 pounds of water circulates to produce 1000 pounds of steam. By contrast, most or all of the water entering a once-through boiler is converted to steam without recirculation.

Some boiler operators have asked why boiler water concentrations change so slowly once a source of contamination is eliminated and the continuous blowdown rate is increased. How quickly can excess chemical be purged from a boiler? How much impurity or additive is needed to upset boiler water chemistry? How quickly do chemical additions circulate through the boiler? To answer these questions and explore some other chemistry-boiler interactions, consider for example a typical 450 MW natural circulation boiler, generating 3,000,000 pounds of steam per hour. It has a room temperature water capacity of 240,000 pounds and an operating water capacity of 115,000 pounds. The furnace wall area is 33,000 square feet, about 5800 of which are in the maximum heat flux burner zone.

Impurities purge slowly from the boiler because the boiler volume is large compared to the blowdown rate. For example, at maximum steaming capacity with a blowdown rate 0.3% of the steam flow from the drum, 17 hours may be required to decrease the boiler water concentration of a non-volatile impurity by 50%. Almost two hours are required to effect a 50% reduction in the boiler water concentration even at a blowdown rate of 3%. Without blowdown, dissolved sodium with a fractional carryover factor of 0.1% would have a half life of 52 hours. While long periods of time are generally required to purge impurities, mixing within the boiler is rapid. For the boiler being used as an example, the internal recycle rate is about one boiler volume per minute, and steam is generated at a rate of one boiler volume every 5 minutes.

The rate of steam generation is such that replacement feedwater must be essentially free of hardness minerals and oxides that deposit in the boiler. For example, feedwater carrying only 1 ppm of hardness minerals and oxides could deposit up to 25,000 lb (11,340 kg) per year of solids in the boiler, so the boiler might require chemical cleaning as often as 3 or 4 times per year. Also, small chemical additions have a large effect on boiler water chemistry. For example, addition of 0.2 lb (0.09 kg) of sodium hydroxide to the boiler water increases the sodium concentration by 1 ppm, which can significantly affect the boiler water chemistry. Similarly, a small amount of chemical hideout can have a large effect on boiler water concentration. Hideout or hideout return of only 0.01 gram per square foot (0.1 g/m²) in the burner zone can change the boiler water concentration by 1 ppm.

Control of deposition, corrosion, and steam purity

The potential for deposition and corrosion is inherent to boilers and increases with boiler operating pressure and temperature. Evaporation of water concentrates boiler water impurities and solid treatment chemicals at the heat transfer surfaces. During the normal nucleate boiling process in boiler tubes, small bubbles form on tube walls and are immediately swept away by the upward flow of water. As steam forms, dissolved solids in the boiler water concentrate along the tube wall. Additionally, the boundary layer of water along the wall is slightly superheated, and many dissolved minerals are less soluble at higher temperatures (common phenomenon referred to as *inverse temperature solubility*). Both of these factors favor deposition of solids left behind by the evolution of steam in high heat flux areas, as illustrated in Fig. 1.

These deposits in turn provide a sheltered environment which can further increase chemical concentrations and deposition rates. In a relatively clean boiler tube, concentration of chemicals at the tube surface is limited by the free exchange of fluid between the surface and boiler water flowing through the tube. Wick boiling as illustrated in Fig. 2 generally produces sufficient flow within the deposits to limit the degree of concentration. However, as heavy deposits as illus-

Fig. 1 Three years of operation resulted in light deposits because of good water treatment. The upper right figure is the heated side, and the lower right figure is the unheated side.

trated in Fig. 3 accumulate, they restrict flow to the surface. Some boiler water chemicals concentrate on tube walls during periods of high load and then return to the boiler water when the load is reduced. This is termed *hideout* and *hideout return*. This can greatly complicate efforts to control boiler water chemistry.

Typical boiler deposits are largely hardness precipitates and metal oxides. Hardness, easily precipitated minerals (mainly calcium and magnesium), enters the cycle as impurities in makeup water and in cooling water from condenser leaks. Metal oxides are largely

Fig. 2 Schematic of the wick boiling mechanism (adapted from Reference 9).

from corrosion of pre-boiler cycle components. *Scaling* occurs when these minerals and oxides precipitate and adhere to boiler internal surfaces where they impede heat transfer. The result can be overheating of tubes, followed by failure and equipment damage. Deposits also increase circuitry pressure drop, especially detrimental in once-through boilers. Effective feedwater and boiler water purification and chemical treatment minimizes deposition by minimizing feedwater hardness and by minimizing corrosion and associated iron pickup from the condensate and feedwater systems. Also, phosphate and other water treatment chemicals are used in drum boilers to impede the formation of particularly adherent and low thermal conductivity deposits.

Some chemicals become corrosive as they concentrate. Corrosion can occur even in a clean boiler, but the likelihood of substantial corrosion is much greater beneath thick porous deposits that facilitate the concentration process. Concentration at the base of deposits can be more than 1000 times higher than that in the boiler water and the temperature at the base of these deposits can substantially exceed the saturation temperature. Hence, as deposits accumulate, control of boiler water chemistry to avoid the formation of corrosive concentrates becomes increasingly important. Since chemistry upsets do occur, operation of a boiler with excessively thick deposits should be avoided.

Because local concentration of boiler water impurities and treatment chemicals is inherent to steam generation, water chemistries must be controlled so the concentrates are not corrosive. On-line corrosion is often caused by concentration of sodium hydroxide, concentration of caustic-forming salts such as sodium carbonate, or concentration of acid-forming salts such as magnesium chloride or sulfate.¹⁰ Effective feedwater and boiler water treatment minimizes corrosion by minimizing ingress of these impurities and by add-

Fig. 3 An example of internal deposits resulting from poor boiler water treatment. These deposits, besides hindering heat transfer, allowed boiler water salts to concentrate, causing corrosion.

ing treatment chemicals (such as trisodium phosphate) that buffer against acid or caustic formation. However, corrosion and excessive precipitation can also be caused by improper use of buffering agents and other treatment chemicals. For example, underfeeding or overfeeding of treatment chemicals, out-of-specification sodium-to-phosphate ratios, or out-of-specification free-chelant concentrations can cause corrosion.

Dissolved carbon dioxide and oxygen can also be corrosive and must be eliminated from feedwater. Carbon dioxide from air in-leakage and from decomposition of carbonates and organic compounds tends to acidify feedwater and steam condensate. Oxygen is especially corrosive because it facilitates oxidation of iron, copper, and other metals to form soluble metal ions. At higher temperatures, oxygen is less soluble in water and the rate of chemical reaction is increased. As boiler feedwater is heated, oxygen is driven out of solution and rapidly corrodes heat transfer surfaces. The combination of oxygen and residual chloride is especially corrosive, as is the combination of oxygen and free chelant.

Carryover of impurities from boiler water to steam is also inherent to boiler operation. Though separation devices remove most water droplets carried by steam, some residual droplets containing small amounts of dissolved solids always carry through with the steam. Also, at higher pressures, there is some vaporous carryover. Excessive impurities can damage superheaters, steam turbines, or downstream process equipment.

Boiler feedwater

To maintain boiler integrity and performance and to provide steam of suitable turbine or process purity, boiler feedwater must be purified and chemically conditioned. The amount and nature of feedwater impurities that can be accommodated depend on boiler operating pressure, boiler design, steam purity requirements, type of boiler water internal treatment, blowdown rate, and whether the feedwater is used for steam attenuation. Feedwater chemistry parameters to be controlled include dissolved solids, pH, dissolved oxygen, hardness, suspended solids, total organic carbon (TOC), oil, chlorides, sulfides, alkalinity, and acid or base forming tendencies.

At a minimum, boiler feedwater must be softened water for low pressure boilers and demineralized water for high pressure boilers. It must be free of oxygen and essentially free of hardness constituents and suspended solids. Recommended feedwater limits are shown in Table 1. Use of high-purity feedwater minimizes blowdown requirements and minimizes the potential for carryover, deposition, and corrosion problems throughout the steam-water cycle.

Operation within these guidelines does not by itself ensure trouble-free operation. Some feedwater contaminants such as calcium, magnesium, organics, and carbonates can be problematic at concentrations below the detection limits of analytical methods commonly used

Table 1
Recommended Feedwater Limits

Pressure, psig (MPa)	Drum Boilers							Once-Through Boilers	
	15 to 300 (0.10 to 2.07)	301 to 600 (2.08 to 4.14)	601 to 900 (4.14 to 6.21)	901 to 1000 (6.21 to 6.90)	1001 to 1500 (6.90 to 10.34)	>1500 (>10.34)	with AVT*	AVT	Oxygen Treatment

* All volatile treatment.

** AVT not recommended for copper-bearing cycles and associated low feedwater pH where the drum pressure is less than 400 psig.

*** By mechanical deaeration before chemical scavenging of residual.

Note:
ppm = mg/kg

for industrial boilers. Also, operators must be sensitive to changes in feedwater chemistry and boiler operating conditions, and must adapt accordingly.

Makeup water

Boiler feedwater is generally a mix of returned steam condensate and fresh makeup water. For utility boilers, most of the steam is usually returned as condensate, and only 1 to 2% makeup is necessary. However, for some industrial cycles, there is little or no returned condensate, so as much as 100% makeup may be necessary.

Chemistry requirements for makeup water depend on the amount and quality of returned steam condensate. Where a large portion of the feedwater is uncontaminated condensate, makeup water can generally be of lesser purity so long as the mixture of condensate and makeup meet boiler feedwater requirements. The feedwater concentration for each chemical species is the weighted average of the feedwater and makeup water concentrations:

$$\text{Feedwater concentration} = (\text{condensate concentration} \times \text{flow} + \text{makeup concentration} \times \text{makeup flow}) / \text{total feedwater flow} \quad (1)$$

The selection of equipment for purification of makeup water must consider the water chemistry requirements, raw water composition, and quantity of makeup required. All natural waters contain dissolved and suspended matter. The type and amount of impurities vary with the source, such as lake, river, well or rain, and with the location of the source. Major dissolved chemical species in source water include sodium, calcium, and magnesium positive ions (cations) as well as bicarbonate, carbonate, sulfate, chloride, and silicate negative ions (anions). Organics are also abundant.

The first steps in water purification are coagulation and filtration of suspended materials. Natural settling in still water removes relatively coarse suspended solids. Required settling time depends on specific gravity, shape and size of particles, and currents within the settling basin. Settling and filtration can be expedited by coagulation (use of chemicals to cause agglomeration of small particles to form larger ones that settle more rapidly). Typical coagulation chemicals are alum and iron sulfate. Following coagulation and settling, water is normally passed through filters. The water is chlorinated to kill micro-organisms, then activated charcoal filters may be used to remove the final traces of organics and excess chlorine.

Subsequently, various processes may be used to remove dissolved scale-forming constituents (hardness minerals) from the water. For some low pressure boilers, removal of hardness minerals and scale-forming minerals is adequate. For other boilers, the concentration of *all* dissolved solids must be reduced or nearly eliminated. For low pressure boilers, the capital and operating cost for removal must be weighed against costs associated with residual dissolved solids and hardness. These include increased costs for boiler water treatment, more frequent chemical cleaning of the boiler, and possibly higher rates of boiler repair. Demineralized water nearly free of all dissolved solids is recommended for higher pressure boilers and espe-

cially for all boilers operating at pressures greater than 1000 psi (6.9 MPa).

Sodium cycle softening, often called *sodium zeolite softening*, replaces easily precipitated hardness minerals with sodium salts, which remain in solution as water is heated and concentrated. The major hardness ions are calcium and magnesium. However, zeolite ion-exchange softening also removes dissolved iron, manganese, and other divalent and trivalent cations. Sodium held by a bed of organic resin is exchanged for calcium and magnesium ions dissolved in the water. The process continues until the sodium ions in the resin are depleted and the resin can no longer absorb calcium and magnesium efficiently. The depleted resin is then regenerated by washing it with a high concentration sodium chloride solution. At the high sodium concentrations of this regeneration solution, the calcium and magnesium are displaced by sodium. Variations of the process, in combination with chemical pre-treatments and post-treatments, can substantially reduce hardness concentrations and can often reduce silica and carbonate concentrations.

For higher pressure boilers, evaporative or more complete ion-exchange demineralization of makeup water is recommended. Any of several processes may be used. *Evaporative distillation* forms a vapor which is recondensed as purified water. *Ion exchange demineralization* replaces cations (sodium, calcium, and magnesium in solution) with hydrogen ions and replaces anions (bicarbonate, sulfate, chloride, and silicate) with hydroxide ions. For makeup water treatment, two tanks are normally used in series in a cation-anion sequence. The anion resin is usually regenerated with a solution of sodium hydroxide, and the cation resin is regenerated with hydrochloric or sulfuric acid. *Reverse osmosis* purifies water by forcing it through a semi-permeable membrane or a series of such membranes. It is increasingly used to reduce total dissolved solids (TDS) in steam cycle makeup water. Where complete removal of hardness is necessary, reverse osmosis may be followed by a mixed-bed demineralizer. *Mixed-bed demineralization* uses simultaneous cation and anion exchange to remove residual impurities left by reverse osmosis, evaporator, or two-bed ion exchange systems. Mixed-bed demineralizers are also used for polishing (removing impurities from) returned steam condensate. Before regenerating mixed-bed demineralizers, the anion and cation resins must be hydraulically separated. **Caustic and acids used for regeneration of demineralizers and other water purification and treatment chemicals present serious safety, health, and environmental concerns. Material Safety Data Sheets must be obtained for each chemical and appropriate precautions for handling and use must be formulated and followed.**

Dissolved organic contaminants (carbon-based molecules) are problematic in that they are often detrimental to boilers but are not necessarily removed by deionization or evaporative distillation. Organic contamination of feedwater can cause boiler corrosion, furnace wall tube overheating, drum level instability, carryover, superheater tube failures, and turbine cor-

rosion. The degree to which any of these difficulties occurs depends on the concentration and nature of the organic contaminant. Removal of organics may require activated carbon filters or other auxiliary purification equipment.

Returned condensate – condensate polishing

For many boilers, a large fraction of the feedwater is returned condensate. Condensate has been purified by prior evaporation, so uncontaminated condensate does not generally require purification. Makeup water can be mixed directly with the condensate to form boiler feedwater.

In some cases, however, steam condensate is contaminated by corrosion products or by in-leakage of cooling water. Where returned condensate is contaminated to the extent that it no longer meets feedwater purity requirements, mixed-bed ion-exchange purification systems are commonly used to remove the dissolved impurities and filter out suspended solids. Such demineralization is referred to as *condensate polishing*. This is essential for satisfactory operation of once-through utility boilers, for which feedwater purity requirements are especially stringent. While high pressure drum boilers can operate satisfactorily without condensate polishing, many utilities recognize the benefits in high pressure plants. These benefits include shorter unit startup time, protection from condenser leakage impurities, and longer intervals between acid cleanings. Condensate polishing is recommended for all boilers operating with all volatile treatment (AVT) and is essential for all boilers operating with all volatile treatment and seawater cooled condensers. Provisions for polishing vary from adequate capacity for 100% polishing of all returned condensate to polishing only a portion of the condensate. However, all must be adequate to meet feedwater requirements under all anticipated load and operating conditions.

Most of the pressure vessels that contain ion exchange resins have under-drain systems and downstream traps or strainers to prevent leakage of ion exchange resins into the cycle water. These resins can form harmful decomposition products if allowed to enter the high temperature portions of the cycle. Unfortunately, the under-drain systems and the traps and strainers are not designed to retain resin fragments that result from resin bead fracture. Also, the resin traps and strainers can fail, resulting in resin bursts. Resin intrusion can be minimized by controlling flow transients, reducing the strainer's screen size, increasing flow gradually during vessel cut-in, and returning the polisher vessel effluent to the condenser during the first few minutes of cut-in.

Feedwater pH control

Boiler feedwater pH is monitored at the condensate pump discharge and at the economizer inlet. When the pH is below the required minimum value, ammonium hydroxide or an alternate alkalinizer is added. Chemicals for pH control are added either downstream of the condensate polishers or at the condensate pump discharge for plants without polishers. For high purity demineralized feedwater, ammonium hydroxide

injection pumps or alternative feedwater pH control is achieved using a feedback signal from a specific conductivity monitor. Conductivity provides a good measure of ammonium hydroxide concentration, and automated conductivity measurement is more reliable than automated pH measurement. Also, the linear rather than logarithmic relationship of conductivity to ammonia concentration gives better control. Fig. 4 shows the relationship between ammonium concentration, pH, and conductivity of demineralized water.

While an equilibrium concentration of ammonium hydroxide remains in the boiler water, much of the ammonium hydroxide added to feedwater volatilizes with the steam. Conversely, the solubility of ammonium hydroxide is such that little ammonia is lost by deaeration. Hence, returned condensate often has a substantial concentration of ammonium hydroxide before further addition.

Common alternative pH control agents include neutralizing amines, such as cyclohexylamine and morpholine. For high pressure utility boilers with superheaters, the more complex amines are thermally unstable and the decomposition products can be problematic.

Deaeration and chemical oxygen scavengers

Oxygen and carbon dioxide enter the cycle with undeaerated makeup water, with cooling water which

Fig. 4 Approximate relationship between conductivity and pH for ammonia solutions in demineralized water.

leaks into the condenser, and as air leaking into the vacuum portion of the cycle.

For turbine cycles, aeration of the feedwater is initially limited by use of air ejectors to remove air from the condenser. Utility industry standard practice is to limit total air in-leakage to less than one standard cubic foot of air per minute per 100 MW of generating capacity (approximately 0.027 Nm³/100 MW), as measured at the condenser air ejectors. Final removal of oxygen and other dissolved gases adequate for boiler feedwater applications is generally accomplished by thermal deaeration of the water ahead of the boiler feed pumps. Thermal deaeration is accomplished by heating water to reduce gas solubility. Gases are then carried away by a counter flow of steam. The process is typically facilitated by the use of nozzles and trays which disperse water droplets to increase the steam-to-water interfacial area. Thermal deaeration can reduce feedwater oxygen concentration to less than 7 parts per billion (ppb). It also essentially eliminates dissolved carbon dioxide, nitrogen, and argon.

Chemical agents are generally used to scavenge residual oxygen not removed by thermal deaeration. Traditional oxygen scavengers have been sodium sulfite for low pressure boilers and hydrazine for high pressure boilers. Sulfite must not be used where the boiler pressure is greater than 900 psig (6.2 MPa). Other oxygen scavengers (erythorbic acid, diethylhydroxylamine, hydroquinone and carbohydrazide) are also used. Hydrazine has been identified as a carcinogen and this has increased the use of alternative scavengers. Scavengers are generally fed at the exit of the condensate polishing system and/or at the boiler feed pump suction.

Attemperation water

Water spray attemperation is used to control steam temperature. Attemperation for utility boilers is discussed in the *Steam temperature adjustment and control* section of Chapter 19, *Boilers, Superheaters and Reheaters*. The spray water is feedwater, polished feedwater, or steam condensate. As the spray water evaporates, all chemicals and contaminants in the water remain in the steam. This addition must not be excessive. It must not form deposits in the attemperator piping, and it must not excessively contaminate the steam. If a superheated steam purity limit is imposed, the steam purity after attemperation must not exceed this limit. To meet this requirement, the weighted average of the spray water total solids concentration and the saturated steam total solids concentration must not exceed the final steam total solids limit. Additionally, spray water attemperation must not increase the steam total solids concentration by more than 0.040 ppm. Independent of other considerations, the spray water solids concentration must never exceed 2.5 ppm. Ideally, the purity of attemperation water should equal the desired purity of the steam.

Drum boilers and internal boiler water

Boiler water that recirculates in drum and steam generation circuits has a relatively high concentration of dissolved solids that have been left behind by wa-

ter evaporation. Water chemistry must be carefully controlled to assure that this concentrate does not precipitate solids or cause corrosion within the boiler circuitry. Boiler water chemistry must also be controlled to prevent excessive carryover of impurities or chemicals with the steam.

Customized chemistry limits and treatment practices must be established for each boiler. These limits depend on steam purity requirements, feedwater chemistry, and boiler design. They also depend on boiler owner/operator preferences regarding economic tradeoffs between feedwater purification, blowdown rate, frequency of chemical cleaning, and boiler maintenance and repair. Direct boiler water treatment (usually referred to as *internal treatment*) practices commonly used to control boiler water chemistry include all volatile treatment, coordinated phosphate treatments, high-alkalinity phosphate treatments, and high-alkalinity chelant and polymer treatments. In all cases, when treatment chemicals are mixed, the identity and purity of chemicals must be verified and water of hydration in the weight of chemicals must be taken into account. The specific treatment used must always be developed and managed by competent water chemistry specialists.

Feedwater is the primary source of solids that concentrate in boiler water, and feedwater purity defines the practical limit below which the boiler water solids concentration can not be reduced with an acceptable blowdown rate. Additionally, hardness and pre-boiler corrosion products carried by the feedwater play major roles in defining the type of boiler water treatment that must be employed. Where substantial hardness is present in feedwater, provision must be made to ensure that the hardness constituents remain in solution in the boiler water or to otherwise minimize the formation of adherent deposits. This is often accomplished by use of chelant, polymer, or high-alkalinity phosphate boiler water treatment. Where substantial hardness is not present, boiler water treatment can be optimized to minimize impurity carryover in the steam and to minimize the potential for boiler tube corrosion.

Because boiler water impurities and treatment chemicals carry over in the steam, steam purity requirements play a major role in defining boiler water chemistry limits. Boiler specifications normally include a list of boiler-specific water chemistry limits that must be imposed to attain a specified steam purity. Limits must always be placed on the maximum dissolved solids concentration. Limits must also be placed on impurities and conditions that cause foaming at the steam-water interface in the drum. These include limits on oil and other organic contaminants, suspended solids, and alkalinity. The *carryover factor* is the ratio of an impurity or chemical species in the steam to that in the boiler water.

Blowdown

The dissolved solids concentration of boiler water is intermittently or continuously reduced by blowing down some of the boiler water and replacing it with feedwater. Blowdown rate is generally expressed as a percent relative to the steam flow rate from the drum.

Blowdown is accomplished through a pressure letdown valve and flash tank. Heat loss is often minimized by use of a regenerative heat exchanger.

The ratio of the concentration of a feedwater impurity in the boiler water to its concentration in the feedwater is the *concentration factor*, which can be estimated by use of Equation 1. However, a more complex formula must be used where there is substantial carryover.

If there is no blowdown, solids concentrate until carryover with the steam is sufficient to carry away all of the solids that enter the boiler with the feedwater. For example, where the feedwater silica concentration is 0.01 ppm and 10% of the silica in the boiler water carries over with the steam, the equilibrium boiler water silica concentration is 0.1 ppm.

Traditional all volatile treatment

For all volatile treatment (AVT), no solid chemicals are added to the boiler or pre-boiler cycle. Boiler water chemistry control is by boiler feedwater treatment only. No chemical additions are made directly to the drum. Feedwater pH is controlled with ammonia or an alternate amine. Because ammonia carries away preferentially with the steam, the boiler water pH may be slightly lower (0.2 to 0.4 pH units) than the feedwater pH. For traditional all volatile treatment, as opposed to oxygen treatment, hydrazine or a suitable alternate is added to scavenge residual oxygen. Table 1 shows the recommended AVT feedwater control limits. Because all volatile treatment adds no solids to the boiler water, solids carryover is generally minimized.

All volatile treatment provides no chemical control for hardness deposition and provides no buffer against caustic or acid-forming impurities. Hence, feedwater must contain no hardness minerals from condenser leakage or other sources. It must be high-purity condensate or polished condensate with mixed-bed quality demineralized makeup water.

All volatile treatment can be, but rarely is, used below 1000 psig (6.9 MPa). Normally it is used only for boilers operating at or above 2000 psig (13.8 MPa) drum pressure. It is not recommended for lower pressure boilers where other options are feasible. While all volatile treatment is one of several options for drum boilers, it is the only option for once-through boilers.

Oxygen treatment

Even in the absence of dissolved oxygen, steel surfaces react with water to form some soluble Fe^{++} ions which may deposit in the boiler, superheater, turbine, or other downstream components. However, in the absence of impurities, oxygen can form an especially protective Fe^{+++} iron oxide that is less soluble than that formed under oxygen-free conditions. To take advantage of this, some copper-free boiler cycles operating with ultra pure feedwater maintain a controlled concentration of oxygen in the feedwater. Most of these are high pressure once-through utility boilers, but this approach is also used successfully in some drum boilers.

Oxygen treatment was developed in Europe, largely by Vereinigung der Grosskesselbetreiber (VGB),¹¹ and there is also extensive experience in the former So-

viet Union (FSU). It can only be used where there is no copper in the pre-boiler components beyond the condensate polisher, and where feedwater is consistently of the highest purity, e.g., cation conductivity $< 0.15 \mu\text{S/cm}$ at 77F (25C). A low concentration of oxygen is added to the condensate. The target oxygen concentration is 0.050 to 0.150 ppm for once-through boilers and 0.040 ppm for drum boilers. With oxygen treatment, the feedwater pH can be reduced, e.g., down to 8.0 to 8.5. An advantage of oxygen treatment is decreased chemical cleaning frequencies for the boiler. In addition, when oxygen treatment is used in combination with lower pH, the condensate polisher regeneration frequency is reduced.

Coordinated phosphate treatment

Coordinated phosphate-pH treatment, introduced by Whirl and Purcell of the Duquesne Light Company,¹² controls boiler water alkalinity with mixtures of disodium and trisodium phosphate added to the drum through a chemical feed pipe. The objective of this treatment is largely to keep the pH of boiler water and underdeposit boiler water concentrates within an acceptable range. Fig. 5 indicates the phosphate concentration range that is generally necessary and sufficient for this purpose. Phosphate treatment must not be used where the drum pressure exceeds 2800 psig (19.3 MPa). All volatile treatment is recommended at the higher pressures.

In sodium phosphate solutions, an $\text{H}^+ + \text{PO}_4^{=}$ \rightarrow HPO_4^- balance buffers the pH (i.e., retards H^+ ion concentration changes). Solution pH depends on the phosphate concentration and the molar sodium-to-phosphate ratio. The relationship between pH, phosphate concentration, and molar sodium-to-phosphate ratio is shown in Fig. 6. Where solutions contain other dissolved salts (e.g., sodium and potassium chloride and sulfate), sodium phosphate can still be used to control pH, and the curves of Fig. 6 are still applicable. However, for such solutions, the sodium-to-phosphate ratio labels on these curves are only apparent values with reference to pure sodium phosphate solutions. Measured sodium concentrations can not be used in calculating sodium-to-phosphate ratios for control of

Fig. 5 Phosphate concentrations to control boiler water chemistry (little or no residual hardness in the feedwater). Indicates phosphate range at a given dissolved solids concentration.

Fig. 6 Estimated pH of sodium phosphate solutions. Note: pH values can differ by up to 0.2 pH units, depending on the choice of chemical equilibrium constants used, but more often agree within 0.05 pH units.

boiler water pH because measured sodium concentrations include non-phosphate sodium salts. While dissolved sodium chloride and sulfate do not alter boiler water pH, ammonia does alter the pH. Hence, the presence of ammonia must be taken into account where ammonia concentrations are significant compared to phosphate concentrations.

Historically, the initial goal of coordinated pH-phosphate control was to keep the effective molar sodium-to-phosphate ratio just below 3, to prevent caustic stress corrosion cracking, acid corrosion, and hydrogen damage. This proved to be an effective method for control of deposition and corrosion in many boilers. However, caustic gouging of furnace wall tubes occurred in some boilers using coordinated pH-phosphate control, and laboratory tests indicated that solutions with molar sodium-to-phosphate ratios greater than about 2.85 can become caustic when highly concentrated. Subsequently, many boilers were operated under congruent control with a target effective sodium-to-phosphate ratio of less than 2.85, generally about 2.6, and often less than 2.6. Again, this proved to be an effective method of control for many boilers, but some of the boilers operating with low molar sodium-to-phosphate ratios experienced acid phosphate corrosion. Instances of boiler tube corrosion generally occurred in boilers that experienced substantial phosphate hideout and hideout-return when the boiler load changed.

Phosphate hideout, hideout-return, and associated corrosion problems are now addressed by *equilibrium phosphate treatment*.¹³ The concentration of phosphate in the boiler water is kept low enough to avoid hideout and hideout return associated with load changes, thus it is always in equilibrium with the boiler. The effective molar sodium-to-phosphate ratio is kept above 2.8. The free hydroxide, as depicted in Fig. 6, is not to exceed the equivalent of 1 ppm sodium hydroxide. Concern about caustic gouging at the higher ratios is largely reduced by experience with this treat-

ment regime and by experience with caustic boiler water treatment.

Tables 2 and 3 show recommended boiler water chemistry limits. Customized limits for a specific boiler depend on the steam purity requirements for the boiler. Boiler and laboratory experience indicate that, under some conditions, phosphate-magnetite interactions can degrade protective oxide scale and corrode the underlying metal. To minimize these interactions, the pH must be greater than that corresponding to the 2.6 sodium-to-phosphate ratio curve of Fig. 6, and preferably greater than that corresponding to the 2.8 curve. The pH must always be above the 2.8 curve when the drum pressure is above 2600 psig (17.9 MPa). The maximum pH is that of trisodium phosphate plus 1 ppm sodium hydroxide. Additionally, the boiler water pH is not to be less than 9 nor greater than 10. As discussed below, it may be necessary to reduce the maximum boiler water phosphate concentration to avoid hideout and hideout return, and to avoid associated control and corrosion problems.

Table 2
Boiler Water Limits

Pressure Range, psig (MPa)	Maximum TDS, ppm	Maximum Suspended Solids, ppm	Maximum Silica, ppm
15 to 50* (0.10 to 0.35)	1250	15	30
15 to 50** (0.10 to 0.35)	3500	15	150
51 to 325 (0.35 to 2.24)	3500	10	150
326 to 450 (2.25 to 3.10)	3000	8	90
451 to 600 (3.11 to 4.14)	2500	6	40
601 to 750 (4.14 to 5.17)	2000	4	30
751 to 900 (5.18 to 6.21)	1500	2	20
901 to 1000 (6.21 to 6.90)	1250	1	8

* For natural separation with no diffuser baffles in the steam drum.

** Where the drum includes baffles that separate water droplets from steam.

Notes:

1. Operation outside the limits defined in this table is not recommended. Within these broad limits, more restrictive limits must be imposed, consistent with the type of boiler water treatment method chosen to control deposition, corrosion, and carryover. For example, the boiler water pH range of 8.5 to 9.0 is only acceptable with all volatile treatment (AVT).

2. ppm = mg/kg

Note: ppm = mg/kg					

Phosphate treatment chemicals may hide out during periods of high-load operation, then return to the boiler water when the load and pressure are reduced. This type of hideout makes control of boiler water chemistry difficult and can cause corrosion of furnace wall tubes. This hideout and return phenomena is caused by concentration of phosphate at the tube/water interface in high heat flux areas. In these areas, phosphates accumulate in the concentrated liquid. The concentrated phosphates then precipitate, or they adsorb on or react with surface deposits and scale.^{13,14,15} Where excessive deposits are not present, this hideout and hideout return associated with load and pressure changes can be eliminated by decreasing the phosphate concentration in the boiler water or possibly by increasing the sodium-to-phosphate ratio. Where hideout and hideout-return are caused by excessive deposits, the boiler must be chemically cleaned. The amount of phosphate hideout or return accompanying load changes must not be more than 5 ppm. Corrective action is necessary if the amount of phosphate hideout or return accompanying load changes is more than 5 ppm and/or the boiler water pH change is more than 0.2 pH units, or where there are changes in the hideout/hideout-return behavior.

This phenomenon must be distinguished from loss of phosphate to passive film formation. As the passive oxide film reforms following a chemical cleaning of the boiler, some phosphate is irreversibly lost from the boiler water. This is minimized if chemical cleaning is followed by a phosphate boilout repassivation of the boiler.

Operators should not over-correct for deviations of

pH and phosphate concentration from target values. Corrective action must be taken with an understanding of system response times, the amounts of impurities being neutralized, and the amount of treatment chemicals likely to be required.

Where phosphate treatment is used, pH is an especially critical parameter, so the accuracy of pH measuring devices and temperature corrections must be assured. The boiler water pH must also be corrected to discount the pH effect of residual ammonia in the boiler water. Fig. 7 shows the estimated effect of ammonia on boiler water pH. The figure indicates the expected pH for solutions with different concentrations of sodium phosphate and 0.2 ppm ammonia. Where these species dominate the solution chemistry, such figures may be used to estimate sodium-to-phosphate molar ratios.

With high purity feedwater, the recommended boiler water pH can be attained with appropriate additions of trisodium phosphate. If the recommended boiler water pH can not be maintained within the above limits using trisodium phosphate or a mixture of trisodium and disodium phosphate, this is indicative of alkaline or acid-forming impurities in the feedwater or excessive hideout, and the root cause must be addressed. An exception is low level equilibrium phosphate treatment, where the small amount of trisodium phosphate added to the boiler water may at times be insufficient to achieve the recommended pH. A small amount of sodium hydroxide may be added to attain the recommended pH, but the excess sodium hydroxide must not exceed 1.0 ppm.¹³ Even 1.0 ppm sodium

Fig. 7 Estimated pH of sodium phosphate solutions containing 0.2 ppm ammonium hydroxide. Note: pH values can differ by up to 0.2 pH units, depending on the choice of chemical equilibrium constants used, but more often agree within 0.05 pH units.

hydroxide may be excessive for some units, for example oil-fired boilers with especially high heat fluxes in some areas of the furnace.

When mixing boiler water treatment chemicals, operators should verify the identity and purity of the chemicals and take into account water of hydration in the weight of the chemicals. Neither phosphoric acid nor monosodium phosphate should be used for routine boiler water treatment. If monosodium phosphate is used to counter an isolated incident of alkali contamination of the boiler water, it must be used with caution, and at reduced load.

High-alkalinity phosphate treatment (low-pressure boilers only)

Minimal carryover and deposition are achieved with demineralized makeup water and minimal dissolved solids, but this is not necessarily cost-effective for all low pressure industrial boilers. Where softened water with 0.02 to 0.5 ppm residual hardness (as CaCO_3) is used as makeup water for low pressure industrial boilers, high alkalinity or *conventional* phosphate treatment may be used to control scale formation. This high alkalinity treatment must only be used for boilers operating below 1000 psig (6.9 MPa). The pH and phosphate concentrations are attained by addition of a trisodium phosphate and (if necessary) sodium hydroxide solution through a chemical feed line into the drum. With high-alkalinity phosphate treatment, the boiler water pH is maintained in the range of 10.8 to 11.4. This high pH precipitates hardness constituents that are less adherent than those formed at lower pH.

Where high alkalinity boiler water is excessively concentrated by evaporation, the concentrate can become sufficiently caustic to produce caustic gouging or stress corrosion cracking of carbon steel. Hence, high-alkalinity boiler water treatment must not be

used where waterside deposits are excessively thick, where there is steam blanketing or critical heat flux (see Chapter 5), or where there is seepage (e.g., through rolled seals or cracks).

Fig. 8 shows phosphate concentration limits for high-alkalinity phosphate treatment. With some feedwaters (e.g., high-magnesium low-silica), lower phosphate concentrations may be advisable. The required pH is attained by adjusting the sodium hydroxide concentration in the chemical feed solution. The total (M alkalinity in calcium carbonate equivalents) must not exceed 20% of the actual boiler water solids concentration.

Dispersants, polymers, and chelants (low pressure boilers only)

Where substantial hardness (e.g., 0.1 ppm as CaCO_3) is present in feedwater, chelant treatment is often used to ensure that the hardness constituents remain in solution in the boiler water, or polymer treatment is used to keep precipitates in suspension. Blowdown of the dissolved contaminants and colloids is more effective than that of noncolloidal hardness precipitates and metal oxides.

While phosphate treatment precipitates residual calcium and magnesium in a less detrimental form than occurs in the absence of phosphate, chelants react with calcium and magnesium to form soluble compounds that remain in solution. Chelants commonly employed include ethylene-diaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA). Because of concern about thermal stability, the use of chelants and polymers should be limited to boilers operating at less than 1000 psi (6.9 MPa).

To be most effective, chelant must mix with the feedwater and form thermally stable calcium and magnesium complexes before there is substantial residence time at high temperature, where free chelant is not thermally stable. Because the combination of free chelant and dissolved oxygen can be corrosive, chelant must be added only after completion of oxygen removal and scavenging. Also, there must be no copper-bearing components in the feedwater train beyond the chelant feed point.

Control limits depend on the feedwater chemistry, specific treatment chemicals used, and other factors. However, the boiler feedwater pH is generally be-

Fig. 8 Phosphate concentration limits for high-alkalinity phosphate treatment.

tween 9.0 and 9.6 and hardness as calcium carbonate is less than 0.5 ppm. The boiler water pH is generally maintained in the range of 10.0 to 11.4. The boiler water pH is attained by a combination of alkalinity derived from the chelant feed (e.g., as Na₄ EDTA), evolution of CO₂ from softened feedwater, and addition of sodium hydroxide. Polymeric dispersants are generally used to impede formation of scale by residual solids.

Once-through universal pressure boilers

In a subcritical once-through boiler, there is no steam drum. As water passes through boiler tubing, it evaporates entirely into steam. Because steam does not cool the tube as effectively as water, the tube temperature increases beyond this dry-out location. Subcritical once-through boilers are designed so this transition occurs in a lower heat flux region of the boiler where the temperature increase is not sufficient to cause a problem. However, because the water evaporates completely, it must be of exceptional purity to avoid corrosion and rapid deposition, and carryover of dissolved solids.

Similarly stringent water purity requirements must be imposed for supercritical boilers. While there is no distinction between water and steam in a supercritical boiler, the physical and chemical properties of the fluid change as it is heated, and there is a temperature about which dissolved solids precipitate much as they do in the dry-out zone of a subcritical once-through boiler. This is termed the *pseudo transition zone*. (See Chapter 5.)

Satisfactory operation of a once-through boiler and associated turbine requires that the total feedwater solids be less than 0.030 ppm total dissolved solids with cation conductivity less than 0.15 μ S/cm. Table 1 lists recommended limits for other feedwater parameters. Feedwater purification must include condensate polishing, and water treatment chemicals must all be volatile. Ammonia is typically added to control pH. For traditional all volatile treatment, hydrazine or a suitable volatile substitute is used for oxygen scavenging. Iron pickup from pre-boiler components can be minimized by maintaining a feedwater pH of 9.3 to 9.6. Prior to plant startup, feedwater must be circulated through the condensate polishing system to remove dissolved and suspended solids. Temperatures should not exceed 550F (288C) at the convection pass outlet until the iron levels are less than 0.1 ppm at the economizer inlet.

Utility once-through boilers with copper-free cycle metallurgy commonly use oxygen treatment. Table 1 includes recommended limits for other feedwater chemical parameters for oxygen treatment. Startup is with increased pH and no oxygen feed. Oxygen addition to feedwater is initiated and pH is reduced only after feedwater cation conductivity is less than 0.15 μ S/cm.

System transients and upsets inevitably cause excursions above recommend limits. Increased rates of deposition and corrosion are likely to be in proportion to the deviations. Small brief deviations may individually be of little consequence, but the extent, duration, and frequency of such deviations should be minimized.

Otherwise, over a period of years the accumulative effects will be significant. Potential effects include increased deposition, pitting, pressure drop, and fatigue cracking. Particular care is required to minimize the extent and duration of chemistry deviations for cycling units where operational transients are frequent.

Steam purity

Purity or chemistry requirements for steam can be as simple as a specified maximum moisture content, or they can include maximum concentrations for a variety of chemical species. Often, for low-pressure building or process heater steam, only a maximum moisture content is specified. This may be as high as 0.5% or as low as 0.1%. Conversely, some turbine manufacturers specify steam condensate maximum cation conductivity, pH, and maximum concentrations for total dissolved solids, sodium and potassium, silica, iron, and copper. Turbine steam must generally have total dissolved solids less than 0.050 ppm, and in some cases less than 0.030 ppm. Individual species limits may be still lower. If steam is to be superheated, a maximum steam dissolved solids limit must be imposed to avoid excessive deposition and corrosion of the superheater. This limit is generally 0.100 ppm or less. Even where steam purity requirements are not imposed by the application, steam dissolved solids concentrations less than 1.0 ppm are recommended at pressures up to 600 psig (4.1 MPa), dissolved solids concentrations less than 0.5 ppm are recommended at 600 to 1000 psig (4.1 to 6.9 MPa), and dissolved solids concentrations less than 0.1 ppm are recommended above 1000 psig (6.9 MPa).

Up to 2000 psig (13.8 MPa), most non-volatile chemicals and impurities in the steam are carried by small water droplets entrained in the separated steam. Because these droplets contain dissolved solids in the same concentration as the boiler water, the amount of impurities in steam contributed by this mechanical carryover is the sum of the boiler water impurities concentration multiplied by the steam moisture content. Mechanical carryover is limited by moisture separation devices placed in the steam path, as described in Chapter 5.

High water levels in the drum and boiler water chemistries that cause foaming can cause excessive moisture carryover and therefore excessive steam impurity concentrations. *Foaming* is the formation of foam or excessive spray above the water line in the drum. Common causes of foaming are excessive solids or alkalinity, and the presence of organic matter such as oil. To keep dissolved solids below the concentration that causes foaming requires continuous or periodic blowdown of the boiler. High boiler water alkalinity increases the potential for foaming, particularly in the presence of suspended matter.

Where a chemical species is sufficiently volatile, it also carries over as a vapor in the steam. Total carryover is the sum of the mechanical and vaporous carryover. Vaporous carryover depends on solubility in steam and is different for each chemical species. For most dissolved solids found in boiler water, it is negligible by comparison to mechanical carryover at pres-

tures less than 2000 psig (13.8 MPa). An exception is silica for which vaporous carryover can be substantial at lower pressures. Fig. 9 shows typical vaporous carryover fractions (distribution ratios) for common boiler water constituents under typical conditions over a wide range of boiler pressures. Fig. 10 shows expected total dissolved solids carryover for typical high-pressure boilers. Vaporous carryover depends on pressure and on boiler water chemistry. It is not affected by boiler design. Hence, if vaporous carryover for a species is excessive, the carryover can only be reduced by altering the boiler water chemistry. Only mechanical carryover is affected by boiler design. Non-interactive gases such as nitrogen, argon, and oxygen carry over almost entirely with the steam, having no relationship to moisture carryover.

Excessive steam impurity concentrations can also be caused by feedwater and boiler water chemistries that favor volatile species formation. Carryover of volatile silica can be problematic at pressures above 1000 psig (6.9 MPa). Fig. 11 shows boiler water silica concentration limits recommended to obtain steam silica concentrations less than 0.010 ppm at pressures up to 2900 psig (20.0 MPa) where the pH may be as low as 8.8. Vaporous silica carryover at a pH of 10.0 is 88% of that at a pH of 8.8. The vaporous silica carryover at a pH of 11.0 is 74% of that at 8.8. The only effective method for preventing excessive silica or other vaporous carryover is reduction of the boiler water concentrations. Another common source of excessive impurities in steam is inadequate attemperation spray water purity. All impurities in the spray water enter directly into the steam. Procedures for measuring steam quality and purity are discussed in Chapter 40.

Fig. 9 Impurity carryover coefficients of salts and metal oxides in boiler water (adapted from Reference 16).

Fig. 10 Solids in steam versus dissolved solids in boiler water.

Water sampling and analysis

A key element in control of water and steam chemistry is effective sampling to obtain representative samples, prevent contamination of the samples, and prevent loss of the species to be measured.¹⁷ References 18 and 19 provide detailed procedures. In general, sample lines should be as short as possible and made of stainless steel, except where conditions dictate otherwise. Samples should be obtained from a continuously flowing sample stream. The time between sampling and analysis should be as short as possible. Samples should be cooled quickly to 100F (38C) to avoid loss of the species of interest. Sample nozzles and lines should provide for isokinetic sample velocity and maintain constant high water velocities [minimum of 6 ft/s (1.8 m/s)] to avoid loss of materials. Sample points should be at least 10 diameters downstream of the last bend or flow disturbance.

Guidelines and techniques for chemical analysis of grab samples are listed in Table 4. The detailed methods are readily available from the American Society for Testing and Materials (ASTM) in Philadelphia, Pennsylvania, U.S. and the American Society of Mechanical Engineers (ASME) in New York, New York, U.S.

Wherever practical, on-line monitoring should be considered as an alternative to grab samples. This gives real-time data, enables trends to be followed, and provides historical data. However, on-line monitors require calibration, maintenance, and checks with grab samples or on-line synthesized standard samples to ensure reliability. Table 5 lists important on-line monitoring measurements and references to specific methods. In addition to the measurements listed, in-

Fig. 11 Boiler water silica concentration limit, where maximum steam silica is 0.010 ppm and boiler water pH is greater than 8.8.

strumentation is commercially available to monitor chloride, dissolved oxygen, dissolved hydrogen, silica, phosphate, ammonia and hydrazine.

Adequate water chemistry control depends on the ability of boiler operators to consistently measure the specified parameters. Hence, formal quality assurance programs should be used to quantify and track the precision and bias of measurements. Detailed procedures should be in place to cover laboratory structure, training, standardization, calibration, sample collection/storage/analysis, reporting, maintenance records, and corrective action procedures. Further discussion is provided in Reference 20.

Common fluid-side corrosion problems

Water and steam react with most metals to form oxides or hydroxides. Formation of a protective oxide layer such as magnetite (Fe_3O_4) on the metal surface causes reaction rates to slow with time. Boiler cycle water treatment programs are designed to maintain such protective oxide films on internal surfaces and thus prevent corrosion in boilers and other cycle components. With adequate control of water and steam chemistry, internal corrosion of boiler circuitry can be minimized. Yet, chemistry upsets (transient losses of control) do occur. Vigilant monitoring of system chemistry permits quick detection of upsets and quick remedial action to prevent boiler damage. Where these measures fail and corrosion occurs, good monitoring and documentation of system chemistry can facilitate identification of the root cause, and identification of the cause can be an essential step toward avoiding further corrosion. Where corrosion occurs and the origin is unknown, the documented water chemistry, location of

the corrosion, appearance of the corrosion, and chemistry of localized deposits and corrosion products often suggest the cause. Common causes are flow accelerated corrosion, oxygen pitting, chelant corrosion, caustic corrosion, acid corrosion, organic corrosion, acid phosphate corrosion, hydrogen damage, and corrosion assisted cracking. Figs. 12 and 13 show typical locations of common fluid-side corrosion problems. Further dis-

Fig. 13 Boiler convection pass showing typical locations of various types of water-side corrosion.

Fig. 12 Typical locations of various types of water-side corrosion in a boiler furnace water circuit.

cussion of corrosion and failure mechanisms is provided in References 21, 22, 23, and 24. For EPRI members, *Boiler Tube Failures: Theory and Practice*²⁵ provides an especially thorough description of utility boiler corrosion problems, causes, and remedial measures.

One distinguishing feature of corrosion is its appearance. Metal loss may be uniform so the surface appears smooth. Conversely, the surface may be gouged, scalloped, or pitted. Other forms of corrosion are microscopic in breadth, and subsurface, so they are not initially discernible. Subsurface forms of corrosion include intergranular corrosion, corrosion fatigue, stress corrosion cracking, and hydrogen damage. Such corrosion can occur alone or in combination with surface wastage. In the absence of component failure, detection of subsurface corrosion often requires ultrasonic, dye penetrant, or magnetic particle inspection (Chapter 45). These forms of corrosion are best diagnosed with destructive cross-section metallography.

Another distinguishing feature is the chemical composition of associated surface deposits and corrosion products. Deposits may contain residual corrosives such as caustic or acid. Magnesium hydroxide in deposits can suggest the presence of an acid-forming precipitation process. Sodium ferrate (Na_2FeO_4) indicates caustic conditions. Sodium iron phosphate indicates acid phosphate wastage. Organic deposits suggest corrosion by organics, and excessive amounts of ferric oxide or hydroxide with pitting suggest oxygen attack.

Flow accelerated corrosion is the localized dissolution of feedwater piping in areas of flow impingement. It occurs where metal dissolution dominates over protective oxide scale formation. For example, localized

conditions are sufficiently oxidizing to form soluble Fe^{++} ions but not sufficiently oxidizing to form Fe^{+++} ions needed for protective oxide formation. Conditions known to accelerate thinning include: flow impingement on pipe walls, low pH, excessive oxygen scavenger concentrations, temperatures in the range of 250 to 400F/121 to 204C (although thinning can occur at any feedwater temperature), chemicals (such as chelants) that increase iron solubility, and thermal degradation of organic chemicals. Thinned areas often have a scalloped or pitted appearance. Failures, such as that shown in Fig. 14, can occur unexpectedly and close to work areas and walkways. To assure continued integrity of boiler feedwater piping, it must be periodically inspected for internal corrosion and wall thinning. Any thinned areas must be identified and replaced before they become a safety hazard. The affected piping should be replaced with low-alloy chromium-bearing steel piping, and the water chemistry control should be appropriately altered.

Oxygen pitting and corrosion during boiler operation largely occur in pre-boiler feedwater heaters and economizers where oxygen from poorly deaerated feedwater is consumed by corrosion before it reaches the boiler. A typical area of oxygen pitting is shown in Fig. 15. Oxygen pitting within boilers occurs when poorly deaerated water is used for startup or for accelerated cooling of a boiler. It also occurs in feedwater piping, drums, and downcomers in some low pressure boilers which have no feedwater heaters or economizer. Because increasing scavenger concentrations to eliminate residual traces of oxygen can aggravate flow accelerated corrosion, care must be taken to distinguish between oxygen pitting and flow accelerated

corrosion which generally occurs only where all traces of oxygen have been eliminated.

Chelant corrosion occurs where appropriate feedwater and boiler water chemistries for chelant treatment are not maintained. Potentially corrosive conditions include excessive concentration of free chelant and low pH. (See prior discussion of boiler water treatment with dispersants, polymers, and chelants.) Especially susceptible surfaces include flow impingement areas of feedwater piping, riser tubes, and cyclone steam/water separators. Affected areas are often dark colored and have the appearance of uniform thinning or of flow accelerated corrosion.

Corrosion fatigue is cracking well below the yield strength of a material by the combined action of corrosion and alternating stresses. Cyclic stress may be of mechanical or thermal origin (Chapter 8). In boilers, corrosion fatigue is most common in water-wetted surfaces where there is a mechanical constraint on the tubing. For example, corrosion fatigue occurs in furnace wall tubes adjacent to windbox, buckstay, and other welded attachments. Failures are thick lipped. On examination of the internal tube surface, multiple initiation sites are evident. Cracking is transgranular. Environmental conditions facilitate fatigue cracking where it would not otherwise occur in a benign environment. Water chemistry factors that facilitate cracking include dissolved oxygen and low pH transients associated with, for example, cyclic operation, condenser leaks, and phosphate hideout and hideout-return.

Acid phosphate corrosion occurs on the inner steam-forming side of boiler tubes by reaction of the steel with phosphate to form maricite (NaFePO_4). Fig. 16 shows ribbed tubing that has suffered this type of wastage. The affected surface has a gouged appearance with maricite and magnetite deposits. Acid phosphate corrosion occurs where the boiler water effective sodium-to-phosphate ratio is less than 2.8, although ratios as low as 2.6 may be tolerated at lower pressures. Though not always apparent, common signs of acid phosphate corrosion include difficulty maintaining target phosphate concentrations, phosphate hideout and pH increase with increasing boiler load or pressure, phosphate hideout return and decreasing pH with decreasing load or pressure, and periods of high iron concentration in boiler water. The potential for acid phosphate corrosion increases with increasing internal deposit loading, decreasing effective sodium-to-phosphate molar ratio below 2.8, increasing phosphate concentration, inclusion of acid phosphates (disodium and especially monosodium phosphate) in phosphate feed solution, and increasing boiler pressure. To avoid acid phosphate corrosion, operators should monitor boiler water conditions closely, assure accuracy of pH and phosphate measurements, assure purity and reliability of chemical feed solutions, assure that target boiler water chemistry parameters are appropriate and are attained in practice, and watch for aforementioned signs of acid phosphate corrosion.

Under-deposit acid corrosion and *hydrogen damage* occur where boiler water acidifies as it concentrates beneath deposits on steam generating surfaces. Hydrogen from acid corrosion diffuses into the steel where

Fig. 14 Rupture of 6 in. (152 mm) feedwater pipe in an area thinned by internal corrosion.

Fig. 15 Oxygen pitting of economizer feedwater inlet.

it reacts with carbon to form methane as depicted in Fig. 17. The resultant decarburization and methane formation weakens the steel and creates microfissures. Thick lipped failures like that shown in Fig. 18 occur when the degraded steel no longer has sufficient strength to hold the internal tube pressure. Signs of hydrogen damage include under deposit corrosion, thick lipped failure, and steel decarburization and microfissures. The corrosion product from acid corrosion is mostly magnetite. Affected tubing, which may extend far beyond the failure, must be replaced. The boiler must be chemically cleaned to remove internal tube deposits, and boiler water chemistry must be altered or better controlled to prevent acid-formation as the water concentrates. Operators should reduce acid-forming impurities by improving makeup water, reducing condenser leakage, or adding condensate polishing. For drum boilers, operators should use phosphate treatment with an effective sodium-to-phosphate molar ratio of 2.8 or greater.

Fig. 16 Acid phosphate corrosion of ribbed tubing.

Fig. 17 Schematic of hydrogen attack, showing steps that occur and the final result. Hydrogen attack can occur in both carbon and low alloy steels in acidic or hydrogen environments.

Caustic corrosion, gouging and grooving occur where boiler water leaves a caustic residue as it evaporates. In vertical furnace wall tubes, this occurs beneath deposits that facilitate a high degree of concentration and the corroded surface has a gouged appearance as shown in Fig. 19. In inclined tubes where the heat flux is directed through the upper half of the tube, caustic concentrates by evaporation of boiler water in the steam space on the upper tube surface. Resulting corrosion is in the form of a wide smooth groove with the groove generally free of deposits and centered on the crown of the tube. Deposits associated with caustic gouging often include Na_2FeO_4 . To prevent reoccurrence of caustic gouging, operators should prevent accumulation of excessive deposits and control water chemistry so boiler water does not form caustic as it concentrates. The latter can generally be achieved by assuring appropriate feedwater chemistry with coordinated phosphate boiler water treatment, taking care to control the effective sodium-to-phosphate molar ratio as appropriate for the specific boiler and the specific chemical and operating conditions. In some instances, where caustic grooving along the top of a sloped tube is associated with steam/water separation, such separation can be avoided by use of ribbed tubes which cause swirling motion that keeps water on the tube wall.

Caustic cracking can occur where caustic concentrates in contact with steel that is highly stressed, to or beyond the steel's yield strength. Caustic cracking is rare in boilers with all welded connections. This

Fig. 18 Brittle tube failure in hydrogen damaged area.

Fig. 19 Caustic gouging initiated along weld backing ring.

generally occurs in boilers using a high alkalinity caustic boiler water treatment, and it is normally associated with unwelded rolled joints and welds that are not stress relieved. On metallographic examination, caustic cracking is intergranular and has the branched appearance characteristic of stress corrosion cracking as illustrated in Fig. 20. It can generally be avoided by use of coordinated phosphate treatment. Where a high alkalinity caustic phosphate boiler water treatment is used for low pressure boilers, nitrate is often added to inhibit caustic cracking.

Overheat failures like that shown in Fig. 21 occur where deposits impede internal heat transfer to the

Fig. 20 Schematic of stress corrosion cracking.

extent that a tube no longer retains adequate strength and bulges or ruptures. Internal tube deposits generally cause moderate overheating for extended periods of time, causing *long-term overheat failures*. *Short-term overheat failures* generally occur only when there is gross interruption of internal flow to cool the tube, or grossly excessive heat input.

Out-of-service corrosion is predominantly oxygen pitting. Pitting attributed to out-of-service corrosion occurs during outages but also as aerated water is heated when boilers return to service. Especially common locations include the waterline in steam drums, areas where water stands along the bottom of horizontal pipe and tube runs, and lower bends of pendant superheaters and reheaters. Pinhole failures are more common in thinner walled reheater and economizer tubing. Such corrosion can be minimized by following appropriate layup procedures for boiler outages and by improving oxygen control during boiler startups.

Pre-operational cleaning

In general, all new boiler systems receive an alkaline boilout, i.e. hot circulation of an alkaline mixture with intermittent blowdown and final draining of the unit. Many systems also receive a pre-operational chemical cleaning. The superheater and reheater should receive a conventional steam blow (a period of high velocity steam flow which carries debris from the system). Chemical cleaning of superheater and reheat surfaces is effective in reducing the number of steam blows to obtain clean surfaces, but is not required to obtain a clean superheater and reheater.

Alkaline boilout

All new boilers should be flushed and given an alkaline boilout to remove debris, oil, grease and paint. This can be accomplished with a combination of trisodium phosphate (Na_3PO_4) and disodium phosphate (Na_2HPO_4), with a small amount of surfactant added as a wetting agent. The use of caustic NaOH and/or soda ash (Na_2CO_3) is not recommended. If either is used, special precautions are required to protect boiler components.

Chemical cleaning

After boilout and flushing are completed, corrosion products may remain in the feedwater system and boiler in the form of iron oxide and mill scale. Chemical cleaning should be delayed until full load operation has carried the loose scale and oxides from the feedwater system to the boiler. Some exceptions are units that incorporate a full flow condensate polishing system and boilers whose pre-boiler system has been chemically cleaned. In general, these units can be chemically cleaned immediately following pre-operational boilout.

Different solvents and cleaning processes are used for pre-operational chemical cleaning, usually determined by boiler type, metallic makeup of boiler components, and environmental concerns or restrictions. The four most frequently used are: 1) inhibited 5% hydrochloric acid with 0.25% ammonium bifluoride, 2) 2%

hydroxyacetic/1% formic acids with 0.25% ammonium bifluoride and a corrosion inhibitor, 3) 3% inhibited ammonium salts of ethylene-diaminetetraacetic acid (EDTA), and 4) 3% inhibited ammoniated citric acid.

Steam line blowing

The steam line blow procedure depends on unit design. Temporary piping to the atmosphere is required with all procedures. This piping must be anchored to resist high nozzle reaction force.

All normal startup precautions should be observed for steam line blowing. The unit should be filled with treated demineralized water. Sufficient feedwater pump capacity and condensate storage must be available to replace the water lost during the blowing period.

Numerous short blows are most effective. The color of the steam discharged to the atmosphere provides an indication as to the quantity of debris being removed from the piping. Coupons (targets) of polished steel attached to the end of the exhaust piping are typically used as final indicators.

Periodic chemical cleaning

Cleaning frequency

Internal surfaces of boiler water-side components (including supply tubes, headers and drums) accumulate deposits even though standard water treatment practices are followed. These deposits are generally classified as hardness-type scales or soft, porous-type deposits.

To determine the need for cleaning, tube samples containing internal deposits should be removed from high heat input zones of the furnace and/or areas where deposition problems have occurred. The deposit weight is first determined by visually selecting a heavily deposited section. After sectioning the tube (hot and cold sides), the water-formed deposit is removed by scraping from a measured area. The weight of the dry material is reported as weight per unit area: either grams of deposit per square foot of tube surface or mg/cm². Procedures for mechanical and chemical methods of deposit removal are provided in ASTM D3483.²⁶ General guidelines for determining when a boiler should be chemically cleaned are shown in Table 6. The deposit weights shown are based on the mechanical scraping method. This removes the porous deposit of external origin and most of the dense inner oxide scale. Values are slightly lower than those obtained from the chemical dissolution method.

Because of the corrosive nature of the fuel and its combustion products, furnace tubes in Kraft recovery and refuse-fired boilers are particularly susceptible to gas-side corrosion which can be aggravated by relatively modest elevated tube metal temperatures. (See Chapters 28 and 29.) Through-wall failures due to external metal corrosion can occur in these tubes at water-side deposit weights much less than 40 g/ft² (43 mg/cm²). In addition, for Kraft recovery boilers there are significant safety concerns for water leakage in the lower furnace. (See Chapters 28 and 43.) For these units, a more conservative cleaning criterion is recommended for all operating pressures.

Fig. 21 Short-term overheating thin edged failure.

Chordal thermocouples

The chordal thermocouple (see Chapter 40) can be an effective diagnostic tool for evaluating deposits on operating boilers. Properly located thermocouples can indicate a tube metal temperature increase caused by excess internal deposits, and can alert the operator to conditions that may cause tube failures. Thermocouples are often located in furnace wall tubes adjacent to the combustion zone where the heat input is highest and the external tube temperatures are also high. (See Fig. 22.)

Deposition inside tubes can be detected by instrumenting key furnace tubes with chordal thermocouples. These thermocouples compare the surface temperature of the tube exposed to the combustion process with the temperature of saturated water. As deposits grow, they insulate the tube from the cooling water and cause tube metal temperature increases.

Beginning with a clean, deposit-free boiler, the instrumented tubes are monitored to establish the temperature differential at two or three boiler ratings; this establishes a base curve. At maximum load, with clean tubes, the surface thermocouple typically indicates metal temperatures 25 to 40F (14 to 22C) above saturation in low duty units and 80 to 100F (44 to 56C) in high duty units as shown in Fig. 23. The temperature variation for a typical clean instrumented tube is dependent upon the tube's location in the furnace, tube thickness, inside fluid pressure, and the depth of the

Table 6
Guidelines for Chemical Cleaning

Fig. 22 Typical locations of chordal thermocouples.

surface thermocouple. Internal scale buildup is detected by an increase in temperature differential above the base curve. Chemical cleaning should normally be considered if the temperature differential at maximum boiler load reaches 100F (56C).

Initially, readings should be taken weekly, preferably using the same equipment and procedure as used for establishing the base curve. Under upset conditions, when deposits form rapidly, the checking frequency should be increased.

Chemical cleaning procedures and methods

In general, four steps are required in a complete chemical cleaning process:

1. The internal heating surfaces are washed with a solvent containing an inhibitor to dissolve or disintegrate the deposits.
2. Clean water is used to flush out loose deposits, solvent adhering to the surface, and soluble iron salts. Corrosive or explosive gases that may have formed in the unit are also displaced.

3. The unit is treated to neutralize and *passivate* the heating surfaces. This treatment produces a passive surface, i.e., it forms a very thin protective film on freshly cleaned ferrous surfaces.
4. The unit is flushed with clean water to remove any remaining loose deposits.

The two generally accepted chemical cleaning methods are: 1) continuous circulation of the solvent (Fig. 24), and 2) filling the unit with solvent, allowing it to soak, then flushing the unit (Fig. 25).

Circulation cleaning method

In the circulation (dynamic) cleaning method (Fig. 24), after filling the unit with demineralized water, the water is circulated and heated to the required cleaning temperature. At this time, the selected solvent is injected into the circulating water and recirculated until the cleaning is completed. Samples of the return solvent are periodically tested. Cleaning is considered complete when the acid strength and the iron

content of the returned solvent reach equilibrium (Fig. 26), indicating that no further reaction with the deposits is taking place. In the circulation method, additional solvent can be injected if the dissipation of the solvent concentration drops below the recommended minimum concentration.

The circulation method is particularly suitable for cleaning once-through boilers, superheaters, and economizers with positive liquid flow paths to assure circulation of the solvent through all parts of the unit. Complete cleaning can not be assured by this method unless the solvent reaches and passes through every circuit of the unit.

Soaking method

The soaking (static) cleaning method (Fig. 25) involves preheating the unit to a specified temperature, filling the unit with the hot solvent, then allowing the unit to soak for a period of time, depending on deposit conditions. To assure complete deposit removal, the acid strength of the solvent must be somewhat greater than that required by the actual conditions; unlike the circulation method, control testing during the course of the cleaning is not conclusive, and samples of solvent drawn from convenient locations may not truly represent conditions in all parts of the unit.

The soaking method is preferable for cleaning units where definite liquid distribution to all circuits (by the circulation method) is not possible without the use of many chemical inlet connections. The soaking method is also preferred when deposits are extremely heavy, or if circulation through all circuits at an appreciable rate can not be assured without an impractically-sized circulating pump. These conditions may exist in large natural circulation units that have complex furnace wall cooling systems.

Advantages of this method are simplicity of piping connections and assurance that all parts are reached by a solvent of adequate acid strength.

Solvents

Many acids and alkaline compounds have been evaluated for removing boiler deposits. Hydrochloric acid (HCl) is the most practical cleaning solvent when using the soaking method on natural circulation boilers. Chelates and other acids have also been used.

An organic acid mixture such as hydroxyacetic-formic (HAF) is the safest chemical solvent when applying the circulation cleaning method to once-through boilers. These acids decompose into gases in the event of incomplete flushing.

For certain deposits, the solvent may require additional reagents, such as ammonium bifluoride, to promote deposit penetration. Alloy steel pressure parts, particularly those high in chromium, should generally not be cleaned with certain acid solvents. A general guideline for solvent selection can be found in Table 7.

Prior to chemically cleaning, it is strongly recommended that a representative tube section be removed and subjected to a laboratory cleaning test to determine and verify the proper solvent chemical, and concentrations of that solvent.

Fig. 23 Temperature difference between surface and saturation thermocouples.

Deposits

Scale deposits formed on the internal heating surfaces of a boiler generally come from the water. Most of the constituents belong to one or more of the following groups: iron oxides, metallic copper, carbonates, phosphates, calcium and magnesium sulfates, silica, and silicates. The deposits may also contain various amounts of oil.

Pre-cleaning procedures include analysis of the deposit and tests to determine solvent strength and contact time and temperature. The deposit analyses should include a deposit weight in grams per square foot (or milligrams per square centimeter) and a spectrographic analysis to detect the individual elements. X-ray diffraction identifying the major crystalline constituents is also used.

If the deposit analysis indicates the presence of copper (usually from corrosion of pre-boiler equipment, such as feedwater heaters and condensers), one of three procedures is commonly used: 1) a copper complexing agent is added directly to the acid solvent, 2) a separate cleaning step, featuring a copper solvent, is used followed by an acid solvent, and 3) a chelant-based solvent at high temperature is used to remove iron, followed by addition of an oxidizing agent at re-

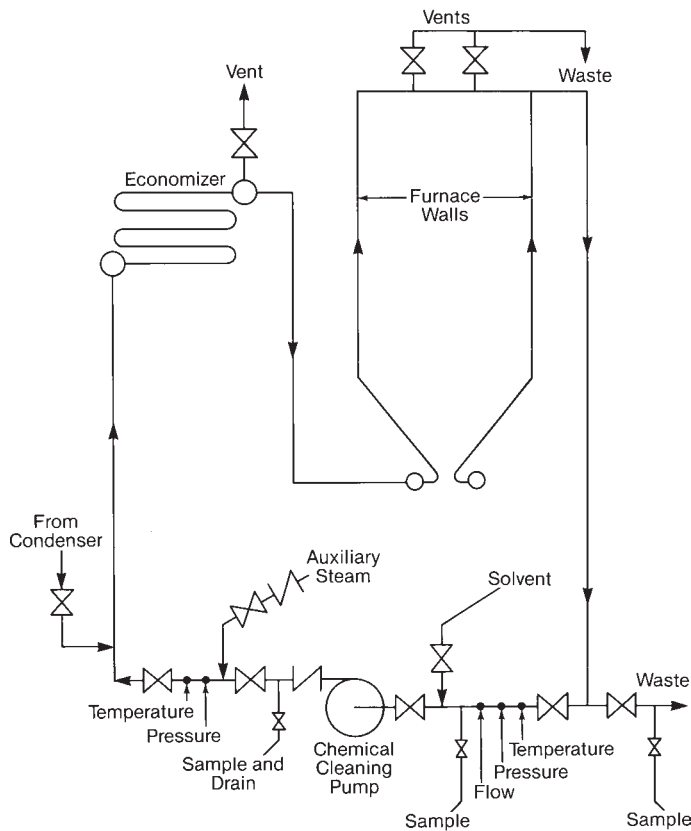

Fig. 24 Chemical cleaning by the circulation method – simplified arrangement of connections for once-through boilers.

Fig. 25 Chemical cleaning by the soaking method – simplified arrangement of connections for drum-type boilers.

duced temperature for copper removal. The decision to use one of these methods depends on the estimated quantity of copper present in the deposit.

When deposits are dissolved and disintegrated, oil is removed simultaneously, provided it is present only in small amounts. For higher percentages of oil contamination, a wetting agent or surfactant may be added to the solvent to promote deposit penetration. If the deposit is predominantly oil or grease, boiling out with alkaline compounds must precede the acid cleaning.

Inhibitors

The following equations represent the reactions of hydrochloric acid with constituents of boiler deposits:

At the same time, however, the acid can also react with and thin the boiler metal, as represented by the equation:

unless means are provided to slow this reaction without affecting the deposit removal. A number of excellent commercial inhibitors are available to perform this function. The aggressiveness of acids toward boiler deposits and steel increases rapidly with temperature. However, the inhibitor effectiveness decreases as the temperature rises and, at a certain temperature, the inhibitor may decompose. Additionally, all inhibitors are not effective with all acids.

Determination of solvent conditions

Deposit samples The preferred type of deposit sample is a small section of tube with the adhering deposit, though sometimes tube samples are not easily obtained. Selection of the solvent system is made from the deposit analyses. After selection of the solvent system, it is necessary to determine the strength of the solvent, the solvent temperature, and the length of time required for the cleaning process.

Solvent strength The solvent strength should be proportional to the amount of deposit. Commonly used formulations are:

1. Natural circulation boilers (soaking method)
 - (a) pre-operational – inhibited 5% hydrochloric acid + 0.25% ammonium bifluoride
 - (b) operational – inhibited 5 to 7.5% hydrochloric acid and ammonium bifluoride based on deposit analysis
2. Once-through boilers (circulation method)
 - (a) pre-operational – inhibited 2% hydroxyacetic-1% formic acids + 0.25% ammonium bifluoride
 - (b) operational – inhibited 4% hydroxyacetic-2% formic acids + ammonium bifluoride based on deposit analysis

Solvent temperature The temperature of the solvent should be as high as possible without seriously reducing the effectiveness of the inhibitor. An inhibitor test should be performed prior to any chemical cleaning

to determine the maximum permissible temperature for a given solvent.

When using hydrochloric acid, commercial inhibitors generally lose their effectiveness above 170F (77C) and corrosion rate increases rapidly. Therefore, the temperature of the solvent, as fed to the unit, should be 160 to 170F (71 to 77C). In using the circulation method with a hydroxyacetic-formic acid mixture, a temperature of 200F (93C) is necessary for adequate cleaning. Chelate-based solvents are generally applied at higher temperatures (about 275F/135C). In these cases, the boiler is fired to a specific temperature. The chelate chemicals are introduced and the boiler temperature is cycled by alternately firing and cooling to predetermined limits.

Steam must be supplied from an auxiliary source to heat the acid as it is fed to the unit. When using the circulation method, steam is also used to heat the circulating water to the predetermined and desired temperature before injecting the acid solution. Heat should be added by direct contact or closed cycle heat exchangers. The temperature of the solvent should never be raised by firing the unit when using an acid solvent.

Cleaning time When cleaning by the circulation method, process completion is determined by analyzing samples of the return solvent for iron concentration and acid strength. (See Fig. 26.) However, acid circulation for a minimum of six hours is recommended.

In using the soaking method, the cleaning time should be predetermined but is generally between six to eight hours in duration.

Preparation for cleaning

Heat transfer equipment All parts not to be cleaned should be isolated from the rest of the unit. To exclude acid, appropriate valves should be closed and checked for leaks. Where arrangements permit, parts of the unit such as the superheater can be isolated by filling with demineralized water. Temporary piping should be installed to flush dead legs after cleaning. In addition to filling the superheater with demineralized water, once-through type units should be pressurized with a pump or nitrogen. The pressure should exceed the chemical cleaning pump head.

Bronze or brass parts should be removed or temporarily replaced with steel. All valves should be steel or steel alloy. Galvanized piping or fittings should not be

Fig. 26 Solvent conditions during cleaning by the circulation method.

Table 7
Comparative Cleaning Effectiveness

Type of Cleaning	Makeup of Deposit			Hardness (Ca/Mg)
	Iron	Copper	Silica	
HCl	Good	Medium	Medium	Good
HAF	Good	Poor	Medium	Medium/poor
EDTA	Good	Medium	Poor	Medium/poor
Citric	Good	Medium	Poor	Poor
Bromate	N/A	Good	N/A	N/A

used. Gauge and meter connections should be closed or removed.

All parts not otherwise protected by blanking off or by flooding with water will be exposed to the inhibited solvent. Vents to a safe discharge should be provided wherever vapors might accumulate, because acid vapors from the cleaning solution do not retain the inhibitor.

Cleaning equipment The cleaning equipment should be connected as shown in Fig. 24 if the continuous circulation method is used, or as shown in Fig. 25 if the soaking method is used. Continuous circulation requires an inlet connection to assure distribution. It also requires a return line to the chemical cleaning pump from the unit. The soaking method does not require a return line. The pump discharge should be connected to the lowermost unit inlet.

The filling or circulating pump should not be fitted with bronze or brass parts; a standby pump is recommended. A filling pump should have the capacity to deliver a volume of liquid equal to that of the vessel within two hours at 100 psi (0.7 MPa). A circulating pump should have sufficient capacity to meet recommended cleaning velocities. With modern once-through boilers, a capacity of 3600 GPM (227 l/s) at 300 psi (2.1 MPa) is common. A solvent pump, closed mixing tank and suitable thermometers, pressure gauges, and flow meters are required. An adequate supply of clean water and steam for heating the solvent should be provided. Provision should be made for adding the inhibited solvent to the suction side of the filling or recirculating pump.

Cleaning solutions Estimating the content of the vessel and adding 10% to allow for losses will determine the amount of solvent required. Sufficient commercial acid should then be obtained. An inhibitor qualified for use with the solvent also needs to be procured and added to the solvent.

Cleaning procedures

The chemical cleaning of steam generating equipment consists of a series of distinct steps which may include the following:

1. isolation of the system to be cleaned,
2. hydrostatic testing for leaks,
3. leak detection during each stage of the process,
4. back flushing of the superheater and forward flushing of the economizer,
5. preheating of the system and temperature control,

6. solvent injection/circulation (if circulation is used),
7. draining and/or displacement of the solvent,
8. neutralization of residual solvent,
9. passivation of cleaned surfaces,
10. flushing and inspection of cleaned surfaces, and
11. layup of the unit.

Every cleaning should be considered unique, and sound engineering judgment should be used throughout the process. The most important design and procedural considerations include reducing system leakage, controlling temperature, maintaining operational flexibility and redundancy, and ensuring personnel safety.

Precautions

Cleaning must not be considered a substitute for proper water treatment. Intervals between cleanings should be extended or reduced as conditions dictate. Every effort should be used to extend the time between chemical cleanings. Hazards related to chemical cleaning of power plant equipment are fairly well recognized and understood, and appropriate personnel safety steps must be instituted.²⁷

Chemical cleaning of superheater, reheater and steam piping

In the past, chemical cleaning of superheaters and reheaters was not performed because it was considered unnecessary and expensive. With the use of higher steam temperatures, cleaning procedures for superheaters, reheaters and steam piping have gained importance and acceptance.

When chemically cleaning surfaces that have experienced severe high-temperature oxide exfoliation (spalling of hard oxide particles from surfaces), it is important to first remove a tube sample representing the worst condition. Oxidation progresses at about the same rate on the outside of the tubes as on the inside; exfoliation follows a similar pattern.

The tube sample should be tested in a facility capable of producing a flow rate similar to that used in the actual cleaning. This allows development of an appropriate solvent mixture.

To determine the circulating pump size and flows required, it is usually necessary to contact the boiler manufacturer.

Figs. 27 and 28 show possible superheater/reheater chemical cleaning piping schematics for drum boiler and once-through boiler systems, respectively.

If, in the case of a drum boiler, the unit is to be cleaned along with the superheater and reheater, it is usually necessary to orifice the downcomers to obtain the desired velocities through the furnace walls.

A steam blow to purge all air and to completely fill the system must precede cleaning in all systems containing pendant non-drainable surfaces. Most drainable systems also benefit from such a steam blow.

Presently, two solvent mixtures are available to clean superheater, reheater and steam piping. One is a combination of hydroxyacetic and formic acids containing ammonium bifluoride; the other is an EDTA (ethylenediaminetetraacetic acid)-based solvent.

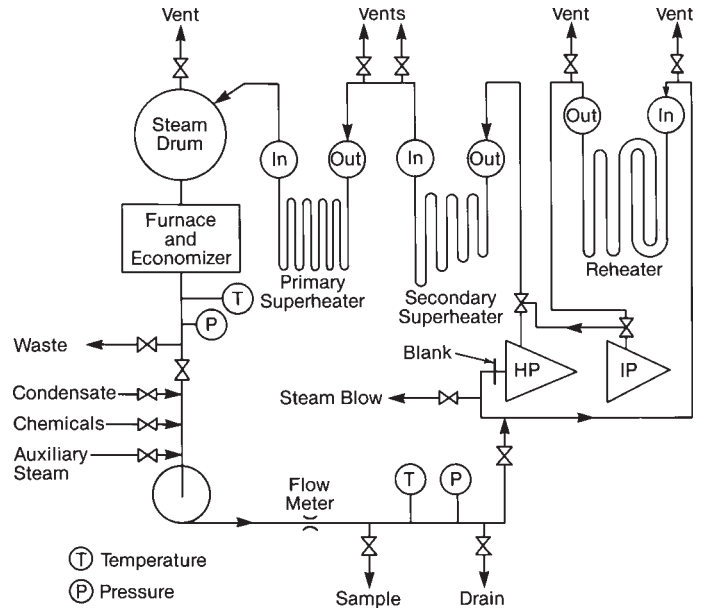

Fig. 27 Typical superheater/reheater chemical cleaning circuit for a drum-type boiler.

Solvent disposal

General considerations A boiler chemical cleaning is not complete until the resultant process waste water stream is disposed of. Selection of handling and disposal methods depends on whether the wastes are classified as hazardous or non-hazardous. Boiler chemical cleaning wastes (BCCW) are different in volume and frequency of generation and have different discharge regulations from other power plant waste streams. Of all power plant discharges, BCCWs are most likely to be classified as hazardous. Depending upon the cleaning process, the resultant BCCW may become one of the driving forces in solvent selection.

Under National Pollutant Discharge Elimination System (NPDES) requirements, boiler cleaning wastes are considered chemical metal cleaning wastes. The primary parameters of concern are iron, copper, chromium and pH. In all cases, waste management must be performed in accordance with current regulatory requirements.

Waste management options Table 8 lists the handling practices for BCCW. In *co-ponding*, the BCCW is mixed in an ash pond with other waste streams from the power plant. Acid wastes are neutralized by the alkaline ash, and the metals are precipitated as insoluble metal oxides and hydroxides, or absorbed on ash particles. Co-ponding is the least expensive and the easiest disposal option.

Incineration of organic-based cleaning wastes by direct injection into the firebox of the utility boiler is another common disposal practice. Potential emissions from the boiler must be carefully monitored to ensure regulatory compliance.

Large quantities of BCCW are often disposed of in a secure landfill. Evaporation can reduce waste volume and, thereby, reduce overall landfill disposal costs.

HCl cleaning wastes can be treated to NPDES standards using lime or caustic precipitation. It is more

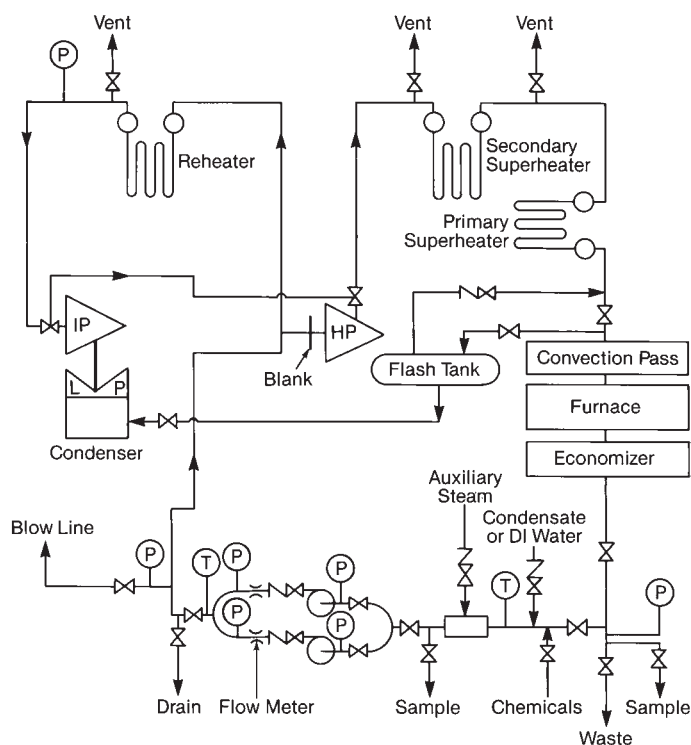

Fig. 28 Typical superheater/reheater chemical cleaning circuit for a once-through boiler.

difficult to treat the organic cleaning agents (such as EDTA) by current techniques. Treatment methods with permanganate, ultraviolet light, and hydrogen peroxide (wet oxidation) have been used with limited success. Several vendors have proprietary processes which claim to successfully treat chelated wastes.^{28,29}

Removing metal ions and reusing chemical cleaning waste are subjects receiving increased attention. As the regulatory environment continues to change, more emphasis will be placed on the treatment and reuse of BCCW.

Layup

During periods when boiler operation is interrupted, substantial pitting and general corrosion can occur within unprotected water-steam circuitry. When boilers return to operation, corrosion products migrate to high heat flux areas of the boiler or carryover to the turbine. Out-of-service corrosion can therefore impede boiler startup and lead to operational problems such as deposition, under-deposit corrosion, corrosion fatigue, and cycle efficiency loss.

Preservation methods inhibit out-of-service corrosion by eliminating or controlling moisture, oxygen, and chemical contaminants that cause corrosion. Table 9 provides a brief summary and comparison of common preservation methods.

These methods are designed to limit corrosion caused by the normal range of boiler and atmospheric contaminants. Gross contamination must be avoided and, if it occurs, the contaminants must be immediately neutralized and removed. Respective vendors should be contacted for specific recommendations for balance-of-plant equipment (turbine, condensate, feedwater, and atmospheric pollution control systems). Vendor procedures should also be followed for boiler auxiliary equipment such as pulverizer gearboxes, sootblowers, fans, and motors.

Boiler shutdown for layup

Appropriate shutdown procedures can facilitate preservation for subsequent idle periods. Reducing load dissipates fluid-side salts that concentrate on tube surfaces in high heat flux areas. As boiler load is reduced, feedwater and boiler water pH should be increased to the upper end of the target operating range, preferably 9.6 or higher. Where an oxygen scavenger/inhibitor is employed, concentration should increase to 0.050 ppm hydrazine* or equivalent. When boiler water is to remain in the boiler for a substantial cold layup period, the oxygen scavenger/inhibitor concentration in the water should be increased to 20 ppm hydrazine or equivalent after the boiler pressure has decayed to below 200 psig (1.4 MPa). At higher pressures and associated temperatures, the scavenger may rapidly decompose. An oxygen scavenger/inhibitor is not added to boilers that employ oxygen treatment. For boilers on oxygen treatment, the oxygen feed should be stopped at least an hour be-

***WARNING: HYDRAZINE IS A PROVEN GENERIC CHEMICAL FOR THIS APPLICATION. HOWEVER, HYDRAZINE IS A KNOWN CARCINOGEN, AND CAN BE REPLACED WITH OTHER PRODUCTS THAT HAVE EQUIVALENT ABILITY TO SCAVENGE OXYGEN AND INHIBIT CORROSION.**

Table 9
Summary and Comparison of Boiler Lay-up Methods

Lay-up Method	Effectiveness	Costs	Safety and Environmental Concerns	Strengths	Weaknesses
Drained and dry for erection or maintenance	Poor	Minimal	Minimal	Allows full access to internal surfaces Quick and easy	Not effective
Vaporous corrosion inhibitors	Variable, generally fair	Chemicals Chemical application Chemical removal and disposal	Handling and disposal of chemicals	Minimal maintenance requirements	Remaining inhibitive capacity is difficult to monitor Chemicals must be replaced periodically Difficult to distribute through components
Nitrogen blanketing	Excellent	Nitrogen distribution system Nitrogen	Nitrogen suffocation	Consistently effective Easy to monitor	Safety concerns Nitrogen leakage
Hot standby	Good	Heat	Residual temperature and pressure	Fast restart	Not recommended for more than 3 days
Cold standby	Poor	Minimal	Minimal	Fast restart	Not recommended for more than 30 days
Wet, water-filled	Variable, generally good	Demineralized water Chemical treatment Disposal of treated water	Handling of chemicals Disposal of treated water	Easily applicable to non-drainable components Facilitates rapid return to service	Freeze damage Valve seepage and associated corrosion damage Difficult to monitor and inspect May corrode copper alloys beyond boiler
Dry, dehumidified air	Excellent	Dehumidifier and blower unit Air recirculation piping	Minimal	Consistently effective Safe No disposal problems Easy to monitor	Boiler must be totally drained Initial plumbing and equipment requirements

fore shutdown; there can be no oxygen leakage into the cycle. Where possible, as steam pressure decays to atmospheric pressure, nitrogen should be introduced through upper vents to keep the internal pressure positive and prevent air ingress. Boiler-specific operating instructions should be consulted for other important shutdown procedures and precautions.

Draining for boiler maintenance and inspection

Draining boilers without further preservation is often necessary for maintenance and inspection, and the unit should be drained and dried as thoroughly as possible. Draining the boiler hot (for example, at 20 psig/0.14 MPa) will facilitate drying, but may leave condensate in non-drainable superheater elements. Boiler components that need not be open for maintenance should, where possible, be isolated and protected. For example, while the lower furnace is open for maintenance, the superheater should, if possible, be protected with an appropriate wet or dry layup method. All openings should remain covered to prevent ingress of contaminants.

The unpreserved maintenance period should be as

brief as possible, preferably less than 3 weeks. Where a long maintenance outage with minimal preservation is necessary, the boiler and open sections of the pre-boiler system should generally be chemically cleaned and repassivated to reform a protective oxide film following the outage.

Hot standby and hot layup

When a boiler returns to operation while steam pressure remains above atmospheric pressure, preservation requirements are minimal. If the shutdown period is less than 72 hours and there is no air in-leakage, ammonia and oxygen scavenger/inhibitor concentrations need only be raised to the high end of the normal operating range with an oxygen scavenger/inhibitor concentration equivalent to about 0.050 ppm hydrazine. Oxygen scavengers are not used for boilers that employ oxygen treatment. However, a low oxygen concentration must be maintained by effective deaeration, and water must remain at a high level of purity with cation conductivity less than 0.15 $\mu\text{S}/\text{cm}$.

Extended hot standby is not recommended. Hot layup can be extended by use of auxiliary heat, but

non-corrosive and non-depositing conditions can be difficult to assure, especially in economizers, superheaters, and reheaters. If temperature is maintained by injecting blowdown from an adjacent boiler, excessive blowdown solids can accumulate under low-flow conditions in the standby boiler. When steam is injected from another boiler, deposition and corrosion problems can arise from temperature and chemistry differentials. Also, care must be taken to avoid cavitation and to control the chemistry of steam condensate. Water leakage across valves can cause corrosion in seepage areas, and the corrosion is aggravated by relatively high material and water temperatures.

Cold standby for up to thirty days

For short periods (not more than a week), boilers may remain on cold standby status with little or no chemical additions. Moderate ammonia and oxygen scavenger/inhibitor additions can extend this period up to thirty days. Treated demineralized water for short-term cold standby should have a minimum concentration of 10 ppm ammonia. The concentration of oxygen scavenger/inhibitor normally used in the boiler should be increased to the equivalent of 25 ppm of hydrazine. Nitrogen blanketing (see below) is recommended.

For boilers employing oxygen treatment, no scavenger should be used for short cold standby periods. However, oxygen ingress must be avoided and low oxygen concentrations must be maintained (for example, by use of nitrogen blanketing of boiler and deaeration of makeup water). Throughout the storage period, the pH must be 9.2 or higher, and cation conductivity throughout the boiler must be less than 0.15 $\mu\text{S}/\text{cm}$.

Boiler storage for more than seven days

Any of several layup practices are acceptable for storage periods up to six months. Alternatives for fluid-side layup include nitrogen blanketing, wet layup with treated demineralized water, and dry dehumidified layup. For extended outages, it is important that the pre-boiler feedwater train, balance of the water-steam cycle, auxiliary equipment, and fireside of the boiler are adequately preserved. For idle periods longer than six months, dry (dehumidified) storage is recommended. For boilers with non-drainable components, water removal issues must be weighed against the advantages of dry layup.

Reheaters – all periods

Reheaters are generally stored dry because they can not easily be isolated from the turbine. Wet storage requires installation of blanks or special valves in the connecting lines. Drying can be performed by exposing reheaters to condenser vacuum after the fires have been removed, the unit tripped, and the turbine seals maintained. With approximately 20 in. (5 kPa) of vacuum on the condenser, vents or drains on the reheater inlet should be opened to allow air to pass through and remove all moisture. Dehumidified dry storage is recommended where the storage period exceeds 30 days. Alternatively, the evacuated reheater may be isolated and nitrogen blanketed, or it may be nitrogen blanketed in conjunction with the turbine.

Nitrogen blanketing

Even where water is present, corrosion can be prevented by eliminating oxygen from the environment. Oxygen can be eliminated by sealing and pressurizing the entire boiler, or the space above water level, with nitrogen to prevent air in-leakage. In the absence of acids and other oxidants, eliminating air stops corrosion. Nitrogen blanketing is a highly effective method for preventing corrosion. It is easy to monitor and alarm, so effective preservation can be assured. However, the boiler must be well sealed to prevent excessive leakage.

It is absolutely imperative that working spaces around nitrogen blanketed equipment be well ventilated. Venting of nitrogen during purging or water filling operations can release large amounts of nitrogen into surrounding areas. Also, before entry, areas that have been nitrogen blanketed must be well ventilated and the air tested to confirm that all parts have adequate oxygen concentrations.

Wet (water-filled) layup

Wet layup in combination with nitrogen blanketing is often the most practical method of protection, especially for boilers that are not fully or easily drainable. However, for longer storage periods, advantages of wet layup are offset by accumulative corrosion in areas of valve seepage and by accumulative cost of replacement water, chemicals, treated water disposal, nitrogen cover gas, and heat in cold climates. Consequently, dry layup is generally recommended for storage periods longer than six months.

Before a boiler is flooded with layup water, provision must be made to support the additional weight when drum (if present), superheater, and steam piping are filled. If the boiler is to be completely filled with layup water, an expansion tank or surge tank above the highest vent is necessary to accommodate volume changes that are caused by normal temperature fluctuations. The expansion space at the top of the boiler (whether in a drum or in a surge tank) should be nitrogen blanketed to assure that there is no air ingress. Where freezing conditions are expected or possible, provision must be made for heating water-filled components.

Wet layup generally requires demineralized water having a specific conductivity less than 1.0 $\mu\text{S}/\text{cm}$ before treatment chemicals are added. Use of demineralized water and all volatile treatment chemicals is essential where boilers include non-drainable or stainless steel components. Use ammonium hydroxide to raise water pH into the range of 10.0 to 10.4. Use an oxygen scavenger/inhibitor to further retard corrosion.

Dry (dehumidified) layup

Dry layup requires the removal of all water and the dehumidification of air to maintain a relative humidity less than 50%, and preferably less than 40%. This prevents corrosion by hygroscopic salts. Dry-air (dehumidified) storage is highly effective, and its continued effectiveness is easy to monitor. Dry layup allows easy and safe access for maintenance, with no potential for suffocation and no exposure to toxic chemicals.

It also eliminates the potential for biological activity, damage from freezing water, and corrosion by leaking water. However, implementation requires that the boiler be completely drained and dried, and this is a major problem for boilers with non-drainable superheaters or other non-drainable circuits. Also, mechanical circulation and dehumidification equipment and piping installation can be costly.

In preparation for dry storage, water must be drained completely from all boiler circuits, including feedwater piping, economizer, superheater, and reheater. All non-drainable boiler tubes and superheater tubes should be blown with pressurized air. Auxiliary sources of heat are used to dry fluid-side surfaces. Deposits of sufficient thickness to retain moisture must also be removed.

The preferred dry layup method is continuous recirculation of dehumidified air. Fans force air through the dehumidifier, boiler fluid-side circuitry, and back to the dehumidifier. The system must include instrumentation for measuring relative humidity. Recirculating dehumidification also requires external (usually flexible plastic) piping to complete the path. The system must be sized to handle the residual moisture and moist air in-leakage, and must be monitored to

assure that relative humidity remains less than 50%.

An alternative, but inferior, dry layup method is the use of static desiccant to absorb moisture with no forced air circulation. This method is effective for boiler components and small (package) boilers, but not generally adequate for large complex boiler circuitry.

Termination of the storage period requires removal of the recirculation, dehumidification, and monitoring materials and equipment. Any loose desiccant particles or dust (which generally contain silica or sulfite chemicals) must be cleaned from the boiler.

Vaporous corrosion inhibitors (VCI)

Vaporous corrosion inhibitors retard corrosion by forming a thin protective film over metal surfaces. Where such chemicals are sealed into a closed space, they can retard corrosion even in the presence of both water and oxygen. These inhibitors are not generally used for completed boilers, where the size and complexity of boiler circuits precludes effective distribution of dry powders. However, they are often used to inhibit internal corrosion of boiler components, as supplements to dry storage for small boilers, and as an alternative treatment for hydrotest water.

Chapter 43

Boiler Operations

Effective operation of steam generating equipment has always been critical to maintaining system efficiency, reliability and availability. With advances in sensor technology, control software, and steam generator hardware, efficient operation today means balancing equipment performance with safety requirements and emissions mandates. The procedures used to run steam generating equipment vary widely depending upon the type of system, fuel and application. Systems can range from simple and fully automated requiring a minimum of attention, such as small gas-fired package boilers, to the very complex requiring constant operator attention and interaction, such as a large utility plant. There are, however, a set of relatively common fundamental operating guidelines that safeguard personnel and optimize equipment performance and reliability. When combined with equipment-specific procedures, these guidelines promote the best possible operations. The first half of this chapter focuses on general practices applicable to large multi-burner fossil-fuel fired natural circulation and once-through boilers, though these practices are also generally applicable to most other boiler designs. Starting with *Operation of Cyclone furnaces*, the remaining sections focus on the unique practices for several important special cases.

Because of the intimate relationship between equipment design and operation, additional operating guidelines may be found in other chapters of *Steam*. Selected areas of particular interest are listed in Table 1.

General boiler operations

Fundamental principles

Although boiler design and power production have become sophisticated, basic operating principles still apply. Combustion safety and proper steam/water cooling of boiler pressure parts are essential.

Combustion safety and steam/water cooling requirements Before firing a furnace, there must be no lingering combustible material inside the unit. *Purging*, or removal of this material, assures that the furnace is ready for firing. A standard operating rule for multiple burner boilers is to purge the unit at no less than 25% of the maximum continuous rating (MCR) mass air flow for the greater of at least five minutes or five volume changes.

Once combustion is established, the correct air/fuel ratio must be maintained. Insufficient air flow may permit the formation of combustible gas pockets and provide an explosion potential. Sufficient air flow to match the combustion requirements of the fuel should be maintained and a small amount of excess air should be admitted to cover imperfect mixing and to promote air and fuel distribution. For emissions reduction, many newer firing systems are staged with overfire air (OFA) ports installed in the upper combustion zones of the furnace. The controlled introduction of combustion air does not eliminate the need to provide adequate operating excess air for safety.

In addition to these combustion precautions, it is important to verify boiler water levels. Combustion should never be established until adequate cooling water is in the tubes and steam drum for natural circulation boilers and minimum flow rates are established for once-through boilers.

General safety considerations Pressure part failure remains a major concern in the boiler industry. The

American Society of Mechanical Engineers (ASME), National Board of Boiler and Pressure Vessel Inspectors, and other organizations have issued extensive codes directed at minimizing these failures. The codes are continuously updated to support quality pressure part design. (See Appendix 2.)

Combustion products have also received considerable safety attention. Carbon dioxide (CO_2), carbon monoxide (CO), sulfur oxides and chlorine compounds must be considered. While CO_2 is not poisonous, it reduces oxygen availability in the flue gas. Sulfur oxides can form acids when breathed into the lungs. Chlorine compounds can form hydrochloric acids or carcinogens such as dioxin.

Safety of fuel ash must also be considered. While few ashes contain hazardous materials, heavy metals and arsenic can be present in dangerous levels. In addition, residual combustion may continue in ash collected in hoppers. This is especially true when new emissions reduction combustion systems are being installed. Carbon-in-ash characteristics may be altered under the new low nitrogen oxides (NO_x) firing configurations.

Finally, safeguards apply when performing maintenance and other work on out-of-service boilers. A confined space may have insufficient oxygen for personnel. Good lighting is important for a safe working environment. In addition, ash accumulations in out-of-service boiler areas may still be too hot for maintenance activities.

Initial commissioning operations

Operator requirements

Good operation begins before equipment installation is complete. It includes training of the operators as well as preparation of the equipment.

Every operator must be trained to understand and fulfill the responsibility assumed for the successful performance of the equipment and for the safety of all personnel involved. To be prepared for all situations that may arise, the operator must have a complete knowledge of all components: their designs, purposes, limitations and relationships to other components. This includes thoroughly inspecting the equipment and studying the drawings and instructions. The ideal time to become familiar with new equipment is during the pre-operational phase when the equipment is being installed.

A distributed control system (DCS) integrates the individual process controllers of a steam generation process into a coordinated, interactive system. It enables the operator to manage the process as a complete system, with control over the interrelationship of various subsystems.

Modern distributed control systems are extendable to provide operating personnel with advanced simulations of equipment behavior. Simulator training is typically in real-time, ensuring not only a working understanding of the various steam generator systems, but also the reaction time and rate of the equipment. Combined with simulated equipment failures and

what-if events, the operating personnel can gain valuable experience prior to initial operation.

Preliminary operation should not be entrusted to inexperienced personnel who are not familiar with the equipment and the correct operating procedures. Considerable equipment damage and potential safety events can result from improper preparation of equipment or its misuse during preliminary checkout.

Operator training takes on special significance during the initial operating period required to prepare the unit for commercial operation. Knowledgeable and experienced operators are valuable during this period when the controls and interlocks are being adjusted, fuel burning equipment is being regulated, operating procedures are being perfected and preliminary tests are being conducted to demonstrate the performance and capabilities of the unit.

Preparations for startup

A systematic approach is required when a new boiler is being installed or when any boiler has undergone major repairs or alterations. The procedure varies with boiler design; however, certain steps are required for all boilers. The steps may be classified as inspection, cleaning, hydrostatic testing, pre-calibration of instruments and controls, auxiliary equipment preparation, refractory conditioning, chemical cleaning, steam line cleaning (blowing), safety valve testing and settings, and initial operations for adjustments and testing.

Inspection An inspection of the boiler and auxiliary equipment serves two purposes: 1) it familiarizes the operator with the equipment, and 2) it verifies the condition of the equipment. The inspection should begin some time during the construction phase and continue until all items are completed.

One item frequently overlooked during the inspection is the provision or lack of provision for expansion. The boiler expands as the temperature and pressure are increased, as do steam lines, flues and ducts, soot-blower piping and drain piping. Before pressure is raised in the boiler, temporary braces, hangers or ties used during construction must be removed.

Cleaning Debris and foreign material that accumulate during shipment, storage, erection or repairs must be removed. Debris on the water side can restrict circulation or plug drain lines. Debris on the gas side can alter gas or air flows. Combustible material on the gas side can ignite and burn at uncontrollable rates and cause considerable damage. Glowing embers can be the source of ignition at times when ignition is not desired.

Fuel lines, especially oil and gas lines, should be cleaned to prevent subsequent damage to valves and the plugging of burner parts. Steam cleaning is recommended for all oil and gas lines. Atomizing steam and atomizing air lines should be cleaned.

Hydrostatic test After the pressure parts are assembled, but before the refractory and casing are installed, a hydrostatic test at 1.5 times the boiler design pressure is applied to all new boilers and maintained for a sufficient time to detect any leaks. Testing is equally important following pressure part replacements at pressures specified in local code requirements.

The hydrostatic test is normally the first time the new boiler is filled with water; therefore, this is the time to begin using high quality water for the prevention of internal fouling and corrosion. (See Chapter 42.) Demineralized water or condensate treated with 10 ppm of ammonia for pH control and 500 ppm of hydrazine for control of oxygen should be used for all nondrainable superheaters and reheaters. A clear filtered water is suitable for components that will be drained immediately after the hydrostatic test.

Temperature plays an important part in hydrostatic testing. The metal temperature and therefore the water temperature must be at or above applicable Code restrictions for hydrostatic testing. For example, these restrictions, as stated in the ASME Code, specify that the hydrostatic test temperature will not be below 70F (21C) to take advantage of the inherent toughness of carbon steel materials as related to temperature. The water temperature should be kept low enough so that the pressure parts can be touched and close inspections can be made. It should not be so high that water escaping from small leaks evaporates immediately or flashes to steam. Also, the water temperature should not be more than 100F (56C) above the metal temperature to avoid excessive metal stress transients.

Finally, no air should be trapped in the unit during the hydrostatic test. As the unit is being filled, each available vent should be open until water appears.

Instrumentation and controls Every natural circulation boiler has at least two indicating instruments: a water/steam pressure gauge and a water level gauge glass. If a superheater is involved, some type of steam temperature indicator is also used. Once-through type boilers have steam pressure gauges, flow meters and temperature indicators. These indicators are important in that the pressure, temperature levels and flows indicated by them must be controlled within design limits. Therefore, the indicators must be correct. Operation should not be attempted until these instruments are calibrated, and the calibrations should include corrections for actual operating conditions. Water-leg correction for the pressure gauge is one example. (See Chapter 40.)

Most modern boilers are controlled automatically once they are fully commissioned. However, before these boilers can be started up, the controls must be operated on manual until the automatic controls have been adjusted for site-specific conditions. Automatic control operations should not be attempted until the automatic functions have been calibrated and proven reliable over the load range.

Auxiliary equipment The auxiliary equipment must also be prepared for operation. This equipment includes fans to supply air for combustion and to transport fuel, feedwater pumps to supply water, fuel equipment to prepare and burn the fuel, and air heaters to heat the air for combustion. This equipment also includes an economizer to heat the water and cool the flue gas, ash removal equipment, a drain system to drain the boiler when required, a functioning sootblowing system to adequately clean the heat transfer surfaces, and post-combustion environmental control equipment.

Chemical cleaning Water-side cleanliness is important for all boilers because water-side impurities can lead to boiler tube failures. They can also lead to carryover of solids in the steam, resulting in superheater tube failure or turbine blade damage.

The flushing of all loose debris from the feedwater system and boiler, and the use of high quality water for the hydrostatic test, must be supplemented by proper water-side cleaning before startup. To remove accumulations of oil, grease and paint, the natural circulation boiler is given a caustic and phosphate boilout after the feedwater system has been given a phosphate flush. The once-through boiler and its associated pre-boiler equipment are given a similar flushing. This boiling out and/or flushing should be accomplished before operation.

After boiling out and flushing are completed, products of corrosion still remain in the feedwater system and boiler in the form of iron oxide and mill scale. It is recommended that acid cleaning for the removal of this mill scale and iron oxide be delayed until operations at fairly high capacities have carried loose scale and oxides from the feedwater system to the boiler. This results in a cleaner boiler for subsequent operations. Chemical cleaning of internal heating surfaces is described in Chapter 42.

Steam line blowing Fine mesh strainers are customarily installed in turbine inlet steam lines to protect turbine blades or valves against damage from scale or other solid material that may be carried by the initial flow of steam. In addition, many operators use high velocity steam to clean the superheater and steam lines of any loose scale or foreign material before coupling the steam line to the turbine. The actual procedure used depends on the design of the unit. Temporary piping for flow bypass to the atmosphere is required with all procedures. This piping and any noise reduction silencers must be securely anchored to resist the high nozzle reaction created during the high velocity blowing period.

Several methods are used for blowing steam lines, including particularly high pressure air and steam blowing. The recommended method and the one most used is steam blowing because experience has shown that temperature shock and high velocities are the most effective means of removing loose scale. Sufficient shock is obtained with a series of blows where the steam temperature changes during each blow. Lower pressure, high velocity steam blowing techniques are also available, including those with high velocity treated water injection to promote thermal shocking of the mill scale and debris. Designed and managed correctly, these techniques provide safe removal of scale and other solid particles detrimental to turbine components.

There are two basic methods of supplying steam for steam line blowing with a natural or forced circulation boiler. The first method is to use steam returning from the flash tank to the superheater on the forced circulation unit or steam flow from the drum on the natural circulation unit. The second method is to use high pressure steam directly from the boiler. The latter method supplies large quantities of steam at higher

pressures. Temporary valving is required to control the flow rates during the blowing period.

Boiler pressure and temperature can be maintained during the blowing period by continuous firing. If firing is discontinued during the blowing period, it must be remembered that any change in boiler pressure changes the saturation temperature throughout the system. To avoid excessive thermal shock, changes in boiler pressure should be limited to those corresponding to 75F (42C) in saturation temperature during the relatively short blowing periods.

Safety valves Safety valves are essential to the safe operation of any pressure vessel, allowing adequate relief of excess pressure during abnormal operating conditions. The set point of each safety valve is normally immediately checked and adjusted if necessary after reaching full operating pressure for the first time with steam. Safety valve seats are susceptible to damage from wet steam or grit. This is an essential reason for cleaning the boiler and blowing out the superheater and steam line before testing safety valves.

Safety valves on drum-type boilers are normally tested both for set point pressure and for the closing pressures. This generally requires that the boiler pressure be raised until the valve opens and then reduced for the valves to close.

The testing of safety valves always requires caution. Safety valve exhaust piping and vent piping should not exert any excessive forces on the safety valve. Gags should always be used as a safety measure while making adjustments to the valves.

As an alternate, safety valves can be tested and set with the boiler pressure below the safety valve design pressure by supplementing the boiler pressure with a hydraulic lift, attached to the valve stem, in accordance with the manufacturer's instructions. This hydraulic assist method reduces the risk of damage to the valve seat from extended steam flow in a conventional test.

Startup Operating procedures vary with boiler design. There are, however, certain objectives that should be included in the operating procedures of every boiler. These objectives include:

1. protection of pressure parts against corrosion, overheating and thermal stresses,
2. prevention of furnace explosions,
3. production of steam at the desired temperature, pressure and purity, and
4. compliance with environmental regulations.

Filling In filling the boiler for startup, certain precautions should be taken to protect the pressure parts. First, high quality water should be used to minimize water-side corrosion and deposits. Second, the temperature of the water should be regulated to match the temperature of the boiler metal to prevent thermal stresses. High temperature differentials can cause thermal stresses in the pressure parts and, if severe, will adversely affect the life of the pressure parts. High temperature differentials can also distort the pressure parts enough to break studs, lugs and other attachments. Differential temperatures up to 100F (56C) are generally considered acceptable.

A third precaution taken during the filling opera-

tion is the use of vents to displace all air with water. This reduces oxygen corrosion and assures that all boiler tubes are filled with water.

A fourth precaution on drum-type boilers is to establish the correct water level before firing begins. The water level rises with temperature. Therefore, only 1 in. (25 mm) of water is typically required in the gauge glass, except with certain special designs that may require a higher starting level in order to fill all circulating tubes exposed to the hot flue gases.

Circulation Overheating of boiler tubes is prevented by the flow of fluid through the tubes. Flow is produced in the natural circulation-type boiler by the force of gravity acting on fluids of different densities. Flow starts when the density of the water in the heated tubes is less than that in the downcomers. This flow increases as firing rate is increased. (See Chapter 5.) Some drum-type boilers are designed for forced circulation and depend on a circulating pump to assist this flow.

The once-through type boiler depends on the boiler feedwater pump to produce the necessary flow. Whenever a once-through boiler is being fired, a minimum design flow must be maintained through the furnace circuits. With the use of the bypass system, the fluid can bypass the superheater and turbine to maintain this minimum design flow until saturated steam is available for admission to the superheater and until the turbine is using sufficient steam to maintain the design minimum furnace circuit flow. (See Chapter 19.)

Purging Considerable attention has been given to the prevention of furnace explosions, especially on units burning fuel in suspension. Most furnace explosions occur during startup and low load periods. Whenever the possibility exists for the accumulation of combustible gases or combustible dust in any part of the unit, no attempt should be made to light the burners until the unit has been thoroughly purged. The National Fire Protection Association Boiler and Combustion Systems Code (NFPA 85:2004) provides the consensus procedures for purging of various boiler and combustion systems. For multi-burner boilers, the purge rate from the forced draft fan through the stack is at least 25% of the full load mass air flow which must be maintained for the greater of five minutes or five volume changes of the boiler enclosure. A maximum of 40% of the full load mass air flow is specified for coal-fired units only, while no upper limit is set for oil- or gas-fired units.

Protection of economizer Very little water, if any, is added to the drum-type boiler during the pressure raising period; consequently, there is no feedwater flow through the economizer. Economizers are located in relatively low temperature zones. Nevertheless, some economizers generate steam during the pressure raising period. This steam remains trapped until feedwater is fed through the economizer. It not only makes the control of steam drum water level difficult; it causes water hammer. This difficulty is overcome if feedwater is supplied continuously by venting the economizer of steam or by recirculating boiler water through the economizer. If a recirculating line is available, the valve in this line must remain open until feedwater is being fed continuously through the economizer to the boiler.

Protection of primary, secondary and reheat superheater During normal operation, every superheater tube must have steam flow sufficient to prevent overheating. During startup and before there is steam flow through every tube, the combustion gas temperature entering the superheater section must be controlled to limit superheater metal temperatures to 900F (482C) for carbon steel tubes and 950 to 1000F (510 to 538C) for various alloy tubes. While firing rate is used primarily to control gas temperatures, other means are useful, e.g., excess air, gas recirculation and burner selection.

Gas temperature entering the superheater during startup is typically measured with retractable thermoprobes that are removed as soon as steam flow is established in every superheater tube. (See Chapter 40.) Other permanent gas temperature monitoring devices are available, but precautions must be taken so that their installed locations, usage and maintenance are adequate for the task of measuring gas temperatures entering the superheater. These devices are required for the first few startups to establish acceptable firing rates. They should always be used on the once-through type boiler.

The two prerequisites for steam flow through every superheater tube are: 1) removal of all water from each tube, and 2) a total steam flow equal to or greater than approximately 10% of rated steam flow. Water is removed from drainable superheaters by simply opening the header drains and vents. Nondrainable superheaters are not as simple, because the water must be boiled away. There will be no steam flow through a tube partially filled with water, and those portions of the tube not in contact with water will be subjected to excessive temperatures unless the gas temperature is limited.

Thermocouples attached to the outlet legs of nondrainable superheater tubes, where they pass into the unheated vestibule, will read saturation temperature at the existing pressure until a flow of steam is established through the tube. The temperature of these outlet legs rises sharply to significant increases above saturation immediately after flow is established. Superheater tubes adjacent to side walls and division walls are normally the last to boil clear. These should, therefore, have thermocouples.

Protection of drums and headers In most installations, the time required to place a boiler in service is limited to the time necessary for raising pressure and protecting the superheater and the reheater against overheating. In some cases, however, the time for both starting up and shutting down may be determined by the time required to limit the thermal stresses in the drums and headers. Protection of drums and headers can pose significant challenges for operators faced with the need to cycle the steam generator on/off for load demand.

Various rules, based on thermal stress analysis and supported by operating experience, have been formulated and accepted as general practice. The rules fall into three categories: one for drums and headers with rolled tube joints, a second set for headers with welded tube joints, and a third set for steam drums with welded tube joints.

On drums and headers with rolled tube joints, the

relatively thin tubes contract and expand at a much faster rate than the thicker drum or header walls; therefore, tube seat leaks are likely to occur if heating and cooling rates are not controlled. Heating and cooling rates have, therefore, been established at 100F (56C) change in saturation temperature per hour.

Headers with welded tube connections present no problem with tube seat leaks or with header distortion because the tubes are welded to the headers and the headers are normally filled with fluid at a constant temperature. The concern is mainly with temperature differentials through the header wall and the resulting incipient cracking if excessive thermal stresses occur.

Steam drums with welded tube connections are not subject to tube seat leaks but, because they contain water in the bottom and steam in the top, the heating and cooling rates vary between the top and the bottom. This results in temperature differences between the top and the bottom. Stress analyses show that the principal criterion for reliable rates of heating and cooling should be based on the relationship between the temperature differential through the drum wall and the temperature differential between the top and bottom of the drum, both of which are measured in the same circumferential plane. Analysis also shows that the allowable temperature differentials are based on tensile strength, drum diameter, wall thickness and pressure. Therefore, each steam drum has its own characteristics.

To determine the temperature differentials during the periods of startup and shutdown, it is necessary to continuously and accurately obtain the outside and inside surface temperatures of the drum shell. Temperatures of the outside of the drum shell are best determined by thermocouples. At least six outside thermocouples are required: two on each end, one on the top and bottom (all outside the internal baffle and scrubber area) and two in the center, one top and one bottom. Temperatures of the inside of the drum shell are best determined by placing thermocouples on one of the riser tubes entering the bottom of the drum, one on each end, and one in the center.

There are two periods when the steam in the top of the drum is hotter than the water occupying the lower half. One period is soon after firing begins on boilers with large nondrainable superheaters. Steam forms first in the superheater and flows back to the steam drum where it heats the top of the drum. A second period is during cooling when cold air is pumped through the boiler by the forced draft fans. The boiler water cools, but the steam in the top of the steam drum remains at essentially the same temperature.

The temperatures of the top and bottom can be brought close together by flooding the steam drum with water. Firing must be stopped and water must not be allowed to spill over into the superheater. A high level gauge glass is needed for this operation. However, thermocouples attached to the superheater supply tubes can be used to indicate when the drum is flooded because there is a sharp change in temperature when water enters these supply tubes. Allowable temperature differentials for cooling are stringent, considerably more so than for heating. Fast cooling

should, therefore, be supervised with the use of thermocouples and a high level gauge glass.

Cooling is particularly important when the boiler is to be drained for short outages. The steam drum must be cooled to permit filling with the available water without exceeding the allowable temperature rate of change. (See Fig. 1.) A wider latitude is permitted if the water used for filling is hotter than the steam drum.

Before removing the unit from service, a more uniform cooling can be achieved by reducing pressure to approximately two-thirds of the normal operating pressure. This reduces the temperature of both the water and steam in the steam drum.

Operating techniques for maximum efficiency

Fuel is a major cost in boiler operation. It is therefore important to minimize fuel consumption and maximize steam production. Although a boiler's efficiency is primarily a result of its design, the operator can maintain or significantly improve efficiency by controlling heat losses to the stack and losses to the ash pit.

Stack losses The total heat that exits the stack is controlled by the quantity and the temperature of the flue gas. The quantity of gas is dependent on the fuel being burned, but is also influenced by the amount of excess air supplied to the burners. While sufficient air must be provided to complete the combustion process, excessive quantities of air simply carry extra heat out of the stack.

The temperature of the flue gas is affected by the cleanliness of the boiler heat transfer surfaces. This in turn is dependent on sootblower and air heater operation. Optimal cleanliness of the heat transfer surfaces is achievable with commercial sensors and control systems that measure the heat transfer effectiveness of the boiler banks, evaluate against the design duty, and clean only on an as-needed basis. While high gas exit temperatures waste energy, excessively low temperatures may also be unacceptable. Corrosion can occur at the acid dew point of the gas where corrosive constituents condense on the cooler metal surfaces. Ash plugging of heat transfer surfaces can be aggravated by the presence of condensate. Equipment protec-

tion and performance of backend environmental components [selective catalytic reduction (SCR) system protection, for example] can also be constraints in desirable steam generator gas temperature.

Pressures and temperatures Most boilers supply steam to turbines or processes that require heat. These processes rely on design pressures and temperatures. Deviations from the set points may result in lower overall efficiency of the power cycle, loss of production, or damage to the product or process.

In units that produce saturated steam, boiler temperature is directly related to the operating pressure. For many industrial applications, the process requirements dictate the steam temperature and consequently the operating pressure.

For electric power producing steam systems, steam temperature has a significant impact on turbine efficiency. Modern controls can typically maintain this temperature within 10F (6C) of the desired setting. Each 50F (28C) reduction in steam temperature reduces cycle efficiency by approximately 1% on a supercritical pressure unit.

Variable pressure operation Historically, utility power boilers in the United States (U.S.) have been operated at a constant steam pressure and the turbine load has been controlled by varying the throttle valves at the turbine inlet. This causes an efficiency loss due to the temperature drop across the throttle valves.

In variable pressure operation, boiler pressure is varied to meet turbine requirements. This can significantly improve cycle efficiency when operating at low loads (15 to 40% of MCR). However, boiler response to turbine requirements is slower in this mode. When fast response is needed, pressure increments are used. At a given pressure, the throttle valves control the steam to the turbine and provide quick response. As turbine requirements increase and the valves approach full open position, the boiler pressure is increased to the next increment. This arrangement provides high efficiency while retaining quick response.

Emissions requirements The majority of the steam generators in operation today were not originally designed for today's environmental regulations. Hardware changes made to accomplish the emissions reduction are typically accompanied by new operating philosophies and guidelines for efficiency and equipment protection. To maintain optimal SCR efficiency and minimal ammonia usage/slip the combustion system is optimized to generate the lowest level of nitrogen oxides (NO_x) possible. Staging of combustion air is frequently used in firing system upgrades. Sufficient care must be taken to ensure that lower furnace corrosion associated with the reducing atmosphere is not excessive, especially with high sulfur content fuels. Depending on system design, there may be tradeoffs between lower NO_x generation and increases in the carbon content in the ash and carbon monoxide (CO) in the flue gas. To maintain ash quality suitable for disposal/sale, operational balance must be achieved within the combustion process. Furnace combustion is also usually controlled to achieve any specific CO emissions rate.

Combustion optimization A modern DCS is equipped

Fig. 1 Permissible rate of change for saturation temperature, drum and furnace.

to offer significantly more information and analysis, assisting the operating personnel in optimizing the steam generator. Closed loop neural network systems and other advanced intelligent control systems have made strides in maintaining optimum operations consistently throughout the operating range. Variants of these systems use complex databases and algorithms of unit-specific operating scenarios to guide the controlling parameters during steady state and transient operation. Extensive parametric testing of the unit is conducted to define the characteristics and boundaries of the operating variables. As long as no subsequent mechanical modifications are added and proper equipment maintenance is available, these advanced control systems are capable of consistently returning the steam generator to its most optimum operating condition. A significant attribute of these systems is the ability to target specific results during optimization and change the targeted parameter as needed. As the result, NO_x can be minimized during selected periods and heat rate can be minimized the rest of the operating year.

Key operation functions

Burner adjustments The fuel and combustion air combine and release heat at the burners. To maintain even heat distribution across the width of the furnace, air and fuel flows must be evenly supplied to all burners. While individual burner adjustments affect a particular burner, they also impact adjacent burners. Most boilers have multiple burners in parallel flow paths on the front and/or rear furnace walls. Burners must be similar in design and must be adjusted in the same way to optimize air flow distribution. For a detailed discussion of burner features refer to Chapters 11 and 14.

Adjustments can typically vary the turbulence and flow rates in burners. Increased turbulence increases the air-fuel mixing. It also increases the combustion intensity, provides faster heat release, reduces unburned carbon (UBC) in the ash, permits operation with less excess air, and increases boiler efficiency. However, increased slagging, increased NO_x emissions and higher fan power consumption can also result.

Fuel adjustments on an individual burner basis are also possible, either through diverter mechanisms in the fuel preparation system or through flow balancing devices in the coal transport piping. While possible, the dynamic balancing of fuel flows is difficult. As with combustion air adjustments, potential impacts to adjacent burners will require reliable feedback on relative flow rates to be effective as a dynamic operational tool. Advances in flame characterization systems and sensors for post-combustion constituents are providing more precise feedback targets for on-line fuel balancing, as are in situ coal and combustion air flow measurement devices.

Overfire air port adjustments Burner systems intended for NO_x reduction are typically staged at the primary combustion elevation and usually operated with less than theoretical air for complete combustion. The remaining air needed to complete the burning process is introduced separately, above the highest burner

zone. The overfire air (OFA) flows are typically varied as a function of load, based on parametric testing performed during commissioning. While normally satisfactory for ensuring complete combustion and emissions compliance, any changes to fuel type, fuel preparation quality, or the fuel/air transport systems will require close monitoring of OFA system performance. More advanced dynamic control schemes are available, dependent on measurement feedback of the combustion process in the upper furnace zones.

Excess air The total combustion air flow to a boiler is generally controlled by adjusting forced and induced draft fan dampers in relation to the fuel flow. *Excess air* is the amount of additional combustion air over that required to theoretically burn a given amount of fuel. The benefits of increasing excess air include increased combustion intensity, reduced carbon loss and/or CO formation, and reduced slagging conditions. Disadvantages include increased fan power consumption, increased heat loss up the stack, increased tube erosion, and possibly increased NO_x formation.

For most coal ashes, particularly those from eastern U.S. bituminous coals, the solid to liquid phase changes occur at lower temperatures if free oxygen is not present (reducing conditions) around the ash particles. As a result, more slagging occurs in a boiler operating with insufficient excess air where localized reducing conditions can occur.

Localized tube metal wastage may also occur in furnace walls under low excess air conditions but the impact is less clearly defined. The absence of free oxygen (a reducing atmosphere) and the presence of sulfur (from the fuel) are known causes of tube metal wastage. The sulfur combines with hydrogen from the fuel to form hydrogen sulfide (H_2S). The H_2S reacts with the iron in the tube metal and forms iron sulfide, which is subsequently swept away with the flue gas. High chlorine levels can also promote tube wastage. Although coals and most conventional fuels burned in the U.S. contain very little chlorine, it is a problem in refuse-derived fuels. (See Chapter 29.)

Fuel conditions Fuel conditions are temperature, pressure and, if solid, mean particle size and distribution. Cooler temperatures, lower pressure and larger particle size contribute to less complete combustion and increased unburned carbon in the ash. Conversely, if the fuel is hotter, finer and at a higher pressure, combustion is improved. Unfortunately NO_x emissions and slagging can also increase with these conditions. Current day combustion technologies employ multi-zone low NO_x burners to control the pace of combustion and are more demanding on mean particle size and distribution for control of NO_x and UBC production.

Effects of fuel preparation equipment on boiler performance Fuel preparation equipment readies the fuel for combustion and can have a significant impact on pollutant emissions. The preparation equipment may be the crushers, pulverizers and drying systems on coal-fired units; fuel oil heaters and pumps on oil-fired units; refuse handling, mixing or drying equipment on refuse-fired boilers; or fuel handling, blending, sizing and delivery equipment on stoker-fired units. If this equipment is not properly operated, the fuel may

not be completely burned, leaving UBC in the ash or carbon monoxide (CO) in the flue gas.

The operator must monitor the fuel preparation equipment. Knowledge of the equipment, its maintenance record and operating characteristics is essential.

Feedwater and boiler water conditioning requirements

The main function of a boiler is to transfer heat from combustion gases through tube walls to heat water and produce steam. Clean metal tubes are good conductors, but impurities in the water can collect on the inside surface of the tubes. These deposits reduce heat transfer, elevate tube temperatures, and can lead to tube failures. Water conditioning is essential to minimize deposits and maintain unit availability. (See Chapter 42.)

Sootblower operations As discussed in Chapter 24, a *sootblower* is an automated device that uses steam, compressed air, or high pressure water to remove ash deposits from tube surfaces. Sootblowing improves heat transfer by reducing fouling and plugging. However, excessive sootblowing can result in increased operating cost, tube erosion and increased sootblower maintenance. Conversely, infrequent sootblower operation can reduce boiler efficiency and capacity. Optimum sootblowing depends on load conditions, combustion quality and fuel. With the increased dependency in the U.S. on Powder River Basin (PRB) coal and the cost attractiveness of spot market fuels, advanced sootblowing control systems are being increasingly deployed to assist the operators. Unlike manual guidelines, these intelligent systems do not rely on fuel characteristics to influence cleaning patterns. Rather, they focus primarily on the heat transfer surfaces and monitor efficiency. Since cleaning decisions are based solely on an as-needed basis, the intelligent sootblowing systems are ideally suited for operations dealing with changing fuel blends. Furnace-based sootblowing equipment is increasingly being controlled with advanced control schemes that monitor the heat flux in select zones, supervise blower operation for effectiveness, and minimize thermal shock to the furnace wall tubes.

Personnel safety Operating instructions usually deal primarily with the protection of equipment. Rules and devices for personnel protection are also essential. The items listed here are based on actual operating experience and point out some personnel safety considerations.

1. When viewing flames or furnace conditions, always wear tinted goggles or a tinted shield to protect the eyes from harmful light intensity and flying ash or slag particles.
2. Do not stand directly in front of open ports or doors, especially when they are being opened. Furnace pulsations caused by firing conditions, sootblower operation, or tube failure can blow hot furnace gases out of open doors, even on suction-fired units. Aspirating air is used on inspection doors and ports of pressure-fired units to prevent the escape of hot furnace gases. The aspirating jets can become blocked, or the aspirating air supply can fail. In some cases, the entire observation port or door can be covered with slag, causing the aspirating air to blast slag and ash out into the boiler room.

3. Do not use open-ended pipes for rodding observation ports or slag on furnace walls. Hot gases can be discharged through the open ended pipe directly onto its handler. The pipe can also become excessively hot.
4. When handling any type of rod or probe in the furnace, especially in coal-fired furnaces, be prepared for falling slag striking the rod or probe. The fulcrum action can inflict severe injuries.
5. Be prepared for slag leaks. Iron oxides in coal can be reduced to molten iron or iron sulfides in a reducing atmosphere in the furnace resulting from combustion with insufficient air. This molten iron can wash away refractory, seals and tubes, and leak out onto equipment or personnel.
6. Never enter a vessel, especially a boiler drum, until all steam and water valves, including drain and blowdown valves, have been closed and locked or tagged. It is possible for steam and hot water to back up through drain and blowdown piping, especially when more than one boiler or vessel is connected to the same drain or blowdown tank.
7. Be prepared for hot water in drums and headers when removing manhole plates and handhole covers.
8. Do not enter a confined space until it has been cooled, purged of combustible and dangerous gases and properly ventilated with precautions taken to keep the entrance open. Station a worker at the entrance and notify the responsible person.
9. Be prepared for falling slag and dust when entering the boiler setting or ash pit.
10. Use low voltage extension cords or cords with ground fault interrupters. Bulbs on extension cords and flashlights should be explosion proof.
11. Never step into flyash. It can be cold on the surface yet remain hot and smoldering underneath for extended periods even after the pressure parts are cool.
12. Never use toxic or volatile fluids in confined spaces.
13. Never open or enter rotating equipment until it has come to a complete stop and its circuit breaker is locked open and any other drive devices are immobilized. Some types of rotating equipment can be set into motion with very little force. These types should be locked with a brake or other suitable device to prevent rotation.
14. Always secure the drive mechanism of dampers, gates and doors before passing through them.
15. Do not inspect for tube leak locations until metal and refractory surfaces are cool, and ash accumulations are removed.

Performance tests Many steam generating units are operating day after day with efficiencies at or near design values. Any unit can operate at these efficiencies with the proper instrumentation, a reasonable equipment and instrument maintenance program, and proper operating procedures.

Early in the life of the unit when the gas side is relatively clean, the casing is tight, the insulation is new, the fuel burning equipment has been adjusted for optimum performance and the fuel/air ratio has

been set correctly, performance tests should be conducted to determine the major controllable heat losses. These losses are the dry gas to the stack and, on coal-fired units, combustible in the ash or slag.

During these tests, accurate data should be taken to serve as reference points for future operation. Sampling points that give representative indications of gas temperatures, excess air and combustibles in the ash should be established and data from these points recorded. Items related to the major controllable losses should also be recorded at this time, e.g., draft losses, air flows, burner settings, steam flow, steam and feedwater temperatures, fuel flow and air temperatures.

Procedures for performance tests are provided in the American Society of Mechanical Engineers (ASME) Performance Test Codes, PTC 4, *Steam Generating Units*; PTC 4.2, *Coal Pulverizers*; and PTC 4.3, *Air Heaters*.

Abnormal operation

Low water If water level in the drum drops below the minimum required (as determined by the manufacturer), fuel firing should be stopped. Caution should be exercised when adding water to restore the drum level due to the potential of temperature shock from the relatively cooler water coming in contact with hot drum metal. Thermocouples on the top and bottom of the drum will indicate if the bottom of the drum is being rapidly cooled by feedwater addition, which would result in unacceptable top-to-bottom temperature differentials. If water level indicators show there is still some water remaining in the drum, then feedwater may be slowly added using the thermocouples as a guide. If the drum is completely empty, then water may only be added periodically with soak times provided to allow drum temperature to equalize. (See *Protection of drums and headers*.)

Tube failures Operating a boiler with a known tube leak is not recommended. Steam or water escaping from a small leak can cut other tubes by impingement and set up a chain reaction of tube failures. By the loss of water or steam, a tube failure can alter boiler circulation or flow and result in other circuits being overheated. This is one reason why furnace risers on once-through type boilers should be continuously monitored. A tube failure can also cause loss of ignition and a furnace explosion if re-ignition occurs. As discussed later in the chapter, process recovery boilers are particularly sensitive to tube leaks because of the potential for smelt-water reactions, which can lead to boiler explosions.

Any unusual increase in furnace riser temperature on the once-through type boiler is an indication of furnace tube leakage. Small leaks can sometimes be detected by the loss of water from the system, the loss of chemicals from a drum-type boiler, or by the noise made by the leak. If a leak is suspected, the boiler should be shut down as soon as normal operating procedures permit. After the leak is then located by hydrostatic testing, it should be repaired.

Several items must be considered when a tube failure occurs. In some cases where the steam drum water level can not be maintained, the operator should shut off all fuel flow and completely shut off any output of steam from the boiler. When the fuel has been turned

off, the furnace should be purged of any combustible gases and feedwater flow to the boiler should be stopped. The air flow should be reduced to a minimum as soon as the furnace purge is completed. This procedure reduces the loss of boiler pressure and the corresponding drop in water temperature within the boiler.

The firing rate or the flow of hot gases can not be stopped immediately on some waste heat boilers or on certain types of stoker-fired boilers. Several factors are involved in the decision to continue the flow of feedwater, even though the steam drum water level can not be maintained. In general, as long as the temperature of the combustion gases is hot enough to damage the unit, the feedwater flow should be continued. (See later discussion for chemical recovery units.) The thermal shock resulting from feeding relatively cold feedwater into an empty steam drum should also be considered. (See *Protection of drums and headers*.) Thermal shock is minimized if the feedwater is hot, the unit has an economizer, and the feedwater mixes with the existing boiler water.

After the unit has been cooled, personnel should make a complete inspection for evidence of overheating and for incipient cracks, especially to headers, drums, and welded attachments. (See *Personnel safety*, especially when the potential of hot materials, boiler fluids, or combustibles is present.)

An investigation of the tube failure is very important so that the condition(s) causing the tube failure can be eliminated and future failures prevented. This investigation should include a careful visual inspection of the failed tube. In some cases, a laboratory analysis or consideration of background information leading up to the tube failure is required. This information should include the location of the failure, the length of time the unit has been in operation, load conditions, startup and shutdown conditions, feedwater treatment and internal deposits.

Shutdown operations

Boiler shutdown is less complicated than startup. The emphasis again is on safety and protection of unit materials. Two shutdown situations may occur: a controlled shutdown, or one required in an emergency.

Under controlled conditions, the firing rate is gradually reduced. Once the combustion equipment is brought to its minimum capacity, the fuel is shut off and the boiler is purged with fresh air. If some pressure is to be maintained the fans are shut down and the dampers are closed. The drum pressure gradually lowers as heat is lost from the boiler setting; a minimal amount of air drifts out of the stack. If inspection and maintenance are required, the draft fans remain on to cool the boiler more quickly. If the unit is equipped with a regenerative air heater, it is shut down, allowing the boiler to cool faster. If a tubular air heater is present, this heat trap can only be bypassed to help cool the boiler. The cool down rate should not exceed 100F (56C) per hour of saturation temperature change to prevent damage due to thermal stress.

In an emergency shutdown, the fuel is immediately shut off and the boiler is purged of combustible gases. Additional procedures may apply to the fuel feed equip-

ment. The boiler may be held at a reduced pressure or may be completely cooled as described above.

Operation of Cyclone furnaces

The Cyclone component of a Cyclone™ furnace is a cylindrical chamber designed to burn crushed coal. The basic design, sizing and general operation of Cyclone furnaces are covered in Chapter 15. The key feature that affects operations is the collection of most of the coal ash as a liquid slag in the Cyclone chamber. This slag is continuously tapped into the furnace through a hole at the discharge end of the Cyclone. The slag collects on the furnace floor and flows through a tap into a water filled tank where the chilling effect of the water leaves the slag in granular form. Unique operational issues center upon maintaining desired furnace slag tapping without excessive maintenance.

Fuels

A key operating parameter of Cyclone units is the selection of a proper coal. Fuels acceptable for Cyclone firing must generally meet the following specifications subject to site-specific conditions:

Bituminous coals:

1. maximum total moisture – 20%
2. ash content – 6 to 25%, dry basis
3. minimum volatile matter – 15%, dry basis
4. ash (slag) viscosity – refer to Table 2
5. ash iron ratio and sulfur content – See Chapter 15, Fig. 4

Subbituminous coals and lignite:

- 1a. maximum total moisture for a direct-fired system, but without a pre-dry system – 30%
- 1b. maximum total moisture with pre-dry system – 42%
2. minimum high heating value – 6000 Btu/lb (13,956 kJ/kg), as-fired
3. ash content – 5 to 25%, dry basis
4. ash (slag) viscosity – refer to Table 2

For proper combustion and efficient unit operation, properly sized crushed coal is required. This is especially important for subbituminous coals, where the higher moisture content requires a finer coal grind to maintain Cyclone temperatures and to minimize unburned carbon in the flyash.

Combustion air

All Cyclone furnaces use heated air at a high static pressure. The air temperature ranges from 500 to 750F (260 to 399C), depending on the unit design and the rank of the fuel. The static differential across the Cyclone ranges from 32 to 50 in. wg (8 to 12.5 kPa). This high pressure produces the very high velocities which, in turn, produce the scrubbing action required for complete combustion of the crushed coal.

A key variable in Cyclone operation is excess air. For bituminous coals, which are generally high in sulfur and iron content, 15 to 18% excess air is recommended at full load operation. Operation at lower excess air can promote an oxygen-deficient reducing atmosphere, which can significantly increase unit

maintenance. Operation with molten slag and deficient air can result in iron sulfide attack (wastage) of the boiler tubes. When operated with insufficient excess air, fuels with high iron content can smelt the iron from the ash. A pig iron, which forms a strong bond to the boiler tubing, can form and may result in tube damage during deposit removal.

Operation with high levels of excess air leads to lower thermal efficiency and results in Cyclone cooling. This hinders slag tapping. On multiple Cyclone units, it is important to accurately measure the secondary air and coal flow to each Cyclone to ensure it is operating with the proper air/fuel ratio.

Because proper excess air is essential, theoretical air curves should be used to readjust the excess air levels when one unit of a multiple Cyclone furnace is removed from service.

Firing subbituminous coals is generally more difficult due to increased fuel moisture which must be evaporated during combustion. Units designed for subbituminous coal firing have provisions for higher air temperature and generally run with 10 to 12% excess air.

Due to environmental concerns, some bituminous coal-fired Cyclone furnaces have been converted to burn low sulfur subbituminous coal or coal blends. Subbituminous coal has a lower ash content than most bituminous coals. As a result, less slag is available to trap the raw coal particles. This, combined with the depressed flame temperature caused by the increased moisture content, can result in less coal being entrapped in the slag where the combustion is completed. Acting on the additional environmental concerns, utilities have installed OFA systems for combustion NO_x control. While furnace wall corrosion remains a concern, worthwhile NO_x reductions have been attained with fuel rich stoichiometry and lower sulfur fuels. These Cyclone operating techniques have changed the operating practices of these slagging combustors.

When firing higher moisture subbituminous coal, smaller crushed coal particle size is required and higher transport air temperature is desired.

Table 2
Ash Viscosity Requirements

Maximum T ₂₅₀ * Coal Rank Ash Viscosity	As-Fired Total Moisture %
Bituminous 2450F (1343C)	0 to 20
Subbituminous – direct-fired 2300F (1260C)	21 to 30
Subbituminous/lignite** 2300F (1260C)	31 to 35
Lignite*** 2300F (1260C)	36 to 42

* T₂₅₀ is the temperature at which the ash viscosity is 250 poise.

** For lignite firing, a fuel pre-dry system is required.

*** For high moisture lignite firing, pre-dry and moisture separator systems are required.

As the moisture content reaches the 20% range at design Cyclone fuel inputs, clinkering and UBC in the Cyclone and on the furnace floor can increase dramatically. Levels of unburned carbon also increase in the ash in the economizer, air heater and precipitator hoppers. Supplemental firing with fuel oil or natural gas along with design changes may be required if the unit was not originally designed for this condition.

Several Cyclone units are operating on high moisture North Dakota lignite fuel. This is accomplished by the use of a pre-dry system, as illustrated in Chapter 15. In this system, hot air [750F (399C)] is introduced to the raw coal stream prior to crushing in a pressurized and heated conditioner. The hot air-coal mixture then travels to a cyclone separator, where the saturated air and some coal fines are separated from the coal stream and are injected into the lower furnace. The dried coal is then carried by a lift line to the Cyclone burner.

Operation of once-through boilers

Principles

In full once-through operation, high pressure water enters the economizer and high pressure steam leaves the superheater; there is no recirculation of steam or water within the unit. The path is through multiple parallel tube circuits arranged in series. Design and construction details are found in Chapters 19 and 26. This type of boiler can be conceptualized as a long heated pipe with continuous coolant flowing through it. As the fluid progresses through the components, heat is absorbed from the combustion process. The final steam temperature is dependent on the feedwater inlet temperature and ratio of the fluid flow to the heat available, which have important implications on unit operation.

Operating practice

The once-through steam generator, referred to by The Babcock & Wilcox Company (B&W) as the Universal Pressure (UP®) boiler, has operating characteristics not seen in drum units. The UP boiler is capable of operating above the critical pressure point [3200 psi (22.1 MPa)] and can deliver steam pressure and temperature conditions without a steam-water separation device after startup. The original UP boilers are typically designed and operated for base load operation. To address the increasing demand for operational flexibility, the B&W Spiral Wound Universal Pressure (SWUP™) boiler is capable of variable pressure operation and on/off cycling, as well as load cycling and base load operation. This spiral wound tube geometry UP boiler, including its startup and bypass systems, minimize the thermal upsets during transients, allowing rapid load changes.

To start up a UP boiler, a steam/water separation device (flash tank or vertical steam separator), with appropriate valving and piping to bypass and return fluid to the cycle, is supplied. The modern bypass systems are highly automated and very effective in achieving smooth operation. The bypass system is in service only during low load operation.

The major control functions for fuel, air, water and steam flow are highly interactive placing unique constraints on operation. Though today's integrated control systems manage many operating functions, it is still important for the operator to fully understand the relationships between short-term (transient) and long-term (steady-state) energy transfer effects and to carefully monitor and coordinate, as required, all control actions. Modern control systems are often referred to as coordinated systems. (See Chapter 41.) The combustion systems are conventional; they are subject to the normal concerns of fuel utilization, efficiency and safety.

The operator has three main controls for operating a UP boiler:

1. firing rate,
2. feedwater control, and
3. steam flow/steam pressure.

Firing rate The long-term demand for firing rate is directly proportional to load. The short-term effects of firing rate impact steam temperature and pressure. During increases in firing rate the steam temperature increases until the feedwater flow is increased to compensate and balance the new firing rate. Steam pressure increases in a similar fashion to that of a drum boiler. In a supercritical pressure application, there is no large rise in specific volume during the transition from liquid to vapor conditions. However, there is still a large increase in specific volume as a supercritical fluid is heated. With this expansion, the turbine control valves are opened and flow is increased to maintain pressure. With the many interactions that are a consequence of firing rate, the operator and automated control system should strive to position firing rate for the desired electrical load and then manipulate other variables to control temperature and pressure.

Feedwater flow The outlet steam temperature is dependent in steady-state conditions on the ratio of feedwater flow rate to firing rate. Because it is desirable to position firing rate based on electrical demand, feedwater flow control is based on outlet steam temperature. The short term effect of feedwater flow changes is to increase or decrease steam pressure and electrical load. The load change results because energy is placed into or brought out of storage through cooling or heating of the boiler metals. However, this load change is transitory. Pressure is a measure of the balance between steam flow and feedwater flow. The outlet pressure is constant if they are matched. The operator can, therefore, use feedwater to assist in recovery from transients and upsets, but ultimately must position feedwater flow for the appropriate outlet steam temperature.

Steam flow/steam pressure In steady-state conditions, steam flow is the same as feedwater flow, and boiler pressure is determined by turbine throttle valve position. In the short term, a change in steam flow impacts steam temperature and electrical load. This is because increasing steam flow at a constant firing rate affects the balance of the two and the steam temperature drops initially as a consequence to electrical load increase. This can not be a lasting effect, however, as steam and feedwater flows eventually match

each other at a different pressure. Similarly, load may be changed by adjusting the turbine throttle valve which increases or decreases steam flow, but this load change comes from depleting or building stored energy in the form of pressure. As above, steam flow may be manipulated to help restore control of steam temperature and load, but it ultimately must be controlled to achieve the desired operating pressure.

Operating skills

Efficiency The supercritical boiler provides very high cycle efficiency. This inherent efficiency can be maintained throughout boiler life with proper instrumentation and maintenance. The operator must be thoroughly trained to know the optimum operating parameters. Deviations in these parameters may then be addressed with instrument maintenance, direct operator action (such as sootblowing) or an engineering investigation. Performance tests should be conducted on a regular basis. Besides the conventional need to minimize heat losses, these tests can be used to confirm control system calibration. Test results should be reviewed with the operator.

Startup systems Chapter 19 provides a comprehensive overview of the configuration and operation of state-of-the-art startup and bypass systems for variable and constant furnace pressure once-through boiler systems. Systems for UP boilers have evolved as the understanding and experience of the once-through concept have increased. A key requirement for the startup system is to maintain adequate flow in the furnace walls (30% for most variable pressure supercritical units, 25% for most constant pressure supercritical units, and 33% for most subcritical units) to protect them from overheating during startup and low load operation. Initial designs (first generation) simply bypassed any excess flow from the furnace, not required for the turbine power generation, directly to the condenser from the high pressure turbine inlet. Second generation startup systems added a steam-water separation device called a flash tank (including steam-water separation equipment) after the convection pass enclosure circuits, but upstream of the primary superheater. This permitted the generation of dry steam for turbine roll and synchronization. The flash tank was effectively a small drum including drum internals. (See Fig. 2.)

Subsequent constant pressure third generation designs moved the bypass line plus necessary valves (200 and 201) downstream of the primary superheater so that the primary superheater is always in the initial flow circuit. (See Fig. 3 for key elements.)

Steam is produced in the flash tank because the pressure reducing valve (207 in Fig. 3) drops the pressure from supercritical to approximately 1000 psig (6.89 MPa) in current designs. For a smooth transition or changeover from startup (flash tank) to once-through operation, the enthalpy of the flash tank steam must be matched with the enthalpy leaving the 201 valve. Because the flash tank generally operates at 1000 psig (6.89 MPa), the throttle pressure to the turbine is only ramped to full pressure after transition from the flash tank.

Due to the need for flexibility of the variable furnace pressure SWUP designs, startup and bypass systems have changed to incorporate features of the subcritical drum and supercritical once-through startup systems. As shown in Fig. 4 (key elements only), the SWUP system has evolved from the second generation system shown in Fig. 2 with the replacement of the valves and flask tank with vertical steam separators, a water collection tank and a boiler circulation pump. At startup and low load, the flow passes through the vertical steam separators where steam is removed and sent to the superheater and water is discharged to the water collection tank. Water then flows through the boiler circulation pump to maintain the minimum furnace wall circulation. Any excess water accumulated during startup is sent to the condenser through the 341 valves. When unit operation reaches the load where the sum of the furnace flow plus the attemperator spray flows is equal to the main steam flow rate, once-through operation is achieved, the 381 valves are closed, and the boiler circulation pump is shut down.

Limits and precautions The once-through nature of UP boilers results in special limits and precautions that must be observed for reliable and dependable operation:

1. Feedwater conductivity – unlike a drum boiler which can release suspended solids through blowdown, all hardness and other contaminants that enter the boiler in the feedwater are deposited on the water side of the heating surface or in the superheater. Deposition can lead to overheating and tube failures. Boiler firing must be stopped if conductivity exceeds 2.0 microsiemens for five minutes or if it exceeds 5.0 microsiemens for two minutes. The operator should be trained in water quality control requirements. (See Chapter 42.)
2. Minimum feedwater flow – firing is not permitted unless the boiler feedwater flow is above the specified minimum. The boiler is to be immediately shut down if flow falls below 85% of minimum for twenty seconds or 70% of minimum for one second.

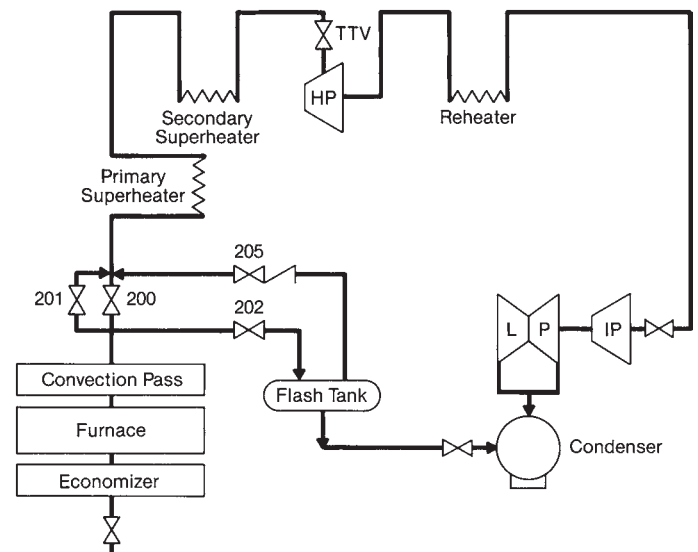

Fig. 2 Second generation UP startup system schematic.

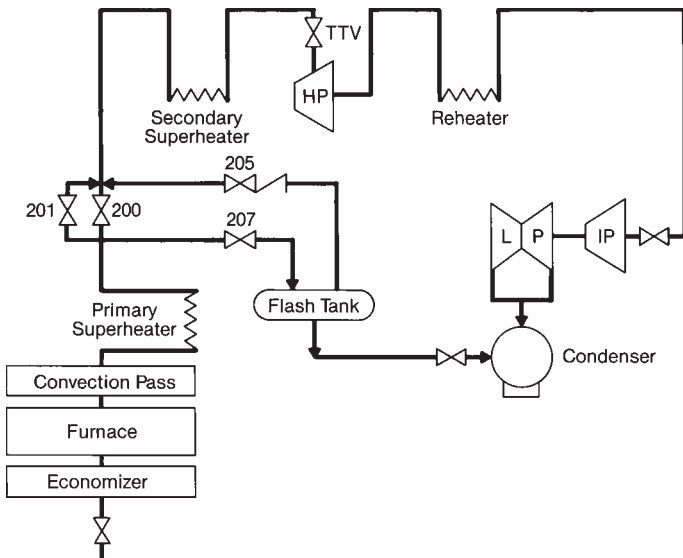

Fig. 3 Third generation UP startup system with primary superheater in initial flow circuit.

3. Feedwater temperature – the heat input required per unit of water flow is dependent on the difference between the feedwater inlet temperature and the controlled outlet steam temperature. If feedwater temperature is reduced while the outlet temperature is maintained (by overfiring), the heat input to the furnace can exceed design levels that may result in damage to the tube material. For units that were not designed for a feedwater heater out of service, removal of a feedwater heater will require that the final steam temperature be reduced to hold furnace heat input rates within design limits. Unless specific information is provided, the general rule is to reduce steam temperature one degree F for every two degrees F that the feedwater temperature is low.

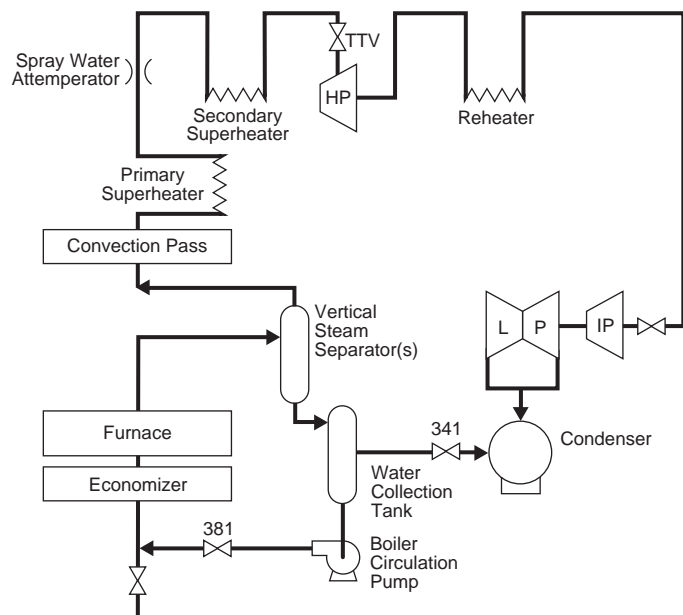

Fig. 4 Startup system for a SWUP boiler (key elements).

4. Overfiring – for supercritical units, the fluid in the furnace has no latent heat of vaporization as in a subcritical boiler. Consequently, as heat is absorbed, the fluid temperature is always increasing and the furnace tube metal temperatures increase. Firing in excess of design rates can result in excessive tube metal temperatures in selected furnace locations. The operator must therefore observe a strict limit of transient heat input. A maximum of 1.15 times the steady-state rate is a typical guideline. This rate, at various load conditions, should be clearly established by combustion tests.
5. Tube leaks – operation with a tube leak is not recommended on any boiler. For once-through units, the situation is more critical because the leakage can reduce cooling flow to subsequent tubes or circuits downstream.
6. Low pressure limit – a constant pressure supercritical UP boiler must be tripped if the fluid pressure in the furnace falls below 3200 psig (22.1 MPa) for fifteen seconds. Failure to do so can result in improper circuit flow, inadequate tube cooling and furnace tube failures. For the SWUP boilers the units are designed for specific variable pressure ramps. To avoid possible tube damage, the units must operate along design pressure ramp curves.

Operation of fluidized-bed boilers

Chapter 17 provides a detailed discussion of fluidized-bed combustion systems. The following sections provide selected remarks on general fluidized-bed boiler operation, both circulating fluidized-bed (CFB) systems and bubbling fluidized-bed (BFB) systems.

CFB systems overview

The CFB is constructed and behaves like a conventional drum boiler in many respects. However, thermal performance, combustion efficiency, furnace absorption pattern and sulfur dioxide (SO_2) control are strongly influenced by the mass of solids in the bed (inventory), the size distribution of the bed material (bed sizing), and the circulating rate of the bed (flow rate). Bed density can be described as bulk density which is a measure of the material weight per unit volume. There is a higher density and inventory in the lower furnace, made of coarser particles (average size 200 to 400 micron), and a lower density and inventory in the upper furnace (also called furnace shaft) made of finer particles (average size 100 to 200 micron). Fig. 5 shows the density of the bed with respect to furnace height and indicates the effect of load.

To integrate these influences into operating procedures, the CFB is equipped with additional instrumentation which provides operator input for bed management. These inputs are as follows:

1. Primary zone ΔP – The gas-side differential pressure is measured across the primary furnace zone [from the air distribution grid to an intermediate elevation of about 6 ft (1.8 m) above the grid] and is an indication of the coarser bed inventory. This variable is managed as a function of boiler load and desired furnace shaft ΔP , utilizing the bed drain flow for control.

2. Shaft ΔP – The furnace shaft ΔP , from the intermediate elevation to the furnace roof, indicates the shaft bed density and is managed to follow boiler load with corrections for primary zone temperature control. It is influenced by the multi-cyclone dust collector (MDC) recycle rate, the primary to secondary air split, and excess air setting.
3. Lower bed (or primary zone) temperature – The lower bed temperature is set by the operator as a primary control variable for optimal combustion and emission performance. The shaft ΔP , primary to secondary air split, and excess air controls are used to control this operating parameter.

The variables mentioned above are typically not available on conventional boilers. However, the overall operation is similar. Fuel feed is set by steam requirements (pressure), total air flow is adjusted to follow fuel flow, and excess air is set to optimize combustion and unit efficiency. Shaft bed density is then predominantly used to control the lower bed temperature, the most important variable on a CFB boiler. The lower bed temperature is usually controlled to a fuel-dependent set temperature [for example 1550F (843C) for lignite and 1620F (882C) for petroleum coke] which results in optimal combustion efficiency and SO_2 absorption. The optimum bed operating temperature from combustion and emission standpoints is from 1500 to 1650F (816 to 899C), depending on fuel.

Another variable that is controlled somewhat differently in a CFB is the air admission to the furnace. The total air flow is divided into primary and secondary flows. Because total air flow is based on fuel flow, the primary to secondary air split becomes another important parameter affecting emissions and bed temperature. The split affects the lower bed density, shaft density, and control of the primary zone temperature. The optimum air split is determined as a function of steam flow during commissioning tests. Once the optimum primary to secondary air split (as a function of steam flow) has been determined for automated control, the operator should not need to independently manipulate the split.

Solids management is also unique to CFBs. Once the bed material inventory has been established, bed inventory is maintained by the fuel ash and sorbent-derived solids flows in most cases. Any change in inventory necessary to accommodate load change comes from the MDC hoppers. In the case of firing low-ash and low-sulfur fuels, solids input with fuel ash and sorbent may not be adequate to provide enough bed material for furnace temperature control. This also may be the case when firing waste fuels requiring a high bed drain rate for removing oversized material, e.g., rocks. If a shortage of solids for maintaining bed inventory occurs, the first source to add bed material would be recycling a usable part (properly sized material) from the lower furnace bed drain. If this is not sufficient, inert bed material fed from an external source, e.g., sand, would be provided.

With the sometimes complex relationships where changes in one variable impact several temperatures and flows, control logics are provided to automatically control these inter-relating parameters with minimal,

if any, operator actions needed. However, the operator must be trained to understand these relationships and to control upsets to establish and maintain stability if necessary.

Fuel sizing and fuel characteristics

Coal firing Fuel sizing is very important to successful boiler operation. It impacts the furnace heat release profile: fine particles tend to burn higher in the furnace shaft while coarse ones burn predominantly in the primary zone. For medium and high ash fuels, fuel sizing also impacts sizing of bed particles and, correspondingly, bottom ash to flyash split. When fuel variation occurs, the operator should be thoroughly trained on the required adjustments in case the variations are outside the range of the programmed control logics.

Biomass firing Biomass fuels provide a particular challenge in CFB operations because of continuous variations in size, shape, moisture content, and heating characteristics. To minimize operating problems, fuel sources should be continuously blended to achieve as uniform a consistency as possible. Modest inventories are needed – large enough to permit blending for uniformity of feed but not large enough to result in excessive inventory storage times. Bed material sizing should be checked on a regular basis to ensure that the bed material is not deteriorating. Care must be taken in such sampling procedures because of the high bed material temperature.

Startup and shutdown considerations Chapter 17 provides general guidelines for the startup of CFBs. Hot and cold startup conditions are distinguished by the temperature of the furnace solids inventory, either higher or lower than the auto-ignition temperature of the main fuel established at the end of the boiler purge sequence. As with any boiler, prior to startup and after shutdown the unit must be purged according to the latest applicable NFPA codes. An important part of a cold startup is the warming of the bed material with auxiliary fuel overbed burners designed for this purpose. During normal operation, a

Fig. 5 Typical bed density profile for a circulating fluidized bed.

CFB is loaded with enough bed material to provide a 20 in. wg (50 kPa) pressure differential across the primary zone. During the warming process, bed materials are introduced to raise the bed pressure drop from 5 in. wg (1.25 kPa). Auxiliary fuel is used to increase and stabilize the primary zone temperature at about 1000F/538C (varies somewhat depending on main fuel) in preparation for main fuel introduction. Simultaneously, the boiler metal temperatures as indicated by steam pressure (saturation temperature) must be within the heatup rate allowed for the boiler pressure parts. Upon ignition of the auxiliary fuel, the flue gas temperature entering the U-beams and the steam-cooled surfaces must be monitored and maintained below 950F (510C) until 10% of the MCR steam flow is established through the steam-cooled circuits. Once the primary zone temperature is stabilized at the fuel auto-ignition point, the main fuel is introduced and the bed temperature can be gradually raised to about 1500F (816C) where the auxiliary burner may be shut off. Boiler load can be increased from this low load operation with circulating mode being established with increasing solids, fuel and air flow. The rate of increase must be controlled such that the bed temperature remains stable. Primary air to total air ratio is further adjusted to improve combustion and reduce emissions.

Overbed burners are used to assist with the burnup of unburned carbon particles in the primary zone of the furnace. If the boiler is being shut down for maintenance and personnel entry into the boiler setting is required, all solids must be completely removed from the boiler and hoppers, and the boiler temperature must be below 120F (49C) prior to entry. (See *personnel safety* discussed earlier.)

BFB systems

Overview As is the case with its CFB counterpart, bed management of a BFB is important. Bed inventory, bed sizing, makeup and drainage must be integrated into operating procedures from data collected during commissioning tests. The BFB is also equipped with additional instrumentation to assist the operator in developing the unit-specific operating guidelines.

1. Primary zone ΔP – the gas-side differential pressure is used as an indication of bed height. The primary zone may be compartmented on the air side for coal firing, and multiple ΔP cells are then displayed.
2. Bed temperature – the typical bed temperature range is 1350 to 1650F (732 to 899C) and is a primary control variable. Because control of this variable is critical, multiple thermocouples are installed in the bed.

The operation of a BFB is similar to that of other combustion technologies in that fuel and air demands are set by the required steaming conditions. Bed temperature is controlled within the desired range by the primary/overfire air split for biomass firing and by selected compartment slumping for coal firing (see Chapter 17). If an SO_2 sorbent is used, it is usually metered in proportion to the fuel flow. Various interactions can

occur when manipulating control variables and the operator must be specifically trained to respond to upsets. These responses include:

1. Fuel flow control – fuel feed is increased or decreased based on steaming requirement. Changes in fuel feed have a short-term impact on bed temperature.
2. Bed height – height is controlled by adding material from the makeup system or by removing material through the drain system.
3. Air control – total air is primarily controlled based on steam flow. Air may be biased by the operator to change bed conditions. Increasing primary or bed air at a given load increases bed turbulence and burnout in the bed, while the secondary air changes opposite to the bed air change to control constant total air at a given load. Reducing bed air at a given load would have the opposite effect. The operator must, therefore, bias the set point based on combustion conditions. Fuel sizing variations, moisture content, and higher heating value are most likely to influence combustion conditions.
4. Bed material flow – material flow to the primary zone is through makeup and bed drains. Because these are generally intermittent devices, the operator must observe control variable trends, particularly height, and make appropriate adjustments.

Coal sizing Careful attention to coal sizing (minimum and maximum) is critical to successful unit operation for both under-bed and over-bed feed systems. Finer particles are elutriated too quickly and coarser particles tend to take too long to burn completely. In either case, UBC and SO_2 emissions (if being controlled) both increase. An optimum size range exists for each fluidized-bed system and fuel type. The proper size range is fine tuned through unit operating practice. In addition, for the over-bed feed system fuel size interacts with spreader speed, angle of injection and gas velocity.

Operation of Kraft recovery boilers

Overview

The Kraft recovery boiler has three purposes in today's pulp and paper industry:

1. recovery of sodium and sulfur compounds from the spent pulping liquor in forms suitable for regeneration,
2. efficient heat recovery from burning the liquor to generate steam for process use, and
3. operation in an environmentally responsible manner, cooling the combustion gases to allow back end particulate collection and minimizing the discharge of objectionable gases.

Steam flows can exceed 1,000,000 lb/h (126 kg/s) at superheater outlet pressures as high as 1500 psi (10.34 MPa) and final steam temperatures of up to 950F (510C). These units burn black liquor with solids contents up to 75 to 80% and with heating values decreased to about 5500 to 5600 Btu/lb (12,793 to 13,026 kJ/kg). A detailed review of designs and general op-

erating practice is provided in Chapter 28. Selected operating issues are highlighted below:

1. black liquor combustion process and air flow,
2. auxiliary burners,
3. operating problems, and
4. smelt-water reactions.

Black liquor combustion process and air flow

Unlike the firing of conventional fossil fuels, recovery boiler combustion goes through several distinct stages. Black liquor firing is composed of drying, volatile burning, char burning and smelt coalescence as discussed in Chapter 28. This has a distinct impact on unit operation and air addition. All modern B&W recovery boilers are equipped with three levels of combustion air. These are known as the primary, secondary and tertiary air streams in order of increasing elevation in the furnace. A fourth level, called quaternary, can be added for additional NO_x and particulate control (see Chapter 28).

Primary air Primary air is in the lowest zone in a recovery boiler furnace. The air ports are located approximately 3 ft (0.9 m) above the furnace floor. Admitted on all four walls of the unit, the primary air provides perimeter air around the bed at low velocity and low penetration, so the boiler does not lose combustion. The primary air is critical to bed stability, bed temperature and reduction efficiency.

Secondary air High pressure secondary air penetrates the full cross-section of the unit and is admitted at the top of the bed providing the combustion air for ignition and the heat to dry black liquor droplets and support pyrolysis. This air also helps control SO_2 , total reduced sulfur (TRS) and CO emissions. Finally, secondary air controls the shape of the top of the bed. Fig. 6 indicates the proper bed shape with the relative locations of the air ports and liquor nozzles.

Tertiary air Tertiary air is admitted at the upper elevation, above the liquor guns. Like secondary air, it is admitted at high pressure to provide penetration across the width of the furnace to complete the combustion process. This is an oxidizing environment to control CO and TRS emissions.

To maintain combustion in the proper location, the air flow splits and pressures must be properly maintained. Ranges of typical air flow distributions, inlet temperatures and pressure differentials are summarized in Table 3 for the two dominant firing systems, stationary and oscillating.

Successful stationary or oscillating firing depends on the correct liquor droplet size. This size must permit complete in-flight drying before reaching the furnace wall or bed. The variables in black liquor combustion include liquor percent solids, temperature and pressure at the spray nozzles, spray nozzle sizing and splash plate angle, and number and position of black liquor guns in service. Other variables include the vertical and angular movement of the oscillators or the off-horizontal angle of the liquor guns for stationary firing. Other factors on the air side include total excess air; air temperature(s); air splits between the primary, secondary and tertiary ports; and the static air pressure in each of these air zones.

Fig. 6 Proper bed shape for a black liquor recovery boiler – three air level design.

The objective in the manipulation of all of these variables is to control the steps of the drying and combustion of the liquor, and control bed temperatures. The result is stability of operation, with minimum plugging and emissions.

A comprehensive discussion of recovery boiler emissions is provided in Chapter 28.

Auxiliary burners

Recovery boilers are equipped with oil- and/or natural gas-fired auxiliary burners located at the secondary and tertiary air port elevations. The burners in the secondary windboxes are used for unit startup, as black liquor can only be fired into a heated furnace with an auxiliary ignition source. The secondary burners are also used to stabilize the smelt bed during an upset condition and to burn the bed out of the unit on shutdown.

Operating problems

Two problems unique to recovery boiler operations are plugging and aggressive tube corrosion.

Plugging of the superheater, boiler bank or economizer is generally caused by two mechanisms. The first is condensation of the fume or normal gases given off by the black liquor combustion. The hot combustion gases that leave the lower furnace contain vaporized compounds that condense when the gas temperature is cooled in the upper zones of the boiler, superheater or boiler bank. This condensation is dependent on gas temperature. The material condenses on the cooled heat transfer surfaces such as furnace screen tubes or primary superheater tubes. It also precipitates out when the gas temperature falls below approximately 1100F (593C). In either case, this material is a source of fouling in convection surfaces. Condensation or precipitation depend upon the temperature regime and chemistry of the fume. The deposit can be in the plastic range and very difficult to remove. On a properly designed and operated unit, this transition of the fume

Table 3
Typical Air Flow Splits and Operating Conditions*

	Stationary Firing	Oscillating Firing
Primary air	30 to 40% 300F (149C) 3 to 4 in. wg ΔP (0.7 to 1 kPa)	40 to 50% 300F (149C) 1 to 3 in. wg ΔP (0.2 to 0.7 kPa)
Secondary air	40 to 50% 300F (149C) 8 to 18 in. wg ΔP (2 to 4.5 kPa)	20 to 30% 300F (149C) 6 to 10 in. wg ΔP (1.5 to 2.5 kPa)
Tertiary air	10 to 20% 80F (27C) 10 to 20 in. wg ΔP (2.5 to 5 kPa)	20 to 30% 300F (149C) 8 to 12 in. wg ΔP (2 to 3 kPa)
Economizer outlet conditions	< 2.5% O ₂ 100 to 200 ppm CO	2.5 to 3% O ₂ 200 to 300 ppm CO

* Units with four air levels are discussed in Chapter 28.

from a dry gas to a sticky substance takes place in the upper furnace, wide spaced screen or superheater. Here the deposits can be controlled by sootblowers. On an overloaded or improperly operated unit, the gas temperature remains elevated farther back into the closer side-spaced boiler bank or economizer, where controlling the plugging with sootblowing equipment becomes difficult. The gas temperature at which the fume turns to a sticky liquid is also liquor chemistry dependent, with higher levels of chlorides or potassium compounds being detrimental to unit cleanability.

The second major cause of plugging is mechanical carryover of smelt, or unburned black liquor, into the convective heat transfer sections of the boiler. This

material is predominantly made of sodium carbonate (Na_2CO_3), sodium sulfate (Na_2SO_4) and sodium sulfide (Na_2S) compounds. The cause of this carryover is related to operation of the liquor nozzles, oscillators and various air port settings. As previously noted, the black liquor firing equipment and air system settings must produce complete in-flight or wall drying of the liquor droplets. If this drying occurs too high above the smelt bed, the less dense droplets are entrained in the gas stream and carry over into the convection sections of the boiler. In practice, most recovery boiler plugging results from a combination of fume condensation and mechanical carryover.

Recovery boilers are also subject to aggressive corrosion compared to conventional fossil fuel-fired units due to the presence of corrosive sulfur, chloride and other trace compounds in an elevated temperature environment. The Kraft recovery boiler also operates in both an oxidizing and reducing atmosphere due to the combustion process. Because of these conditions, the floor and lower furnace walls are constructed using one or a combination of corrosion protection systems: metallic spray coatings or carbon steel tubes, high-density pin studs with refractory, 304L stainless steel tubes, Incoloy® alloy 825 and Inconel® alloy 625 composites tubes, and weld overlay of carbon steel tubes.

Smelt-water reactions

One unique and undesirable feature of a Kraft recovery boiler is the possibility of water entering an operating furnace through a tube leak or external source, resulting in a smelt-water reaction. A smelt-water reaction occurs when water combines with hot or molten smelt, and a violent explosion can result. This concern has resulted in years of study and testing and has prompted enhanced industry standards on unit design, operation and maintenance. Modern units are equipped with the provisions for an emergency shutdown procedure. This is initiated if water is suspected to have entered the furnace of an operating recovery boiler. Refer to Fig. 7 for procedural overview.

Fig. 7 Emergency shutdown procedure overview for an operating recovery boiler (adapted from the Black Liquor Recovery Boiler Advisory Committee, October, 2003).

Section VII

Service and Maintenance

This section describes the last element of a successful steam generating system life cycle plan – service and maintenance.

As owners and operators of steam plants search for optimum performance, efficiency, and life cycle for all equipment, issues of maintenance and availability have become increasingly important.

The section begins with a discussion of service and maintenance encountered with all plants, both utility and industrial. A well-crafted service and maintenance program is essential in sustaining the availability of critical steam generating assets and maximizing overall performance and output. Condition assessment is then addressed with detailed discussion about examination techniques, assessment of various components, and analysis techniques for determining remaining life. The effects of cycling operation are also addressed.

Chapter 44

Maintaining Availability

The design of boiler systems involves the balancing of near-term and long-term capital costs to maximize the availability and useful life of the equipment. Fossil fuel-fired boilers operate in a very aggressive environment where: 1) materials and technology are pushed to their economic limits to optimize efficiency and availability, and 2) the erosive and corrosive nature of the fuels and combustion products result in continuous and expected degradation of the boiler and fuel handling components over time. As a result, the original boiler design is optimized to balance the initial customer capital requirement and the long-term expected maintenance, component replacement, and service costs for a possible operating life of many decades.

When a new power plant is started up, there is a relatively short learning period when the operators and maintenance crews learn to work with the new system and resolve minor issues. This period may be marked by a high forced outage rate, but this quickly declines as the system is broken in and operating procedures are refined.

As the plant matures, the personnel adapt to the new system, and any limitations in the plant design are either overcome or better understood. During this phase, the forced outage rate remains low, availability is high, and the operating and maintenance costs are minimal. The power plant is usually operated near rated capacity with high availability.

As the plant continues to operate, a number of the major boiler pressure part components reach the point where they are expected to be replaced because of erosion, corrosion, creep, and fatigue. Without this planned replacement, increasingly frequent component failures occur resulting in reduced availability. In some instances such as waste-to-energy systems, this period can be as short as one to three years for superheaters because of the very corrosive flue gas composition. However, for most fossil fuel-fired utility boilers operating on their design fuels, major pressure part components are economically designed for more than two decades of operation before economic replacement. Failures of major components such as steam lines, steam

headers and drums can cause major, prolonged forced outages. Significant capital expenditures are normally required to replace such components.

A strategic availability improvement program that includes capital expenditures to replace or repair this equipment before major forced outages occur can smooth out and raise the availability curve. Higher availabilities usually require higher maintenance, higher capital expenditures, and better strategic planning. The large expenditures needed for high availability in older plants require a strategic plan to yield the best balance of expenditures and availability.

Strategic plan for high availability

Mature boilers represent important resources in meeting energy production needs. A systematic strategic approach is required to assure that these units remain a viable and productive resource. The more efficient, but older boilers in the system can be the backbone of the commercially available power for a utility.

Emphasis on high availability

Today, the need for high commercial availability is of prime importance to the financial livelihood of a power supplier. This means that the low-cost units in a system must be available for full capacity power production during critical peak periods, such as hot summer days. Competition in the electrical supply industry requires that low-cost units be available so that the system can supply power to the grid at low overall costs. Usually, the large fossil powered units are the lowest cost units in the system. Lost revenue associated with having a large, low-cost unit out of service for repairs can be in excess of one million U.S. dollars per day. Owners are attempting to maintain availability levels of 90% or more on these large workhorses in the system.

The emphasis on maintaining or even improving availability means that a strategic plan must be put in place. Times between planned outages have been

increased. Planned outage times have been decreased. Units are being run continuously for more than a year. In some instances, units are run up to four years without being shut down. This requires complete system and component reliability. Problems that were once tolerated can not be permitted to exist.

One example of a change in availability philosophy is illustrated by the technique used to maintain low water-side tube deposit levels in the furnace. It was once common to chemically clean the boiler furnace every four to seven years. Deposit buildup in the unit dictated the cleaning cycle. Chemical cleaning normally required extending an outage time by several days to a week. Today, many units have undergone extensive changes to the boiler water treatment system. Many high pressure boilers have been converted to oxygen water treatment (see Chapter 42). Reports have indicated that oxygen water treatment has drastically reduced the rate at which furnace wall deposits form, and as a result, chemically cleaning the furnace in these high pressure units has been dramatically reduced. The reduced furnace deposits resulting from oxygen water treatment and the associated reduced need for chemical cleaning are significant factors in improving unit availability. This is a good example of how new technology and a systems approach to availability can have dramatic effects on overall operating costs.

Increased capacity and operability

During the early phases of a boiler's life cycle, less maintenance is required to maintain high availability. However, as the unit matures and components wear, more significant steps become necessary to maintain the desired availability. As the plant matures, the need for component replacement becomes expected and routine. Often at this point in the life of a power plant, system demands, fuels and cost structures have changed. Units must operate in ways unforeseen when they were built. They must have greater operability, or the ability to effectively perform their role in the manner required at the time. A plant that meets environmental emissions limits by means of system changes and fuel switching may have introduced capacity problems and operability limits that can become intolerable. Strategic equipment plans must address this issue of operating under new circumstances.

Boiler changes should be considered that incorporate technology advances to increase unit capability, operability and availability. This also provides the opportunity to address current operating issues or changing operating needs. Design changes might be incorporated to accommodate new fuel sources or to more successfully withstand cycling service. The potential for improvement is extensive. However, without a strategic plan, the replacement and repair of boiler components might be unsystematic, and the results may not achieve the desired returns on investment.

Key issues to consider when optimizing a unit include understanding how boilers age, identifying the critical components, and determining the general types of changes and enhancements possible. These elements are then combined with operating experience

and equipment condition assessment (see Chapter 45) to develop an integrated strategic plan for each boiler and each component in the boiler.

Strategic plans yield high returns on investment

While the driving force for the availability improvement plan may be to stretch present capacity resources to meet current demands as well as to improve operability and availability, a well conceived strategic plan can also achieve an attractive return on investment. The payback can be realized when the capital improvement results in higher availability, a lower heat rate, higher capacity, reduced routine maintenance, or lower forced outage rates. There have been numerous programs that have significantly improved plant capacity, operability and availability while achieving a payback in as little as one year.

Impact of environmental regulations

In most developed nations today, regulations at national and local levels control air emissions from power plants and other industrial boiler applications (see Chapter 32). Evolving emissions control limits and changing plant operating requirements add another dimension to the strategic plan. These interactions typically take the form of:

1. increasing plant capacity resulting in absolute emissions constraints,
2. increasing plant availability and operation (MWh) resulting in absolute emissions constraints,
3. economic fuel switching, changing absolute emissions and emissions rates,
4. increasingly stringent emissions requirements, reducing plant availability, and
5. reduced plant output due to parasitic load.

To take full advantage of the plant capacity as well as maintenance and upgrade capital expenditures, the addition of appropriate emissions control technology becomes an integral part of the strategic plan for all plants. In fact, combining the addition of emissions control equipment with plant upgrades can result in enhanced power plant economic performance that offsets part or all of the emissions equipment expenditures. Thus, the full strategic plan incorporates appropriate retrofits and upgrades of emissions control equipment.

Maintaining availability

The availability of a boiler is determined by the combined availability of its various critical components. If critical components become unreliable, boiler availability declines. These critical components include the pulverizers and burners, pressure retaining components such as economizers and superheater headers, and the various balance of plant components such as fans, controls, valves, etc.

The following section discusses the factors that affect the availability of key components of a typical boiler. The mechanisms that affect component degradation and reliability are revealed. Strategies are out-

lined in this section for improving availability through selective replacement upgrades of components that have become unreliable through normal degradation. Examples of these upgrades are detailed in this section.

Pulverizer availability improvement strategies – E and EL mills

Reliable pulverizer performance is an important element of the combustion system, and is essential for responsive power plant operation with good availability. Other subcomponents of the fuel preparation and delivery system such as burners, coal feeders, motors, dampers, coal pipes, combustion controls and combustion air fans must also perform reliably if the combustion system is to ensure good unit availability. See Chapters 12, 13, 14, 25 and 41 for more information about these components.

The first vertical air-swept coal pulverizer by The Babcock & Wilcox Company (B&W) was the E pulverizer introduced in 1937, as shown in Fig. 1a. The EL pulverizer (Fig. 1b) was developed in the 1950s as an upgrade to the E pulverizer. However, there are still a number of E pulverizers in operation today. Both the E and EL pulverizers are of the ball-and-ring (sometimes referred to as a ball-and-race) design.

Pulverizer degradation mechanisms

As discussed in Chapter 13, the E pulverizer is a machine that tends to wear from the inside due to the abrasive action of a continuous stream of fine coal particles. As the throat of the E pulverizer wears out, coal begins to fall past seals and into the lower parts

Fig. 1a Babcock & Wilcox E-type pulverizer.

of the pulverizer (*dribble*) causing severe wear to these parts. To prevent higher coal dribble rates as the throat wears, operators must increase air flow to maintain adequate velocity through the ever-widening throat gap. However, as air flow increases, fineness deteriorates, and erosion wear of other downstream pulverizer components increases. Upgrading the E pulverizer can help solve this problem and increase pulverizer availability.

Impact loading and thermal stresses may cause the E pulverizer rings to fail. Under certain operating conditions, there is considerable vibration generated and transmitted to the pulverizer components. As a result, shaft or spring fatigue failures can result which cause the loss of pulverizer availability.

E and EL type pulverizers can experience operating problems such as cracking of the upper or lower grinding rings. In addition, as grinding balls attempt to leave the ball race under the centripetal force of their rotation around the ring, they put asymmetrical loads on the rings and main shaft. Main shaft breakage can result.

E and EL upgrades

Since the introduction of the E and EL pulverizers, a significant number of functional and mechanical improvements have been made. Some of the major improvements leading to increased pulverizer availability and reliability are summarized below.

E to EL conversion The preferred improvement to an E pulverizer is to upgrade it to an EL mill. The EL pulverizer is much less prone to coal dribble problems due to improvements to the bottom grinding ring and

Fig. 1b Babcock & Wilcox EL-type pulverizer.

throat configuration. A complete E to EL conversion as shown in Fig. 2 includes new top and bottom grinding rings, springs, classifier, a more wear-resistant throat, relief gate, and housing units to protect the inside wall of the pulverizer just above the throat. Larger pulverizer motors and primary air (PA) fans may be needed to improve capacity. E to EL conversions have significantly improved the availability, capacity and reliability of E type pulverizers.

EL grinding zone improvements The B&W On-Track™ grinding zone retrofit package incorporates a number of design improvements that increase EL pulverizer availability and reliability by reducing grinding zone overhauls. Five key design changes are included:

1. **Deep dish grinding rings** The upper and lower grinding rings include a deeper and improved grinding track contour that limits radial movement of the balls as they travel around the grinding track. (See Fig. 3). This lowers the asymmetric loading and displacement of the upper ring and lowers the loading on the lower ring and main shaft, helping to prevent failures of the ring and shaft.
2. **Integrally cast metal snubbers** Snubbers (or bumpers) are cast into the upper ring. The snubbers help reduce the excessive side-to-side movement of the top grinding rings. Excessive side-to-side movement causes bending stresses and premature failure of the main shaft. With snubbers, spring and main shaft loading is reduced and breakage is less likely.
3. **Heavy duty upper ring flutes** Heavy duty outer flutes incorporated in the upper ring resist breaking of the fluted areas of the rings, enabling the upper rings to remain in service until they reach the end of their normal wear cycle. Fig. 4 shows the increased cross section of the heavy duty flutes compared to the narrower standard flutes. These larger flutes result in smaller gaps between the flutes and therefore, provide more control over the grinding balls as they orbit around the pulverizer track. This helps reduce stresses on the main pulverizer shaft.
4. **Larger diameter grinding balls** Larger diameter (13.63 in./34.61 cm) grinding balls increase the time be-

tween grinding zone overhauls because there is more wear metal on each ball compared to the smaller 12.5 in. (31.75 cm) diameter standard grinding balls. Longer wear cycles associated with these larger balls improve pulverizer availability and reduce pulverizer operating costs.

5. **Internally reinforced lower ring** The lower grinding ring of the EL pulverizer may experience thermal stress cracking over time. These cracks may require replacement of the lower ring, affecting mill availability. Efforts have been made to allow cracked rings to remain functional in the pulverizer without the need for replacement. One solution to bottom ring cracking is the internally reinforced ring. The grinding ring looks like the standard ring externally, but it is internally reinforced with steel. The harder, less ductile wear material of the ring propagates cracks much easier than tough mild steel. The mild steel reinforcement does not crack easily and holds the cracked segments of the ring together so the ring can remain in service.

Erosion protection for EL pulverizers Pulverizers experience internal wear from the erosive properties of coal circulating within the mill. High quantities of silica and alumina in the coal can reduce the life of most internal components. Fig. 5 shows the areas of an EL pulverizer that typically experience high wear from the erosive effects of coal. These areas can be protected by cladding with Cera-VAM® high density alumina ceramic. This ceramic cladding significantly reduces erosion rates and reduces maintenance work during overhauls. The application of ceramic lining materials to existing pulverizers must be done with care to minimize the impact on other operational areas.

Roll wheel pulverizer upgrades

Roll wheel pulverizers are described in detail in Chapter 13. These pulverizers are installed on many modern coal-fired boilers. As with the ball and race mill, wear affects the pulverizer availability. Upgrades can increase wear resistance.

Improved roll wheel design The typical pulverizer roll wheel wears in a pattern shown in Fig. 6. When localized wear reaches a point where the wheel must be replaced, there is considerable metal left in the remainder of the wheel.

To improve wear life, the standard *tires* may be

Fig. 2 E to EL pulverizer upgrade.

Fig. 3 Improved upper grinding ring for an EL pulverizer.

Fig. 4 Heavy duty flutes for upper grinding ring.

upgraded to an asymmetric design that places more material in the high wear area. As a further enhancement, the tires may incorporate a low profile. This lower profile enhances wear life and improves mill performance in certain circumstances. The upgraded tires reduce the frequency of mill overhauls and improve mill availability.

Rotating throat The throat area of a roll wheel pulverizer (see Chapter 13, Fig. 3) is critical to the distribution of air through the pulverizer. This area can experience high erosion rates from the fluidized air/coal particle mixture, which could lead to premature component failure or increased maintenance. High erosion rates can also lower component availability. High velocities and turbulent air flow lead to relatively high pressure drop through most standard stationary throat designs.

The B&W rotating throat (shown in Fig. 7) is designed to improve mill performance while dramatically

Fig. 5 EL pulverizer with Cera-VAM® ceramic cladding.

reducing the maintenance costs associated with stationary throat wear. The wear resistance of the throat segment is increased by applying chromium carbide weld overlay to the upper area of the vanes. The B&W rotating throat incorporates a patented air foil vane design that promotes more uniform air flow within the port, and has resulted in significant reductions in pulverizer pressure drop. In addition, the uniform air flow combined with the carbide weld overlay significantly reduces throat segment wear.

Low temperature pressure components

The low temperature pressure components are defined here as those below 900F (482C) metal temperature. These components normally are the economizer, furnace and convection pass walls, drums and flash tanks (steam separators), along with their downcomers and connecting piping and headers. These components suffer from corrosion, erosion, fatigue and overheating. Creep failure of these components only occurs when local overheating occurs.

Fig. 6 Typical roll wheel wear pattern.

Fig. 7 B&W rotating throat for a roll wheel pulverizer.

Degradation mechanisms

Corrosion Corrosion occurs inside and outside the tubes, pipes, drums and headers of these lower temperature components. Internal corrosion is usually associated with the boiler water, contaminants in the water, and improper chemical cleaning or poor storage procedures (see Chapter 42). External corrosion can be caused by corrosive combustion products, a reducing atmosphere in the furnace, moisture between insulation and a component, and acid formed on components in the colder flue gas zones when the temperature reaches the acid dew point. Corrosion results in wall metal loss. This wall thinning raises the local stresses of the component and can lead to leaks or component failure.

Corrosion may also be accelerated by the thermal fatigue stresses associated with startup and shutdown cycles. Furnace wall tubes, in areas of high structural restraint or high heat flux, often contain internal longitudinal or external circumferential or longitudinal corrosion fatigue cracks in cycled units.

Corrosion fatigue can occur in the steam drum around rolled tube joints. The residual stresses from the tube rolling process are additive to the welding and operating pressure stresses. Corrosion from chemical cleaning and water chemistry upsets acts on this highly stressed area to produce cracking around the seal weld or the tube hole. Extensive cracking can require drum replacement. Corrosion problems are further discussed in Chapter 42.

Erosion Erosion of boiler components is a function of the percent ash in the fuel, ash composition, and local gas velocity or sootblower activity. Changing fuels to a high-ash western United States (U.S.) fuel may lead to more erosion, slagging and fouling problems. Changing fuels might also require a change in the lower temperature convection pass elements to accommodate higher fouling and erosion. The tube wall loss associated with erosion weakens the component and makes it more likely to fail under normal thermal and pressure stresses. Erosion is common near sootblowers; on the leading edges of economizers, superheaters and reheaters; and where there are vortices or around eddies in the flue gas at changes in gas velocity or direction. Such changes are caused by closely spaced tube surfaces, slag deposits, or other obstructions including extended surfaces and staggered tube arrangements.

Fatigue The thermal stresses from temperature differentials that develop between components during boiler startup and shutdown can lead to fatigue cracks. These cracks can develop at tube or pipe bends; at tube-to-header, pipe-to-drum, fitting-to-tube, and support attachment welds; and at other areas of stress concentration. Smaller, lower temperature boilers are less prone to fatigue failures because the thermal differentials are lower and operate over small distances in these units. As unit size and steam temperature increase, the potential for thermal stresses and the resulting fatigue cracking also rises.

Overheating Overheating is generally a problem that occurs early in the life of the plant and can often result in tube ruptures. The nature of failures attributable to overheating is discussed in Chapters 7, 42 and 45. These problems may go undetected until a tube failure occurs. Overheating attributable to operation is generally resolved during the early stages of boiler life. Other problems regarding overheating may be difficult to ascertain, and specialized boiler performance testing (see Chapter 40) is generally required to identify the source and determine corrective actions.

In spite of these aging mechanisms, low temperature components are normally expected to be replaced after more than two decades without major overhauls unless the unit burns a corrosive fuel, burns fuel in a reducing atmosphere, or is improperly operated. When erosion, corrosion, fatigue, or overheating lead to frequent leaking, failures, or the threat of a major safety related failure, then component repair, redesign, or replacement is appropriate.

Hydrogen damage Boilers operating at pressures above 1200 psi (8274 kPa) and 900F (482C) final steam temperature suffer from more complicated aging mechanisms than lower temperature units. These boilers are generally larger than the low pressure, low temperature units and this increases the likelihood of thermal fatigue from boiler cycling. The higher pressures and associated higher furnace wall temperatures make these units more susceptible to water-side corrosion. The high temperatures in combination with any furnace wall internal deposits may promote hydrogen damage of the furnace tubing in areas of high corrosion or heavy internal deposits. Chapter 42 discusses hydrogen damage in more detail. Severe cases

of furnace wall hydrogen damage have forced the retirement of older units.

Furnace wall wastage mechanisms associated with staged low NO_x burners The advent of low NO_x (nitrogen oxides) burners with staged combustion for coal-fired units has increased the wastage rates of some boiler furnace walls near the burner zone. Corrosion rates as high as 0.040 in. (1.02 mm) per year have been reported for small local regions in furnaces of units with staged combustion. The pattern of high corrosion rates is not uniform throughout the furnace or from boiler to boiler. The pattern seems to be unit-specific and rather unpredictable as to its extent and rate. Normal combustion gases with unstaged combustion lead to an oxidizing flue gas that is not particularly corrosive. However, in staged combustion there is incomplete mixing of the air and fuel, and pockets of a reducing gas are formed in the furnace in the burner zone. The reducing gas is high in H₂S, CO and unburned fuel (carbon and iron pyrites), and is low in O₂. This gas mixture together with the sulfur and chlorides in the fuel does not allow the tubing to form a protective oxide outer covering. High corrosion rates can occur in areas in contact with the reducing gas and unburned fuel.

The corrosion rate in the high wastage areas of the boiler furnace is temperature dependant. As a result, the corrosion rate is higher for high pressure units with staged combustion than for lower pressure units with the same burner arrangement. Inside diameter (ID) deposits in the furnace wall tubing also raise the metal temperature and increase the outside diameter (OD) wastage rate. The highest corrosion rates typically occur in localized areas adjacent to and above the burner elevation up to just below the overfire air ports, where the reducing gas concentrations are the highest adjacent to the walls.

Availability improvement strategy examples

Economizer upgrades One example of an availability improvement strategy involves an upgraded bare tube economizer. A 600 MW coal-fired boiler was designed with a staggered, finned tube economizer. The economizer, shown in Fig. 8, was equipped with longitudinal fins. In clean condition, these fins increase heat transfer and reduce the amount of tubing required.

The economizer experienced severe flyash plugging. As the plugging spread through both banks, system gas flow resistance more than doubled. The increased flue gas resistance pushed the boiler fan to its limit and restricted boiler load. High velocity gas lanes were created around the plugged areas. Extremely high ash velocities caused tube erosion and resulted in numerous tube failures. Unit availability and reliability were greatly reduced.

An engineering evaluation determined that the existing finned economizer was not appropriate for the high ash coal used as the main fuel. The staggered tube pattern only increased the severe flyash plugging. An analysis showed that an in-line bare tube economizer with equivalent performance could be fitted into the existing space. Fig. 9 illustrates the upgraded in-line economizer design.

The upgraded economizer included the following features:

1. Vertical spacing between tubes was decreased to allow installation of more tube rows and to minimize gas-side resistance.
2. An in-line arrangement was used to reduce gas-side pressure drop and potential for ash erosion.
3. The economizer tube diameter was increased from 1.75 to 2 in. (44.5 to 50.8 mm) to achieve a higher flue gas velocity and better convection heat trans-

Fig. 8 Original staggered, finned tube economizer that experienced severe flyash plugging.

fer without exceeding the allowable velocity limit for the percent ash and percentage of abrasive silica and alumina constituents in the fuel. Bare tubes arranged in-line are most conservative in such hostile environments, are least likely to plug, and have the lowest gas-side resistance per unit of heat transfer. The weight of the new economizer did not exceed the original weight. Also, the new economizer required no more space than the original design.

4. The tube bends were protected by new erosion barriers on top and bottom of both banks. Properly designed perforated barriers do not noticeably reduce the effective heating surface, but they are very effective in throttling the flue gas flow across the tube bends along the enclosure walls. Without barriers, the open space between the return bends and the enclosure walls would be the path of least resistance, and flue gas would stream through these gaps at very high velocities. The effect would be excessive erosion of the bends, reduced overall heat transfer across the banks, and possible damage to uncooled casing. The existing inlet and intermediate headers were reused. Access doors and platforms did not have to be relocated or modified.

The upgraded economizer has experienced no flyash plugging. The recurring tube erosion problem has also been eliminated. As a result, unit reliability and availability have been significantly restored. The boiler operates at full load and has not been limited by economizer problems.

Furnace wall corrosion reduction Another example of an availability improvement strategy involved the reduction in furnace wall corrosion associated with staged combustion low NO_x burners burning higher sulfur coals. As discussed earlier, staged combustion

can lead to localized corrosion of the furnace wall tubes in areas where reducing conditions are produced near the walls. In this example, the corrosion rates in some regions of the furnace approached 0.040 in. (1.02 mm) per year. The areas of high corrosion on the furnace side walls are shown in Fig. 10. The corrosion was highest on the side walls near the corners of the furnace at the burner elevation.

The high corrosion pattern shown in Fig. 10 was caused by pockets of high CO, unburned fuel and H₂S formed in areas adjacent to the furnace walls (see Fig. 11). These areas resulted in high corrosion rates that led to repeated tube leaks and boiler outages. Considerable outage time was required to repair leaks and replace tube wall panels on a recurring basis. The unit suffered from low availability due to furnace corrosion.

The current method of combating this high corrosion is to protect the tubing with a cladding that is more resistant to the corrosive atmosphere. High chromium nickel alloys similar to Inconel® alloy 622 (21% Cr, 13% Mo, 4% Fe, 3% W, and balance Ni) are being clad over the boiler tube material. Cladding can be applied onto the tubing or furnace panels, or can be formed as part of the tube during the production process (coextrusion). Other coatings have been tried over the years, such as high-velocity oxy-fuel (HVOF) spray coatings. These spray coatings are satisfactory where low corrosion rates [less than 0.010 in. (0.25 mm) per year] are involved. However, where more severe corrosion is encountered, the use of weld clad tubing or coextruded tubing for corrosion protection is most often chosen. Fig. 12 shows the laser cladding of a furnace wall panel with Inconel alloy 622. In this example, the panel was fabricated, laser clad, and then installed in the side walls to protect the walls from corrosion.

Fig. 13 shows a laser clad sootblower opening. This opening had experienced rapid corrosion rates due to

Fig. 9 Upgraded bare tube in-line economizer for high ash coal.

Fig. 10 High corrosion pattern on furnace side walls.

Fig. 11 Computer model showing areas of high CO near the side walls.

adjacent reducing conditions and the action of the sootblowers. Inconel alloy 622 has been shown to dramatically decrease corrosion (as well as erosion) in areas that have experienced high wastage.

Boilers that are experiencing corrosion from staged combustion conditions should be carefully monitored. Wall thickness measurements at suspected high corrosion areas should be taken at frequent intervals (e.g., yearly or every two years). Maps of the wall thickness changes (such as shown in Fig. 10) can help determine which areas to protect with cladded tubing. With the lower corrosion rates associated with cladded tubing, the frequency of weld repairs and wall panel replacements is dramatically reduced. The beneficial effects on unit availability can be dramatic.

Hopper panel impact protection Many units burning western U.S. coals and to a lesser degree eastern U.S. coals experience slagging problems. Large accumulated masses of slag can fall onto the hopper slopes of the lower hopper area of the boiler furnace (see Fig. 14 for a hopper design). Falling slag results in very high impact loads on the hopper panel tubes and the supporting structure. Tubes erode, deform, crack, and eventually leak. Hopper supports deform and lose their functionality. This situation may lead to unexpected major outages for lower hopper repairs or replacement.

An innovative hopper design has been patented (U.S. patent no. 5,692,457) that improves the ability of the hopper to withstand these massive slag falls. (See Fig. 14.) The heart of the system is the crush tube that is designed to absorb the impact load. The crush tube is replaceable and located under the hopper panel and is designed to deform preferentially (or crush on impact loading) compared to the pressure-containing

tube of the hopper panel and the support truss members. In addition, the hopper panel tube is typically made thicker to improve its ability to withstand falling slag. The hopper tubes can also be weld clad to resist erosion and improve longevity in this harsh environment as the ash and slag slide down the hopper.

The combination of a reinforced hopper tube with the impact absorption capability of the replaceable crush tube improves the likelihood that the hopper can withstand a typical slag fall. The crush tubes that have been deformed are replaced during regular

Fig. 12 Laser cladding process on a furnace wall panel (courtesy of Praxair Surface Technologies).

Fig. 13 Laser clad sootblower opening.

maintenance outages. Hoppers utilizing this unique design concept have performed well in service for many years and have improved unit availability.

Wear resistant materials Most older boiler components do not contain highly wear resistant materials in high erosion areas. These areas, such as within coal pulverizers, require frequent and sometimes costly maintenance. Down time to repair and replace these eroded components reduces availability.

Advanced materials have been developed specifically for boiler fuel handling applications. Materials have evolved from basic low carbon steels to ceramic linings. These linings include high density, high alumina ceramics and silicon carbide ceramics. The alumina ceramics with 96% alpha alumina and a density of about 232 lb/ft³ (3716 kg/m³) are ideal for components exposed to high velocity coal particles. These alumina linings provide up to ten times the wear resistance of carbon steel. The nitride-bonded silicon carbide ceramics have good erosion and corrosion properties, and they provide high thermal conductivity and superior thermal shock resistance. These ceramics are used in the most severe environments.

Typically, ceramic linings are used in coal transport equipment, pulverizers, piping, exhaust fans and burner nozzles. The extent of application depends upon the relative erosive nature of the specific coal and

the associated velocities. Table 1 offers guidelines for applying ceramic linings to coal piping.

Ash composition affects the erosiveness of the coal. Large percentages of clay, alumina, silica, pyrite and quartz also increase coal's abrasiveness. The guidelines given in Table 1 assume a silica composition of 40%. High alumina and silica content increases the abrasiveness of the coal. Following these guidelines can help improve unit availability by reducing repair frequency and the associated replacement time.

Additional availability improvement strategies are contained in the following chapters:

Chapter 7 discusses various materials that might be used in upgrades for new components.

Chapter 20 discusses economizer design.

Chapter 42 contains information about proper water chemistry and layup procedures.

Chapter 45 discusses methods for evaluating the condition of low temperature components.

Fig. 14 Impact resistant hopper design.

Table 1
Recommendations for the Application of High Density Alumina Ceramic Linings in Coal Piping

Ash Content of Coal	Recommendations
Less than 6%	No ceramic lining required.
6% to 9%	Use ceramic lining from the pulverizers to the first major bend plus two pipe diameters beyond the bend. Line all short radius bends and two pipe diameters beyond these bends.
More than 9%	Same as above except, also line all bends and the pipe two diameters beyond these bends.

High temperature pressure components

The high temperature pressure components are defined here as those that operate at or above 900F (482C) metal temperature. The components normally at this higher temperature are the superheaters, reheaters and attemperators with their connecting tubing and piping. These components operate in a temperature range high enough where they can experience degradation from oxidation, fuel ash corrosion, carburization, graphitization and creep. These are the high temperature failure modes. Corrosion, erosion, fatigue, and overheating are also possible in a manner similar to that discussed in this chapter on the lower temperature components. (See Chapter 45 for information on evaluating the condition of these components and some of their common failure modes.)

High temperature creep rupture and creep fatigue failure (see Chapters 7 and 45) are the two primary aging mechanisms for the high temperature components. All components that operate at temperatures above 900F (482C) are subject to some degree of creep. Most of the tubes, piping and headers from the primary superheater to the turbine, including the superheater and reheater, are designed to operate in the creep regime. As a result, most of these high temperature components have a finite useful life and can fail by creep or creep fatigue after 20 to 40 years of operation. Replacement and redesign must be considered in any strategy for operating high temperature, high pressure boilers.

Chapter 45 discusses methods for predicting creep ruptures in high temperature superheaters and reheaters, and for assessing the condition of high temperature piping and headers. Availability of these high temperature units in the later years of operation generally falls, mainly because of creep ruptures and creep fatigue failures. It is common to replace a superheater after 25 years of service due to creep rupture incidents. Superheater outlet headers have also been replaced after 25 years due to creep fatigue cracking. Fig. 15 illustrates the typical replacement age for reheaters in power boilers.

The aging process and rate of component degradation vary from unit to unit. Table 2 presents the com-

ponent replacement sequence for a typical high pressure, high temperature unit.

High temperature component degradation mechanisms

Oxidation The most common degradation mechanism for superheaters and reheaters is tube OD oxidation. At higher temperatures the oxidation rates from metals increase. Chapter 7 discusses the oxidation limits placed on tube metals to prevent rapid oxidation. Superheater and reheater tubes are designed with OD metal temperatures below the oxidation limits. However, some oxidation does take place. The rate of oxidation is typically 0.001 to 0.002 in. (0.025 to 0.051 mm) per year. Failures from oxidation do not usually occur to tubes unless the oxidation process is accelerated by overheating or sootblower activity.

When oxidation does occur it appears as wastage on the upstream side of the tube OD. Flat spots on the OD or thin spots in the tubing may be obvious where the wastage has occurred. The wastage is usually highest on the upstream side of the leading edge tubing near the sootblowers. Wastage from oxidation may also occur on the tubing OD near the outlets, or near changes to higher material grades (higher metal temperatures). When oxidation occurs, the ID oxide scale thickness will also usually be thicker than expected for the hours of operation. Fuel ash corrosion can accelerate oxidation wastage and is discussed below.

Changes in operating conditions that are associated with changes in fuel type or changes in burner designs may alter the operating temperature of a tube. A temperature increase above the oxidation limit can cause rapid wall loss from oxidation. When this occurs, tube failures can follow. The tube that is thinned by oxidation will ultimately fail by a creep mechanism due to the higher stresses in the thinner wall (see *Creep* section below).

Tubes that operate near sootblowers are periodically cleaned by the sootblower action. This action removes some of the protective oxide from the tube OD. The tube regenerates this protective layer, but in doing so, some wall is lost to form the protective oxide. Over time this repeated oxidation/cleaning/oxidation cycling can lead to wall loss that is sufficient for creep fail-

Fig. 15 Reheater replacement projects by age.

Table 2
Component Replacement Schedule for a Typical
High Temperature, High Pressure Boiler

Typical Replacement Period (Years)	Component Replaced	Cause for Replacement
20	Miscellaneous tubing	Corrosion, erosion, over- heating
	Attemperator	Fatigue
25	Secondary superheater (SSH)	Creep
	SH outlet header	Creep fatigue
	Burners and throats	Overheating, corrosion
30	Reheater	Creep
35	Primary superheater and economizer	Corrosion
40	Lower furnace	Overheating, corrosion

Note: The actual component replacement period is highly variable depending on the specific design, operation, maintenance and fuel.

ures to occur. Often, oxidation around the sootblower area is mistakenly labeled as coal ash corrosion. Coal ash can cause corrosion failures that appear to be similar to oxidation failures (see section below). Oxidation, however, does not rely on a corrosive ash.

Fuel ash corrosion Fuel ash corrosion is sometimes very aggressive, but usually does not occur or becomes only a minor problem. It is sometimes confused with oxidation because both occur in the same components and have similar appearance. Fuel ash corrosion is the wastage of tubing caused by a chemical reaction with the fuel ash. Elements in the fuel can react with the normally protective oxides. Chloride and sulfur are examples of elements that degrade the oxidation resistance of the metal tubing and markedly increase oxidation rates.

Usually, in fuel ash corrosion, the ash forms a liquid layer on the tubing during unit operation. Complex alkali metal salts form the liquid corrosive layer in some coal-fired boilers. $\text{Na}_3\text{Fe}(\text{SO}_4)_3$ is one member of the complex sodium or potassium metal (Fe or Al) sulfate family that forms a corrosive liquid film on superheaters and reheaters in some coal-fired boilers. The liquid layer is a low melting point mixture of compounds formed by the ash and it dissolves away the normally protective oxide scale. In other cases, corrosive liquid deposits can be formed by vanadium compounds or chlorides in combination with sulfates.

It is difficult to distinguish between oxidation and fuel ash corrosion. They may be similar in appearance. One way to distinguish if a superheater or reheater is suffering from oxidation or fuel ash corrosion is to analyze the OD scale on the tubing with x-ray diffraction and chemical analysis. Metallographic examination of the tube metal near the OD surface may also help show the advance of corrosive compounds along tube grain boundaries. If the tube scale is shown to have high percentages of elements or compounds [such as $\text{Na}_3\text{Fe}(\text{SO}_4)_3$] associated with fuel ash corro-

sion, then fuel ash corrosion is present, not just oxidation. Oxidation by itself does not show evidence of high percentages of these elements or compounds, although low concentrations may be present.

Carburization Although some carburization is often associated with fuel ash corrosion, carburization of superheaters and reheaters is rare. It has become more common with the advent of staged combustion for low NO_x burners. Carburization occurs when incomplete combustion of the coal occurs before the flue gas passes through the superheater or reheater. Incomplete combustion leads to increased amounts of CO and unburned fuel contacting the superheater tubes.

Metal tubes require an oxidizing atmosphere to form a protective oxide film on the surface of the tube. When localized reducing conditions exist around the tube at an elevated temperature, the tube can not protect itself from wastage from the sulfur and other corrosive species. In addition, both the unburned carbon in the fuel, and flue gas CO, react with the dissolved chromium in the tube to form chrome carbides.

Carbon diffuses into the surface of the tube, raises the carbon level, and forms chrome carbides. If this occurs, there is so much carbon in the metal that all of the available chromium reacts to form chromium carbides. When the chromium is tied up as chromium carbide it can not strengthen the metal and can not help form protective chromium-rich oxides. Essentially, the affected portion of the tube near the OD becomes a weak low-chromium steel material that is less corrosion-resistant at the elevated temperatures encountered in superheaters and reheaters.

Graphitization Carbon in both carbon steel and carbon-moly tubes (example: SA209-T1a) is free to diffuse through the metal. Carbon is most stable as graphite in the metal, so with time, the carbon may coalesce into graphite flakes. These flakes may line up in a linear and continuous spiral pattern along the tube. When they form this pattern, the graphite forms spiraling planes of weakness in the tube. Under the influence of operational stresses, cracks can develop along the spiraling paths of graphite. Sudden tube failures occur with no warning. Reliability suffers when this process nears its final phase, as tube failure rates increase.

Graphitization can occur when carbon steel or carbon-moly steel tubes are heated to operational temperatures above about 900F (482C) for long periods of time. Not all units experience graphitization of the carbon or carbon-moly tubing. It is currently not clear why some tubes undergo graphitization and others do not. When severe graphitization occurs, the tubes fail with little ductility and the fracture occurs in a spiral around the tube. Tubes with chromium do not suffer this problem because the carbon becomes associated with the chromium as chromium carbides. (See Chapter 7 for more information.)

Creep Chapter 7 discusses creep and creep rupture of tubing. Superheaters and reheaters will eventually fail by creep if other failure mechanisms are not present. Most of the reheaters replaced in Fig. 15 were replaced due to creep rupture failures. Overheating due to some form of internal obstruction can lead to creep

failures in short periods of time. Normally, creep rupture failures take many years to occur. As the frequency of these failures increases, then component replacement is required in order to maintain unit availability.

Availability improvement strategy examples

Superheater upgrade to improve fuel ash corrosion resistance One example of an availability improvement strategy involves an upgraded superheater. This eastern U.S. utility had recurring tube failures in the secondary superheater of an oil-fired boiler, and the boiler suffered from low availability as a result of these failures. Fuel ash corrosion from the fuel oil caused failures in the tubes exposed to the higher operating temperatures. Fig. 16 illustrates the arrangement of the boiler and shows the problem superheater.

The furnace gas temperature at the leading edge of the superheater was nearly 2800F (1538C). High superheater tube temperatures resulted from this unusually high furnace exit gas temperature (FEGT). External tube corrosion was accelerated by this high temperature and by the high vanadium and sodium contents in the oil. Tube failures occurred so frequently that the bottom three rows of the horizontal superheater had to be replaced every 18 months.

An upgrade in superheater design usually requires field testing to define the operating conditions, followed by a detailed engineering study. To correctly design the upgraded superheater, boiler operating temperatures were obtained. A computerized boiler model was used for the performance testing. This system revealed that the actual FEGT was 125F (69C) higher than the design value. The high FEGT was a result of furnace design and burner arrangement. Because it was impractical to redesign the furnace or change to a less corrosive fuel, and the owner did not wish to lower the unit rating in order to lower the corrosion rate, a design study concentrated on a superheater upgrade.

A new superheater was designed using the actual FEGT that was obtained from the computer model of the unit. The new design accommodated the higher operating metal temperatures and allowed the tubes to continuously function at the higher temperatures without producing overheat or corrosion related failures. In the final upgrade arrangement, the three lowest tube rows that had been attacked by corrosion were replaced with Inconel® 671/800HT®, a corrosion resistant coextruded high chromium nickel alloy material. The tubing was made by co-extruding an Inconel alloy 671 layer 0.070 in. (1.78 mm) thick on the outside of the inner core of Incoloy® alloy 800HT. The outer layer of Inconel alloy 671 provided the high corrosion resistance while the inner core of Incoloy alloy 800HT provided the high strength at the elevated tube temperatures. The remaining tubes in this bank were replaced with a stainless steel material to accommodate the higher metal temperatures. A new support method that allowed greater material expansion at the elevated operating temperatures was included.

The modified superheater allowed the unit to run with high availability and at full rated capacity. The fuel ash corrosion problem was greatly reduced.

Superheater upgrade to restore full load capability and improve availability This example of a superheater and reheater upgrade also involved the upgrade of the outlet headers to P91 (SA335P91) material. The boiler was a B&W coal-fired unit with single reheat. The radiant boiler provided 1,600,000 lb/h (201.6 kg/s) main steam at 1050F (566C) and 2203 psig (15.2 MPa), and 1,263,800 lb/h (159.2 kg/s) reheat steam at 1050F (566C) and 525 psig (3.6 MPa). The goals of the project were to restore unit capacity and improve availability.

Steam generator reliability had been high until the late 1980s, when superheater components began to suffer from the latter stages of normal aging processes, including outlet header maintenance. The unit had also lost 10 MW of capacity. Subsequent study suggested that an increase in throttle pressure of 70 psig (483 kPa) would restore the lost 10 MW. This meant that the boiler steam-side pressure drop needed to be reduced by approximately 70 psig (483 kPa).

The project involved an upgraded superheater, reheater and primary superheater together with the superheater and reheater outlet headers as shown in Fig. 17.

Selected features of the redesigned high temperature components include:

Fig. 16 Boiler arrangement showing secondary superheater (SSH) directly above furnace where gas temperatures reach 2800F (1538C).

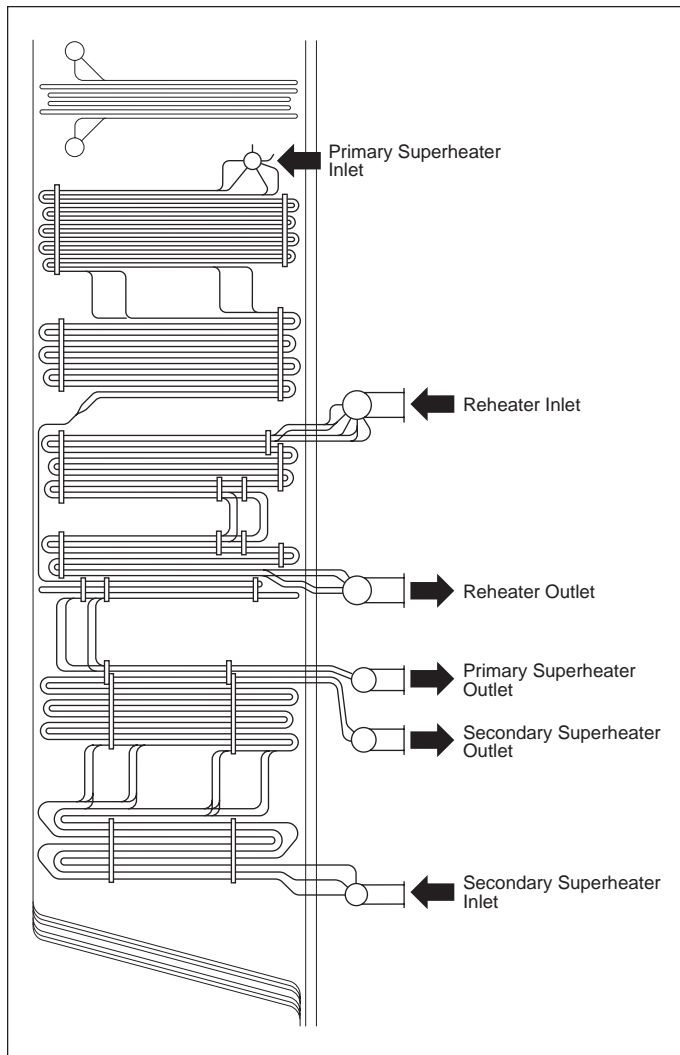

Fig. 17 Upgraded superheater and reheater sections and headers.

1. Tube material of T91 (SA213T91) was used in the secondary and reheat outlet banks to provide longer component life and reduce steam-side pressure drop.
2. Reduced diameter reheat outlet tube legs and header stubs [2 in. (5.08 cm) OD versus original 2.5 in. (6.35 cm) OD] were used to improve flexibility and reduce stress in an area where tube failures had been occurring.
3. Secondary superheater outlet header material of P91 (SA335P91) was used to reduce size and increase component life.
4. The number of parallel steam flow paths in the primary superheater (PSH) inlet bank, PSH intermediate bank and secondary superheater (SSH) outlet bank were increased to reduce steam-side pressure drop. A reduction in steam drum to SSH steam outlet pressure drop by 70 psig (483 kPa) was accomplished by increasing the number of parallel steam flow paths and employing upgraded tube alloys permitting thinner tube walls. The superheater pressure drop reduction permitted a corresponding increase in turbine throttle pressure to regain the original 10 MW higher generator output.

Superheater header upgrades Chapter 45 describes the mechanisms for reheater and superheater outlet header failures. The main failure modes are tube-to-header weld failures, ligament cracking and nozzle cracking. These failures are caused by the combined effects of thermal cycling and creep, often called *creep fatigue*. Advanced design standards for headers have been developed to help reduce these failures. When an outlet header must be replaced, a design upgrade should be considered. An upgraded header can provide long-term, reliable service even under cycling conditions.

Nozzle cracking is associated with the weld in a tee nozzle or in the internal sharp corners of a forged design. Any header upgrade could include a forged tee to eliminate the welded connection. The forging would include generous radii to reduce stress concentrations.

Under cycling service, the tube-to-header weld area may develop cracks due to inadequate tube leg flexibility or due to thermal stresses in the header. Cracking due to inadequate tube leg flexibility can be overcome by providing longer or more flexible tube legs between the furnace penetration and the header. However, this modification may require header relocation and/or relocation of the tube penetrations.

Relocating the tube penetrations around the header may also be necessary to avoid header ligament cracking. Many headers were designed with closely spaced or non-symmetrical tube penetrations, as shown in Fig. 18, that are more prone to creep fatigue ligament

Fig. 18 Increased ligament size for longer design life.

cracking. Studies have shown that creep fatigue cracking can be decreased by using larger ligaments. Upgraded headers with widely spaced tube penetrations provide larger ligaments and lower ligament temperatures and stresses. As a result, header life is significantly increased.

Redesign of the tube-to-header weld configuration, as shown in Fig. 19, can also increase the life of a high temperature header. Chamfering the tube end and redesigning the weld preparation allows the weld to be made with a near full penetration tube-to-header weld. Reduction of the large partial penetration area at the end of the tube stub reduces the stresses around the weld joint and reduces the rate of crack propagation from this area of the weld joint.

The tube hole in the header creates a sharp discontinuity at the intersection of the hole and header internal surface. Very high stresses associated with this sharp corner cause creep fatigue cracks to initiate from the hole. A redesigned header may also be fabricated with a chamfer at the tube hole penetration as shown in Fig. 19. The chamfer lowers the stress around the hole and reduces creep fatigue cracking.

The most common upgrade for a high temperature header is an upgrade in material. American Society of Mechanical Engineers (ASME) SA335P11 headers may be upgraded to SA335P22 or P91 materials, and SA335P22 headers may be upgraded to SA335P91. The material upgrade generally results in a dramatic increase in header life, and in many cases, it is anticipated that these upgrades may nearly double the life of certain header components.

Additional availability improvement strategies are contained in the following chapters:

Chapter 7 discusses various materials that might be used in upgrades for new components.

Chapter 19 explains boiler, attemperator, superheater and reheater design.

Chapter 45 discusses methods for evaluating the condition of high temperature components.

Circulation upgrades

Cycling boiler upgrades

Many older and larger fossil utility boilers were not designed to accommodate frequent on/off cycles. Design criteria for cycling service boilers are limited due to the lack of long-term experience with large units. Cycling service can cause fatigue failures in the economizer tubing and inlet header, lower furnace wall tubes and headers, structural components such as buckstays, and some steam drum internals. This fatigue cracking can be caused by the sudden flow of cold water into hot boiler components. Thermal differentials of 200 to 400F (111 to 222C) can be created. Furnace subcooling, boiler-forced cooling during a shutdown, and intermittent cold feedwater flow into the boiler during startup are three sources of thermal differentials and cyclic cracking. The thermal stresses produced within the components may be sufficient to produce low cycle fatigue cracks. The solution in most

Fig. 19 Header upgrade with redesigned tube penetration.

cases is to modify the boiler and/or feedwater system to prevent the sudden entry of cold water into hot boiler components.

When a boiler is experiencing cracking due to subcooling and cold feedwater flow upon startup, an off-line pump-assisted circulation system may be installed to reduce the thermal transients. The system, as shown in Fig. 20, consists of an off-line circulation pump, a thermal sleeved tee connection between the off-line pump and the feedwater line, a connection line from the boiler downcomer to the pump, a warming bypass system, various valves, and a control system.

The off-line pump is only operated when the boiler is shut down. Its purpose is to provide a small amount

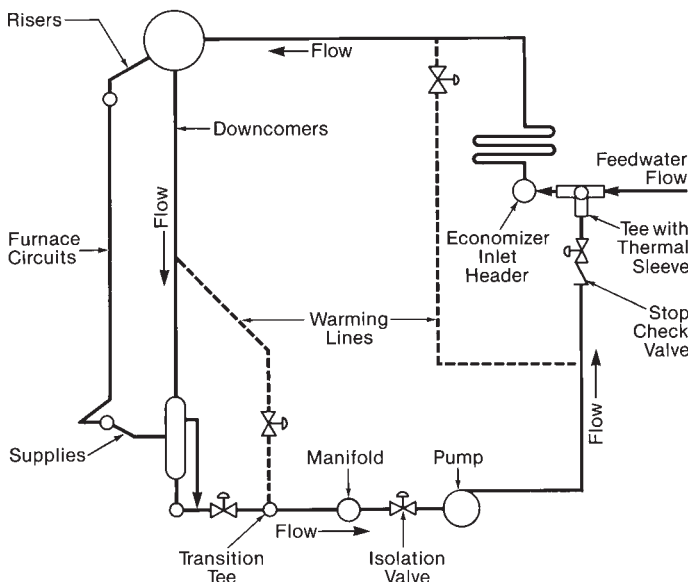

Fig. 20 Off-line recirculation system to reduce thermal shock.

of circulation within the furnace circuit and through the economizer to prevent temperature stratification in the water circuits. The tee connection permits the introduction of a small amount of hot water from the furnace into the feedwater stream when feedwater is intermittently supplied to the boiler and before a steady feedwater flow is established. The warm furnace water introduced at the tee connection raises the feedwater temperature enough to prevent thermal shock to the economizer. The connection contains an internal thermal sleeve that protects the tee from a thermal shock when cold feedwater is first fed to the economizer. A control system monitors the feedwater temperature and flow and controls the recirculation pump. When the boiler startup sequence is initiated, the off-line system is shut down and isolated. Warming lines permit natural circulation through the pump when it is shut down and the boiler is off-line.

Experience with off-line recirculation systems has shown that thermal shock differentials can be reduced to less than 100F (56C) from previous levels of 200 to 400F (111 to 222C). Such a reduction may eliminate the fatigue cracking that is associated with frequent unit cycling.

Drum boiler bypass system upgrade

Steam turbine transient stresses associated with on/off operation or load cycling shorten turbine life. Long startup times required to minimize these stresses lead to costly fuel consumption. Drum boilers can be upgraded with a superheater bypass system for improved cycling capability. The bypass system upgrade can be installed on a drum boiler to minimize startup time, provide control of steam temperature to match turbine metal temperature, and allow dual pressure operation of the boiler and turbine for better load response. These features reduce turbine stresses for improved availability and reduced maintenance costs.

The common means of steam temperature control in a drum boiler (water attemperation in conjunction with parallel convection surface, gas recirculation, excess air, or burner input adjustments) do not permit easy control of turbine temperatures during startup and low loads. This is because there is a large mismatch between flue gas flow and steam flow. The drum boiler bypass system, shown in Fig. 21, provides direct control of the steam temperature by saturated attemperation of the superheat and reheat outlet steam. This arrangement provides the desired steam temperature for the turbine without undue restrictions on the startup firing rate.

The drum boiler bypass system substantially reduces cold startup time because it controls the temperature differences of the saturated boiler surface, superheater surface, and turbine. The bypass system consists of a control system with steam piping and valves and is described in detail in Chapter 19.

The system has a set of superheater stop and bypass control valves downstream of the primary superheater to allow dual pressure operation; the turbine throttle pressure is controlled separately from drum pressure. This control system is designed to maintain constant pressure operation of the drum and boiler

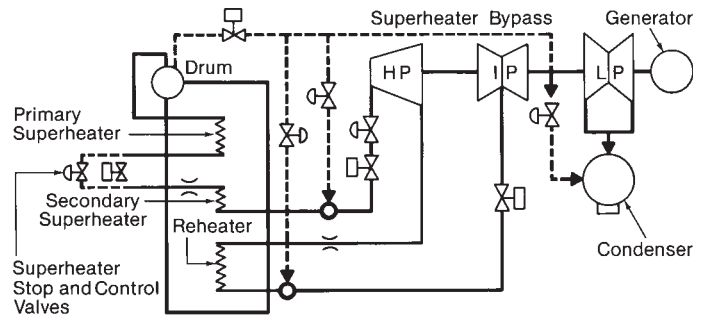

Fig. 21 Typical superheater bypass system for a drum boiler to minimize turbine stress.

furnace circuits and variable pressure operation of the turbine because the turbine throttle valve is open over most of the load range.

Dual pressure operation minimizes thermal stresses to the boiler and the turbine. A dual pressure shutdown keeps the boiler near full pressure and the turbine metal near full load temperature in preparation for a quick restart. In addition, it allows more rapid load changes than variable boiler pressure operation.

A superheater bypass diverts excess steam from the boiler to the condenser, thereby separating firing rate from drum pressure during shutdown and startup. Gas temperature probes, located near the superheater and reheater outlet tubes, monitor flue gas temperatures.

The superheater bypass system permits cycling the unit rapidly and often without accumulating major fatigue turbine damage.

Circulation improvements

Water circulation upgrades are often required to overcome operational and maintenance problems. Symptoms of a circulation problem include localized tube failures in particular boiler circuits, increases in water-side and steam-side deposits and pressure drops, fluctuations in feedwater control, and drum water level excursions and fluctuations. Occasionally, circulation problems may appear when supply tubes or headers for the furnace waterwall circuits crack and distort. Circulation problems can directly affect boiler performance and, if severe, can reduce capacity and availability.

Determining causes and solutions for circulation problems requires boiler performance testing, heat transfer and circulation computer modeling, and a thorough knowledge of boiler dynamics. Thorough discussions of heat transfer and circulation are covered in Chapters 4 and 5.

Consider an example boiler with circulation problems. This unit was experiencing an abnormally high forced outage rate due to tube failures in the platen wing walls as well as extensive failures of the furnace rear wall arch tubes. Fig. 22a illustrates the upper furnace configuration and arrangement of the wing walls.

The majority of tube failures in this unit were found in the lower 17 deg (0.3 rad) inclined portion of the wing walls. Some time later, the rear wall arch tubes began failing, especially in the lower inclined area. Poor water chemistry and resultant heavy internal tube deposits were originally blamed for the

tube failures. However, water chemistry was monitored and found to be acceptable in this case.

A complete engineering study was required to review the plant operating procedures and the original boiler design. The study goals included:

1. analyzing the overall boiler circulation system,
2. reviewing the platen wing wall design,
3. examining the design and performance of steam drum internals,
4. investigating the rear wall arch and supply circuit design, and
5. providing operational and hardware modifications to eliminate the tube failures in the platen wing walls and rear wall arch tubes.

Field tests were conducted to verify the operating parameters. A computer simulation focused on the circulation of the steam drum, wing wall and rear wall arch tube circuits. Mass flow velocities in these tubes were found to be low. These low velocities contributed to flow imbalances between circuits as well as film boiling conditions inside the tubes. The steam film acted as an insulator, producing numerous overheat failures.

The existing drum internals were also found to be significant contributors to the circulation problem. The separators in the steam drum generated a high pressure drop, by reducing the pumping head and causing flow imbalances. The drum water level, 10 in. (254 mm)

below the drum centerline, permitted steam to be drawn into the downcomers. This further reduced the effective water density (pumping head) and mass flow velocities in the furnace circuits.

The key modifications implemented in the circulation upgrade were as follows (See Fig. 22b):

1. New drum internals. Three rows of highly efficient, low pressure drop cyclone separators replaced the existing two rows of high pressure drop turbo-separators. (See Fig. 23.) The drum water level was increased from -10 in. (-254 mm) to the centerline. These modifications increased the available head for all circuits.
2. Redesigned wing walls. The overall length of the wing walls was increased to raise the heat absorption in these vulnerable circuits, based on the natural circulation principle of more heat, more flow. This also lowered the furnace exit gas temperature by about 35F (19C) which reduced the tendency of slagging beyond the furnace. A third benefit was a slight reduction in superheat and, especially, reheat spray, both being excessive on the existing unit.

The bottom slope was increased from 17 to 40 deg (0.3 to 0.7 rad) and the tube diameter was decreased. Multi-lead ribbed tubes were used instead of internally smooth tubes in the sloped portion.

Fig. 22a Original upper furnace arrangement.

Fig. 22b Upper furnace arrangement for a circulation upgrade.

These measures were aimed at eliminating film boiling and flow instabilities, identified as the root cause of tube failures in these circuits. Film boiling in these circuits promoted formation of internal deposits and corrosion due to stagnant flow conditions. The increased flow resistance was more than offset by the greater pumping head generated by the new design.

3. Redesigned water supply system. The existing downcomers were lengthened and closed off by new downcomer bottles. Each bottle was equipped with eight supply pipes, four feeding each vertical wing wall inlet header.
4. Redesigned rear wall arch. Multi-lead ribbed tubes were installed in the rear wall arch in the form of shop-membraned tube panels. This eliminated the failures in the lower bend area. The original transition from the 2.5 in. (63.5 mm) OD rear wall tubes to the 3 in. (76.2 mm) arch tubes created a steam-water jet along the unheated side (inside of the extrados) of these bends and a corresponding void on the inside of the tube bends. This had caused the crucial bend sections facing the furnace heat to fail due to insufficient cooling. For additional margin, the arch tubes were also redesigned as multi-lead ribbed tubes.

The overall boiler circulation was significantly improved, and a high design margin prevented the recurrence of failures in the wing walls or rear wall tubes. The circulation upgrade restored 100% load capability and improved unit reliability and availability.

Strategies for fuel switching while maintaining high commercial availability

To help reduce sulfur dioxide (SO_2) emissions, many power plants are now burning a Powder River Basin (PRB) coal blend. The ash of some PRB blends forms a white deposit in the furnace and elsewhere in the boiler. The deposit tends to be reflective. This characteristic suppresses heat transfer, especially in the furnace, and leads to flyash plugging of the tightly-spaced convection heating surfaces. The inhibition of heat transfer raises flue gas temperatures, and often results in some loss of thermal efficiency.

The elevated gas temperatures can lead to long-term overheating of the non-cooled mechanical economizer support hangers, causing premature failure. Under some conditions, the temperature of the flue gas leaving the economizer can exceed the design temperature of the casing enclosure and flues between the economizer and the air heater downstream. The high gas temperature can also elevate economizer water outlet enthalpy, which causes cavitation problems in boiler circulation pumps in forced circulation boilers.

A boiler's economizer is, by definition, intended to reduce operating costs by recovering energy from the flue gas. This heat energy is transferred to water entering the boiler. Since overall boiler efficiency is increased 1% for every 40F (22C) reduction in flue gas stack temperature, the design of the economizer and its interaction with the boiler's fuel and flue gas are important concerns to power plant operators.

Fig. 23 Cyclone steam separator installation.

Many utility boilers were installed with continuous fin surface (CFS) economizers using a staggered tube arrangement. This surface used 2.0 in. (5.08 cm) high and 0.25 in. (0.635 cm) thick fins welded to the top and bottom of each tube [usually 2 in. (5.08 cm) outside diameter] parallel to the tube axis. CFS economizers originally appealed to many plant designers because the torturous path created for the flue gas enhanced heat absorption, and the fins could capture heat and transfer it to the tubing. This made the CFS economizer less costly and permitted installation in a relatively small area.

With the increasing use of western U.S. and lower quality fuels over the past few decades, however, the very factor that had been an advantage of the CFS economizer design became a disadvantage. The spacing proved more susceptible to plugging and flyash erosion and required more frequent cleaning.

Fuel switching can, therefore, lead to many related boiler problems that affect efficiency, availability and capacity. Power plant operators are faced with many interrelated problems when operating a plant that has changed from the design fuel to a low cost compliance fuel such as a PRB coal. Margins for acceptable operation are reduced and the power plant can suffer from high heat rates (i.e., lower efficiency), high operating costs, and frequent outages to remove ash buildup. A strategy is needed to deal with these problems so that the new low-cost compliance fuel can be used without the plant suffering from degradations in capacity, heat rate, operating cost and availability.

Fuel switching example

In one example of fuel switching, the economizer experienced ash plugging problems with PRB coal, making the unit unable to achieve the design main steam temperature at higher loads. The ash plugging resulted in periodic shutdowns for cleaning and main-

tenance. Because of the economizer's staggered, finned tube design, plant operators could not use sootblowers to restore heat transfer capabilities. At higher loads, the superheater temperature could not reach design levels, leading to a reduction in boiler efficiency. The resulting low main steam temperature to the turbine is equivalent to a reduction in cycle efficiency.

The example unit is a 750 MW (gross), pulverized coal-fired, balanced draft boiler. At maximum continuous rating (MCR), original design conditions were 4,985,000 lb/h (628 kg/s) main steam flow at 2400 psig (16.5 MPa) throttle pressure and 1007F (542C). The ash plugging resulted in periodic shutdowns for cleaning and maintenance.

The primary goal of the upgrade project was to replace the worn and increasingly unreliable economizer with a design that corrected these existing problems, and while doing so, return the main steam temperature to its original design level. Additional project tasks included complete boiler modeling, pressure part design and fabrication (including the complete redesign of the economizer support system), supply of sootblower equipment and hangers, and the fabrication and supply of steam-cooled wall openings for the sootblowers and access doors.

The existing economizer was replaced with a bare tube, in-line design. (See the example of a finned tube economizer replacement earlier in this chapter.) The bare tube, in-line economizer design minimized the erosion and ash trapping problems that are common to staggered arrangements. The in-line design also improved the effectiveness of sootblowers and resulted in the maintenance of adequate heat transfer. Fig. 24 illustrates the upgraded design and its redesigned economizer, primary superheater and sootblowers.

To maintain the necessary amount of heat transfer surface, the upgrade increased the number of economizer elements by about 25%. The installation of a new inlet header and a number of intermediate headers accommodated the increased number of water flow circuits. Tube shields to protect the tubes in the sootblower lane were added, in addition to erosion barriers along the walls of the unit.

To raise the superheat steam temperature, relatively small horizontal primary superheater loops above the economizer were added. The existing economizer support tubes were modified to provide water-cooled support for the small bank of new primary superheater surface.

New sootblowers were also incorporated into the retrofit design. Limited outboard space prohibited the installation of full travel, long retract sootblowers. Extended lance, half-track sootblowers were installed as part of the upgrade. Gas temperatures entering the economizer exceeded the traditional maximum temperature for these extended lances, so the lances were manufactured from a high temperature alloy material.

The eight sootblowers were supplied with the Progressive Helix Mechanism feature to reduce the potential for boiler tube erosion (see Chapter 24). This patented sootblower enhancement reduces tube erosion by shifting the nozzle cleaning path on every blowing cycle. More than 400 cycles occur before any nozzle path is repeated.

The previous economizer design had suffered from failures of the supports that were of a welded design. To simplify installation and to provide a support system that did not rely on tension welds, the economizer support system was designed to accommodate small banks of elements and to support the banks with pins and collector plates. Stainless steel and Incoloy alloy 800HT pins and plates were used to ensure high-temperature strength and oxidation resistance without relying on welds. Fig. 25 shows the collector plates and pin connections used in this upgrade.

The use of factory-installed pins and plates reduced on-site installation times. Construction crews removed the pins as the sections were brought up to elevation, and then reinstalled the pins after the collector plates had been mated to the support brackets. Because the process required no field welding of supports, the entire installation proceeded smoothly. After the sections had been hung in place, project personnel performed tube-to-tube welds between banks as time and space permitted.

The finned tube economizer replacement resulted in the following unit enhancements:

1. provided a solution to the problem of burning the PRB fuel blend,
2. eliminated plugging of the finned tube economizer,
3. reduced draft loss,

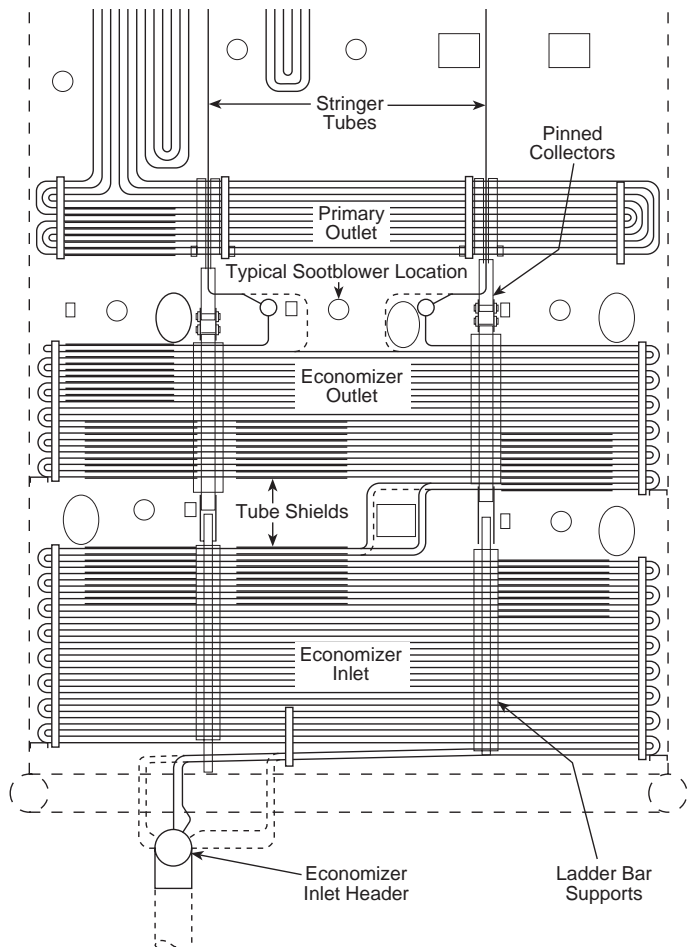

Fig. 24 Upgraded economizer and superheater arrangement to accommodate PRB fuel.

Fig. 25 The use of pins and collectors simplified construction and improved reliability by eliminating original welded supports.

4. reduced economizer exit gas temperatures to improve unit efficiency,
5. returned main steam temperatures to original design conditions to improve unit efficiency, and
6. improved unit availability through elimination of fouling problems and restoration of unit capacity and efficiency.

Capacity upgrades and environmental regulations

A capacity increase with higher efficiency and availability (sometimes called uprates), together with lower emissions, can lead to attractive returns on investment. Increases up to 10% in capacity and improvements in heat rate of 1 to 2% have been demonstrated.

With the current interpretation of the rules for environmental standards relative to capacity increases, the boiler operator must consider meeting, for example, U.S. New Source Performance Standards when a capacity upgrade is implemented. The addition of scrubbers and selective catalytic reduction (SCR) systems for the boiler flue gas must be considered when appropriate. This environmental equipment, combined with the capacity upgrade, may result in lower total regulated emissions when the project is properly configured. However, future changes in rules and policies may change the feasibility of this scenario.

Example strategy for capacity upgrade while maintaining high commercial availability

The typical capacity upgrade starts with an engineering study. To optimize the return on investment for the capacity increase, the project requires cooperation between the boiler manufacturer and the turbine vendor. During the engineering study, there is an interaction between the boiler and the turbine equipment suppliers such that the boiler and turbine uprate designs may be considered simultaneously. A series of design discussions must be held between the boiler and turbine designer to develop an upgrade strategy that can provide the optimum combination of performance and capital expenditure while considering the limits

of the existing equipment and the potential design improvements. Often, new technology has been developed for the boiler and turbine generator set since the commissioning of the power station, and therefore, there is an opportunity to apply this new technology to enhance the efficiency and capacity of the unit.

The boiler manufacturer looks at key components that will be affected by the increased steam and water flow requirements. Operating pressures and heat transfer are affected by the increased flows. The designer must look at each of the key components versus the original design and possible design improvements to develop a plan for the capacity increase. As an example, a furnace circulation analysis must be run to determine if the furnace has the capacity to operate safely with the higher flows and heat input. Components that are commonly evaluated are shown in Table 3.

To properly evaluate the unit in the engineering study, a performance test of the unit under various conditions is required. This test will calibrate and validate the boiler computer model that is used to evaluate the boiler upgrade. The boiler model takes into account changes in boiler surface and fuels that have occurred since the boiler was first commissioned. The model will also consider changes to the unit, or operating procedures that were made for any pollution control equipment that may have been added or modified.

The increased firing rate will increase gas velocities in the convection pass and will increase the possibility for fouling and slag accumulation. The need for increased sootblowing and erosion protection is evaluated.

After the engineering study is completed and the equipment modifications are determined, costs are evaluated. A typical upgrade might include advanced turbine components to accommodate the higher steam flows and to achieve higher efficiency.

Controls

Because turbine efficiency is determined by the design of the steam path components such as the nozzles, bucket profiles, as well as the leakage flows, these components may be upgraded with significant impact on overall plant performance. Much work has been done to improve the aerodynamics and reduce losses associated with buckets and nozzles. Most turbine upgrades involve a reduction in secondary flow losses. Designs have evolved that improve the resistance to solid particle erosion for longer efficient design life. There are numerous examples of the advantages of turbine upgrades. However, the best strategy is to coordinate the boiler and turbine upgrade to achieve the best return on investment.

Normally, a capacity uprate capital project improves heat rate and extends times between major turbine overhaul outages. These benefits are the result of replacing nozzles and final stage buckets with improved designs and improvements in steam losses together with higher steam flows.

Typical improvements to the boiler might include the replacement of the superheater or reheater outlet bank(s), a new attemperator, new burners, new higher efficiency separators in the steam drum, and the addition of air quality control equipment. The actual modifications are very specific to the original unit design, the fuel, and the environmental constraints.

Chapter 45

Condition Assessment

The assessment of accumulated damage, or condition assessment, has a long history in the boiler industry. Whenever a component was found to contain damage or had failed, engineers asked what caused the damage and whether other components would fail. These questions typically pertained to tubing and headers, which caused the majority of downtime. As boiler cycling became more common, the need for more routine condition assessment increased to avoid component failure and unscheduled outages.

Condition assessment includes the use of tools or methods in the evaluation of specific components and then the interpretation of the results to identify 1) the component's remaining life and 2) areas requiring immediate attention.

A boiler component's damage assessment, typically compared to its design life, is based on accumulated damage, and can be performed in three phases. In Phase 1 of the assessment, design and overall operating records are reviewed and interviews are held with operating personnel. In Phase 2, nondestructive examinations, stress analysis, verification of dimensions, and operating parameters are undertaken. If required, the more complex Phase 3 includes finite element analysis, operational testing and evaluation, and material properties measurement.¹ (See Fig. 1.)

Condition assessment examination methods

The major boiler components must be examined by nondestructive and destructive tests.

Nondestructive examinations

Most nondestructive examination (NDE) methods for fossil fuel-fired plants have been in use for many years, although new methods are being developed for major components. Nondestructive testing does not damage the component.

The NDE methods used in evaluating electric utility power stations and industrial process plants include: visual, magnetic particle, liquid penetrant, ultrasonic, eddy current, radiography, nuclear fluorescence, elec-

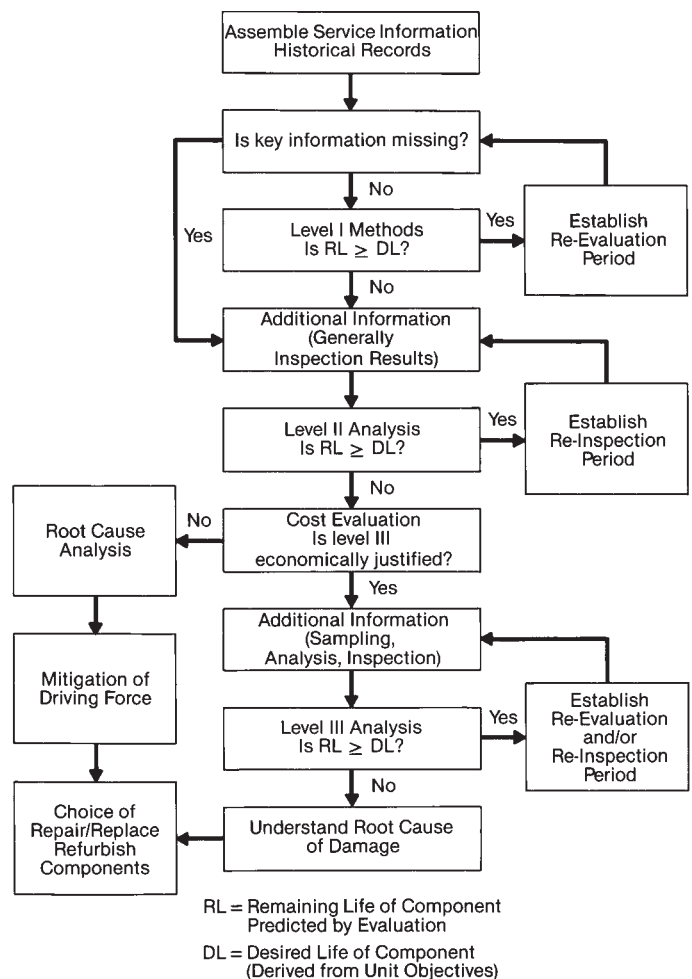

Fig. 1 Three phases (levels) of boiler damage assessment (courtesy of the Electric Power Research Institute).¹

tromagnetic acoustics, acoustic emissions, metallographic replication, strain measurement and temperature measurement.

Visual Whether the inspected component is subject to mechanical wear, chemical attack, or damage from thermal stress, visual examination can detect and identify some of the damage. Visual inspection is enhanced

by lighting, magnification, mirrors, and optical equipment such as borescopes, fiberscopes and binoculars.

Magnetic particle Magnetic particle testing (MT) and wet fluorescent magnetic particle testing (WFMT) detect surface and near surface flaws. Because a magnetic field must be imparted to the test piece, these tests are only applicable to ferromagnetic materials.² The choice between these techniques generally depends on the geometry of the component and the required sensitivity. For typical power plant applications, one of two methods is used: 1) the component is indirectly magnetized using an electromagnetic yoke with alternating current (AC), or 2) the part is directly magnetized by prods driven by AC or direct current (DC).

In magnetic particle testing, any discontinuity disrupts the lines of magnetic force passing through the test area creating a leakage field. Iron particles applied to the area accumulate along the lines of magnetic force. Any leakage field created by a discontinuity is easily identified by the pattern of the iron particles. Dry magnetic particle testing is performed using a dry medium composed of colored iron particles that are dusted onto the magnetized area. In areas where a dry medium is ineffective, such as in testing overhead components or the inside surfaces of pressure vessels, the wet fluorescent method is more effective. With this method, fluorescent ferromagnetic particles are suspended in a liquid medium such as kerosene. The liquid-borne particles adhere to the test area. Because the particles are fluorescent, they are highly visible when viewed under an ultraviolet light.

Liquid penetrant Liquid penetrant testing (PT) detects surface cracking in a component. PT is not dependent on the magnetic properties of the material and is less dependent on component geometry.² It is used by The Babcock & Wilcox Company (B&W) in limited access areas such as tube stub welds on high temperature headers which are generally closely spaced. PT detects surface flaws by capillary action of the liquid dye penetrant and is only effective where the discontinuity is open to the component surface. Following proper surface cleaning the liquid dye is applied. The penetrant is left on the test area for about ten minutes to allow it to penetrate the discontinuity. A cleaner is used to remove excess penetrant and the area is allowed to dry. A developer is then sprayed onto the surface. Any dye that has been drawn into the surface at a crack bleeds into the developer by reverse capillary action and becomes highly visible.

Ultrasonic Ultrasonic testing (UT) is the fastest developing technology for nondestructive testing of pressure components. Numerous specialized UT methods have been developed. A piezoelectric transducer is placed in contact with the test material, causing disturbances in the interatomic spacings and inducing an elastic sound wave that moves through the material.³ The ultrasonic wave is reflected by any discontinuity it encounters as it passes through the material. The reflected wave is received back at the transducer and is displayed on an oscilloscope.

Ultrasonic thickness testing Ultrasonic thickness testing (UTT) is the most basic ultrasonic technology. A common cause of pressure part failure is the loss of

material due to oxidation, corrosion or erosion. UTT is relatively fast and is used extensively for measuring wall thicknesses of tubes or piping.

The surface of the component must first be thoroughly cleaned. Because ultrasonic waves do not pass through air, a couplant such as glycerine, a water soluble gel, is brushed onto the surface. The transducer is then positioned onto the component surface within the couplant. A high frequency (2 to 5 MHz) signal is transmitted by the transducer and passes through the metal. UTT is performed using a longitudinal wave which travels perpendicular to the contacted surface. Because the travel time for the reflected wave varies with distance, the metal thickness is determined by the signal displacement, as shown on the oscilloscope screen (Fig. 2).

Ultrasonic oxide measurement In the mid 1980s, B&W developed an ultrasonic technique specifically to evaluate high temperature tubing found in superheaters and reheaters. This NDE method, called the *Non-destructive Oxide Thickness Inspection Service* (NOTIS[®]), measures the oxide layer on the internal surfaces of high temperature tubes. The test is generally applicable to low alloy steels because these materials are commonly used in outlet sections of the superheater and reheater.

Low alloy steels grow an oxide layer on their internal surfaces when exposed to high temperatures for long time periods (Fig. 3). The NOTIS test is not applicable to stainless steels because they do not develop a measurable oxide layer.

The technique used for NOTIS testing is similar to UTT; the major difference between the two is the frequency range of the ultrasonic signal. A much higher frequency is necessary to differentiate the interface between the oxide layer and inside diameter (ID) surface of the tube. Using data obtained from this NOTIS testing, tube remaining creep life can also be calculated as discussed later in *Analysis techniques*. NOTIS and UTT are methods in which the transducer is placed in contact with the tube using a couplant gel. Because of the high sensitivity of the NOTIS method, it is less tolerant of rough tube surfaces or poor surface preparation.

Ultrasonic measurement of internal tube damage Several ultrasonic methods have been investigated for detecting damage within boiler tubes. All techniques

Fig. 2 Typical ultrasonic signal response.⁴

Fig. 3 Steam-side oxide scale on ID surface.

use contact UT where a transducer is placed on the outside diameter (OD) or tube surface using a couplant, and an ultrasonic signal is transmitted through the material. The techniques can be categorized by type of signal evaluation: backscatter, the evaluation of UT wave scatter when reflected by damaged material; attenuation, the evaluation of UT signal loss associated with transmission through damaged material; and velocity, the measurement and comparison of UT wave velocity through the tube material.⁴

When a longitudinal wave passes through a tube, part of the signal is not reflected to the receiver if it encounters damaged material. The damaged areas reflect part of the wave at various angles, backscattering the reflected signal. The loss of wave amplitude that is received back at the transducer is then used to evaluate the degree of damage.

Damage in the tube can also be assessed by evaluating the loss of signal amplitude (attenuation) as a shear wave is transmitted through the tube wall. The technique uses a fixture with two transducers mounted at angles to each other. One unit transmits a shear wave into the tube and the second transducer, the receiver, picks up the signal as the wave is reflected from the tube ID. A drop in signal amplitude indicates damage in the tube wall.

This technology is the basis of the B&W patented *Furnace wall Hydrogen damage Nondestructive Examination Service (FHyNES®)* test method (Fig. 4). The velocity test method uses either longitudinal or shear ultrasonic waves. As a wave passes through a chordal section of tube with hydrogen damage, there is a measurable decrease in velocity. Because the signal is not reflected from the tube inside surface, ultrasonic velocity measurement is not affected by damage to the inside of the tube and therefore specifically detects hydrogen damage.

Immersion ultrasonic testing In immersion ultrasonic testing, the part is placed in a water bath which acts as the couplant. B&W uses a form of immersion UT for tube wall thickness measurements. In two-drum industrial power boilers, process recovery boilers and some utility power generation boilers, most of the tubes in the convective bank between the drums are inaccessible for conventional contact UTT measurements. For these applications, an ultrasonic test probe was developed which is inserted into the tubes from the steam drum; it measures the wall thickness from inside the tubes. As the probe is withdrawn in measured increments, the transducers measure the tube wall thicknesses. A limitation of this technique is that the ID surface of the tubes must be relatively clean.

Shear wave ultrasonic testing This is a contact ultrasonic technique in which a shear wave is directed at an angle into the test material. Angles of 45 and 60 deg (0.79 and 1.05 rad) are typically used for defect detection and weld assessment. The entire weld must be inspected for a quality examination.

Time of flight diffraction (TOFD) TOFD is an ultrasonic technique that relies on the diffraction of ultrasonic energies from defects in the component being tested. The primary application is weld inspection on piping, pressure vessels, and tanks. TOFD is an automated inspection that uses a pitch-catch arrangement with two probes, one on each side of the weld. The weld material is saturated with angled longitudinal waves to inspect for discontinuities. Because the time separation of the diffracted waves is directly related to flaw size (height), TOFD can detect both the flaw and allow estimation of the flaw size.

Eddy current Measuring the effects of induced eddy currents on the primary or driving electromagnetic field is the basis of eddy current testing. The electromagnetic induction needed for eddy current testing is created by using an alternating current. This develops the electromagnetic field necessary to produce eddy currents in a test piece.

Eddy current testing is applicable to any materials that conduct electricity and can be performed on magnetic and nonmagnetic materials. The test is therefore

Fig. 4 Shear wave technique for detecting hydrogen damage.

applicable to all metals encountered in power station condition assessment work.

Parameters affecting eddy current testing include the resistivity, conductivity, and magnetic permeability of the test material; the frequency of the current producing the eddy currents; and the geometry and thickness of the component being tested.

Radiography Radiography testing (RT) is the most common NDE method used during field erection of a boiler. Radiography is also valuable in condition assessments of piping. As x-rays and gamma rays pass through a material, some of the rays are absorbed. Absorption depends upon material thickness and density. When the rays passing through an object are exposed to a special film, an image of the object is produced due to the partial absorption of the rays.

In practical terms, a radioactive source is placed on one side of a component such as a pipe, at a weld, and a film is placed on the opposite side. If x-rays are directed through the weld and there is a void within the weld, more rays pass through this void and reach the film, producing a darker image at that point. By examining the radiographic films, the weld integrity can be determined. During the field erection of a boiler and power station, thousands of tube and pipe welds are made and radiographed. (See also Chapters 38 and 39.)

The major disadvantage of radiography is the harmful effect of excessive exposure to the radioactive rays. RT is also limited in its ability to provide the orientation and depth of an indication.

Nuclear fluorescence The primary use of this testing in condition assessment is the verification of alloy materials in high temperature piping systems. When certain elements are exposed to an external source of x-rays they fluoresce (emit) additional x-rays that vary in energy level. This fluorescence is characteristic of the key alloys common to high temperature piping and headers. Chromium and molybdenum are the key elements measured. The nuclear alloy analyzer is a portable instrument that contains a low level source of x-rays. A point on the surface of the pipe is exposed to x-rays emitted from the analyzer. As the source x-rays interact with the atoms of the metal, the alloys emit x-rays back to the analyzer. Within the detector system of the analyzer, the fluoresced x-rays are separated into discrete energy regions. By measuring the x-ray intensity in each energy region, the elemental composition is also determined.

Electromagnetic acoustics Electromagnetic acoustics combine two nondestructive testing sciences, ultrasonics (UT) and electromagnetic induction. This technology uses an electromagnetic acoustic transducer (EMAT) to generate high frequency sound waves in materials, similar to conventional ultrasonics. Conventional UT transducers used for field testing convert electrical impulses to mechanical pulses by use of piezoelectric crystals. These crystals must be coupled to the test piece through a fluid couplant. For electrically conductive materials, ultrasonic waves can be produced by electromagnetic acoustic wave generation.⁵ In contrast to conventional contact UT where a mechanical pulse is coupled to the material, the acoustic wave is produced by the interaction of two mag-

netic sources. The first magnetic source modulates a time-dependent magnetic field by electromagnetic induction as in eddy current testing. A second constant magnetic field provided by an AC or DC driven electromagnet or a permanent magnet is positioned near the first field. The interaction of these two fields generates a force, called the Lorentz force, in the direction perpendicular to the two other fields. This Lorentz force interacts with the material to produce a shock wave analogous to an ultrasonic pulse, eliminating the need for a couplant.

Fig. 5 shows the basic principles of EMAT operation. A strong magnetic field (B) is produced at the surface of the test piece by either a permanent magnet or electromagnet. Eddy currents (J) are induced in the test material surface. An alternating eddy flow in the presence of the magnetic field generates a Lorentz force (F) that produces an ultrasonic wave in the material. For boiler tubes that are electromagnetically conductive (including alloys such as SA-213T22), the EMAT technology is ideal.

B&W, working with the Electric Power Research Institute (EPRI), developed a nondestructive rapid scan system to inspect boiler tubes using EMAT technology. This EMAT based system is known as the Fast-Scanning Thickness Gage (FST-GAGE®) and was developed specifically to scan boiler tubes and provide a continuous measurement of tube wall thickness. (See Fig. 6.) The system conducts tests at exceptional speeds, allowing scanning of thousands of feet (m) of boiler tubing in a single shift. To perform an inspection, the FST-GAGE system is manually scanned along individual boiler tubes. System sampling rates greater than 65 samples per second supports rapid scanning of tubes. During a scan, the system provides an immediate display of both tube wall thickness and signal amplitude. At the conclusion of each tube scan, a complete record of the inspection is electronically stored and is traceable to each boiler tube and position.

As with conventional UT, the FST-GAGE system can assess internal tube damage by evaluating the loss of signal amplitude (attenuation) as a shear wave is transmitted through the tube wall. By monitoring and indicating signal amplitude, the system can also be used to detect tube damage such as hydrogen damage, similar to B&W's patented FHyNES technique. The FST-GAGE has also demonstrated the ability to detect internal tube pitting, caustic gouging, and under-deposit corrosion.

Fig. 5 Basic principles of EMAT operation.

Fig. 6 B&W's Fast-Scanning Thickness Gage (FST-GAGE®) EMAT based system can provide continuous measurement of tube wall thickness.

As with any NDE method, surface preparation is important for effective testing with EMATs. However, EMAT is not as sensitive to scale as conventional UT since it produces the ultrasonic wave within the material. Some scales, such as magnetite oxide of uniform thickness, have no detrimental effect on the signal generation of the EMAT probe. When the plant burns a clean fuel such as natural gas, testing may be conducted without any special surface cleaning. To protect the coil from damage, surface preparation will normally be required for boilers firing oil or solid fuels. Some gas-fired units may require surface cleaning if external buildup or corrosion is present. Grit blasting or water blasting are effective methods of cleaning larger areas. Smooth metal is the preferred surface to ensure rapid testing.

EMAT technology continues to be applied where its unique properties have advantages over conventional UT techniques. B&W and EPRI are developing a system for the detection of cracking in boiler tubes associated with corrosion fatigue. Waterside corrosion fatigue is a serious boiler tube failure mechanism. The failures usually occur close to attachments such as buckstay welds, windbox attachment welds, or membrane welds. The combination of thermal fatigue stresses and corrosion leads to ID-initiated cracking that is oriented along the tube axis. The EMAT system under development for corrosion fatigue has unique characteristics that enhance its ability to scan past welds and attachments and scan the full circumference of the boiler tube. The EMAT equipment uses a tone burst EMAT signal allowing the use of horizontally polarized shear wave (SH waves) to detect cracking adjacent to external tube attachment welds.

B&W has developed an EMAT application to inspect horizontal banks (i.e., economizer, reheater) of tubing within the boiler. Horizontal bank tubing may experience tube failures caused by out of service corrosion pitting forming aligned voids in the tube ID. The purpose of this EMAT test is to detect the internal aligned

pitting at the lower portion of the horizontal tube internal surface. The test is accomplished by scanning along the outside of the horizontal tube at either the 3 or 9 o'clock positions with an EMAT transducer generating a Lamb wave (ultrasonic waves that travel at right angles to the tube surface) which is focused at the 6 o'clock position on the tube.

B&W has also developed a surface wave EMAT application to show surface indications including axially oriented cracks in boiler tubes. Conventional surface nondestructive test methods were unsatisfactory because they lacked adequate sensitivity and had slow production rates for testing on large areas. A tone burst EMAT technique was developed that uses a bidirectional focused surface wave EMAT that follows the tube surface circumferentially until the signal is reflected back from a longitudinally orientated OD crack.

Acoustics Acoustics refers to the use of transmitted sound waves for nondestructive testing. It is differentiated from ultrasonics and electromagnetic acoustics in that it features low frequency, audible sound. B&W uses acoustic technology in testing tubular air heaters. Because the sound waves are low frequency, they can only be transmitted through air. A pulse of sound is sent into the air heater tube. As the wave travels along the tube, it is reflected by holes, blockage or partial obstructions. By evaluating the reflected wave on an oscilloscope, the type of flaw and its location along the tube can be determined.

Acoustic emissions Acoustic emissions (AE) detect subsurface crack growth in pressure vessels. When a structure such as a pipe is pressurized and heated, the metal experiences mechanical and thermal stresses. Due to the stress concentration at a defect such as a crack, a small overall stress in the pipe can produce localized yield and fracture stresses resulting in plastic deformation. These localized yields release bursts of energy or stress wave emissions that are commonly called acoustic emissions. AE testing uses acoustic transducers that are positioned along the vessel being monitored. AE signals are received at various transducers on the vessel. By measuring the time required for the signal to reach each of the transducers, the data can be interpreted to identify the location of the defect.

Metallographic replication Metallographic replication is an in situ test method that enables an image of the metal grain structure to be nondestructively lifted from a component. Replication is important in evaluating high temperature headers and piping because it allows the structure to be examined for creep damage. Prior to the use of replication techniques, it was necessary to remove samples of the material for laboratory analysis. The replication process involves three steps: grinding, polishing and etching, and replicating. In the first step, the surface is rough ground then flapper wheel ground with finer grit paper. In the second step, the surface is polished using increasingly finer grades of diamond paste while intermittently applying a mixture of nitric acid and methanol in solution. The acid solution preferentially attacks the grain boundaries of the metal. In the final step, the replica, which is a plastic tape, is prepared by coating

one face of the tape with acetone for softening. The tape is then firmly pressed onto the prepared surface. Following a suitable drying time, the tape is removed and mounted onto a glass slide for microscopic examination.

Strain measurement Strain measurements are obtained nondestructively by using strain gauges. Gauges used for piping measurements are characterized by an electrical resistance that varies as a function of the applied mechanical strain.⁶ For high temperature components, the gauge is made of an alloy, such as platinum-tungsten, which can be used at temperatures up to 1200F (649C). The gauge is welded to the surface of the pipe and the strain is measured as the pipe ramps through a temperature-pressure cycle to operating temperature. Strain gauges used for lower temperature applications such as for analysis of hanger support rods are made of conventional copper-nickel alloy (constantan). These low temperature gauges are made of thin foil bonded to a flexible backing and are attached to the test surface by a special adhesive.

Temperature measurement Most temperature measurements can be obtained with sheathed thermocouples (TC). In special applications where temperature gradients are needed such as detailed stress analysis of header ligaments, special embedded TCs are used. The embedded unit is constructed by drilling a small hole into the header. A sheathed TC wire is then inserted and peened in place. (See Chapter 40.)

Destructive examinations

B&W tries to minimize the use of sample analysis because it is generally more expensive to perform destructive testing. However, for certain components, complete evaluation can only be done by removing and analyzing test samples. Destructive testing is described for two types of specimens, tube samples and boat samples.

Tube samples Tubes are the most common destructively tested components. Tube samples are generally removed from water- and steam-cooled circuits. A relatively large number of samples may be removed for visual inspections, from which a smaller number are selected for complete laboratory analysis. A tube analysis usually includes the following: 1) as-received sample photo documentation, 2) complete visual inspection under magnification, 3) dimensional evaluation of a ring section removed from the sample, 4) material verification by spectrographic analysis, 5) optical metallography, and 6) material hardness measurement. On waterwall tubes removed from the boiler furnace, the analysis includes a measurement of the internal deposit loading [g/ft^2 (g/m^2)] and elemental composition of the deposit. On steam-cooled superheater and reheater tubes, the thickness of the high temperature oxide layer is also provided.

Specialized tests are performed as required to provide more in-depth information. Failure analysis is a common example. When failures occur in which the root cause is not readily known from standard tests, fractography is performed. Fractography involves examination of the fracture surface using a scanning electron microscope.

Boat samples Boat samples are wedge shaped slices removed from larger components such as headers,

piping and drums. The shape of the cut allows the material to be replaced by welding. Because the repairs usually require post weld heat treating, the use of boat samples is expensive. In most instances, replication is adequate for metallographic examination of these components and boat sample removal is not required.

Condition assessment of boiler components and auxiliaries

In Phase 1 of a condition assessment program, interviews of plant personnel and review of historical maintenance records help identify problem components. These components are targeted for a closer on-site examination during Phase 2 of the program. Non-destructive and destructive examination methods can then be used to evaluate the remaining life of the boiler components and its major auxiliaries.

Boiler drums

Steam drum The steam drum is the most expensive boiler component and must be included in any comprehensive condition assessment program. There are two types of steam drums, the all-welded design used predominantly in electric utilities where the operating pressures exceed 1800 psi (12.4 MPa), and drums with rolled tubes. The steam drum operates at saturation temperature [less than 700F (371C)]. Because of this relatively low operating temperature, the drum is made of carbon steel and is not subject to significant creep. Creep is defined as increasing strain at a constant stress over time.

Regardless of drum type, damage is primarily due to internal metal loss. The causes of metal loss include: corrosion and oxidation, which can occur during extended outages; acid attack; oxygen pitting; and chelant attack discussed in Chapter 42. Damage can also occur from mechanical and thermal stresses on the drum that concentrate at nozzle and attachment welds. These stresses, most often associated with boilers that are on/off cycled, can result in crack development. Cyclic operation can lead to drum distortion (humping) and can result in concentrated stresses at the major support welds, seam welds, and girth welds. The feedwater penetration area has the greatest thermal differential because incoming feedwater can be several hundred degrees below drum temperature.

A problem unique to steam drums with rolled tube seats is tube seat weepage (slight seeping of water through the rolled joint). If the leak is not stopped, the joint, with its high residual stresses from the tube rolling operation, can experience caustic embrittlement. (See Chapter 42.) In addition, the act of eliminating the tube seat leak by repeated tube rolling can overstress the drum shell between tube seats and lead to ligament cracking.

Condition assessment of the steam drum can include visual and fiber optic scope examination, MT, PT, WFMT, UT and replication.

Lower drum The lower or mud drum is most often found in industrial boilers. (See Chapter 27.) Part of the boiler's water circuit, the lower drum is not sub-

ject to large thermal differentials or mechanical stresses. However, as in steam drums with rolled tubes, seat weepage and excessive stresses from tube rolling can occur. In most cases, visual inspection, including fiber optic probe examination of selected tube penetrations, is sufficient. Kraft recovery boiler lower drums are subject to corrosion of the tube-drum interface on the OD. This area of the drum is inaccessible, therefore inspections are conducted from the ID using UTT and EMATs to check for cracking and wall thinning.

The downcomers carry water from the steam drum to the mud drum and the various wall circuits. Two areas on the downcomers that should be inspected are termination welds for cracks and horizontal runs of piping for internal corrosion pitting and thinning.

Boiler tubing

Steam-cooled Steam-cooled tubing is found in the superheater and reheat superheater. Both components have tubes subjected to the effects of metal creep. Creep is a function of temperature, stress and operating time. The creep life of the superheater tubes is reduced by higher than expected operating temperature, thermal cycling, and by other damage mechanisms, such as erosion and corrosion, causing tube wall thinning and increased stresses. Excessive stresses associated with thermal expansion and mechanical loading can also occur, leading to tube cracks and leaks independent of the predicted creep life.

As discussed in Chapters 19, 21, 29 and 45, superheater tubing can also experience erosion, corrosion, and interacting combinations of both.

Condition assessment of the superheater tubes includes visual inspection, NOTIS, UTT and tube sample analysis. Problems due to erosion, corrosion, expansion, or excessive temperature can generally be located by visual examination.

Water-cooled Water-cooled tubes include those of the economizer, boiler (generating) bank and furnace. The convection pass side wall and screen tubes may also be water-cooled as discussed in Chapter 19. These tubes operate at or below saturation temperature and are not subject to significant creep. Modern boilers in electric utilities and many industrial plants operate at high pressures. Because these boilers are not tolerant of waterside deposits, they must be chemically cleaned periodically, which results in some tube material loss. As discussed in Chapter 42, proper water chemistry control will limit tube inside surface material loss due to ongoing operations and cleaning.

With the exception of creep deformation, the factors that reduce steam-cooled tube life can also act upon water-cooled tubes. Erosion is most likely to occur on tube outside surfaces in the boiler or economizer bank from sootblowing or ash particle impingement. Corrosion of the water-cooled tubes is most common on internal tube surfaces and results from excessive waterside deposits. Deposit accumulations promote corrosion, caustic gouging or hydrogen damage.

Risers The riser tubes are generally found in the penthouse or over the roof of the boiler. They carry the saturated steam-water mixture exiting the upper waterwall headers to the steam drum. Condition as-

essment includes UTT measurements on nondrainable sections and on the extrados (outside surface) of bends. When access is available it is advantageous to perform internal visual inspection with a fiber optic or video probe.

Headers

Headers and their associated problems can be grouped according to operating temperature. High temperature steam-carrying headers are a major concern because they have a finite creep life and their replacement cost is high. Lower temperature water- and steam-cooled headers are not susceptible to creep but may be damaged by corrosion, erosion, or severe thermal stresses.

High temperature The high temperature headers are the superheater and reheater outlets that operate at a bulk temperature of 900F (482C) or higher. Headers operating at high temperature experience creep under normal conditions. The mechanics of creep crack initiation and crack growth are further discussed in the data analysis section of this chapter. Fig. 7 illustrates the locations where cracking is most likely to occur on high temperature headers. In addition to material degradation resulting from creep, high temperature headers can experience thermal and mechanical fatigue. Creep stresses in combination with thermal fatigue stress lead to failure much sooner than those resulting from creep alone.

There are three factors influencing creep fatigue in superheater high temperature headers: combustion, steam flow and boiler load. Heat distribution within the boiler is not uniform: burner inputs can vary, air distribution is not uniform, and slagging and fouling can occur. The net effect of these combustion parameters is variations in heat input to individual superheater and reheater tubes. When combined with steam flow differences between tubes within a bank, significant variations in steam temperature entering the header can occur. (See Fig. 8.) Changes in boiler load further aggravate the temperature difference between the individual tube legs and the bulk header. As boiler load increases, the firing rate must increase to maintain pressure. During this transient, the boiler is temporarily over fired to compensate for the increasing steam flow and decreasing pressure. During load decreases, the firing rate decreases slightly faster than steam flow in the superheater with a resulting decrease in tube outlet temperature relative to that of the bulk header (Fig. 9). As a consequence of these

Fig. 7 Header locations susceptible to cracking.

Fig. 8 Steam temperature variation in a header.

temperature gradients, the header experiences localized stresses much greater than those associated with steam pressure and can result in large ligament cracks as shown in Fig. 10.

In addition to the effects of temperature variations, the external stresses associated with header expansion and piping loads must be evaluated. Header expansion can cause damage on cycling units resulting in fatigue cracks at support attachments, torque plates, and tube stub to header welds. Steam piping flexibility can cause excessive loads to be transmitted to the header outlet nozzle. These stresses result in externally initiated cracks at the outlet nozzle to header saddle weld.

Condition assessment of high temperature headers should include a combination of NDE techniques that are targeted at the welds where cracks are most likely to develop. Creep of the header causes it to swell; the diameter should be measured at several locations on the header and the outlet nozzle. All major header welds, including the outlet nozzle, torque plates, support lugs, support plates and circumferential girth welds, should be examined by MT or PT. A percentage of the stub to header welds should be examined by PT. Each section of the header should be examined by eddy current or acid etching to locate the seam if it is not readily apparent. The seam weld is examined for surface indications by MT or PT, and ultrasonic shear wave testing is performed to locate subsurface flaws. To examine the header for creep damage, metallographic replication is performed. The last test that should be performed on any high temperature header is internal examination of at least two tube bore holes.

Fig. 9 Superheater tube leg temperatures vary with load.

This test is considered the most effective. Ideally, the evaluation should correspond to the hottest location along the header.

Low temperature The low temperature headers are those operating at temperatures below which creep is a consideration. These include waterwall headers, economizer inlet and outlet headers, and superheater inlet and intermediate headers. Any damage to the low temperature headers is generally caused by corrosion or erosion.

Waterwall headers, found in most electric utility and industrial power generation boilers, are generally located outside the hostile environment of the combus-

Fig. 10 Large ligament cracks on header ID.

tion zone. One exception is the economizer inlet header; this may be in the gas stream and is subject to unique problems associated with cycling. Boilers that are held overnight in a hot standby condition without firing can experience severe damage to the economizer inlet header in a very short time. This damage is typically caused by thermal shock.

The magnitude of the thermal shock is a function of the temperature differential between the feedwater and the inlet header. It is also a function of water flow, which is usually large because the feedwater piping/valve train is sized for rated boiler capacity. The thermal shock is worst near the header feedwater inlet and rapidly decreases as flow passes into the header and tubes. The primary concern with other low temperature headers is internal and external corrosion during out of service periods. Lower waterwall headers on stoker-fired boilers that burn coal or refuse may experience erosion along the side walls adjacent to the stoker grates.

Attemperators

The attemperator, or desuperheater, is located in the piping of the superheater and is used for steam temperature control. (See Chapter 19.) The spray attemperator is the most common type used. (See Fig. 11.) In the spray unit, high quality water is sprayed directly into the superheated steam flow where it vaporizes to cool the steam. The attemperator is typically located in the piping between the primary superheater outlet header and the secondary superheater inlet header. Steam exiting the primary header at temperatures of 800 to 900F (427 to 482C) enters the attemperator, where relatively cool water [approximately 300F (149C)] is sprayed into the steam and reduces the temperature to the inlet of the secondary superheater. Because of the large temperature difference between the steam and spray water, parts of the attemperator experience thermal shock each time it is used. Over a period of years this can lead to thermal fatigue and eventual failure (Fig. 12).

Condition assessment of the attemperator requires removal of the spray nozzle assembly. The thermal stresses occurring in the attemperator are most damaging at welds, which act as stress concentrators. The spray head and welds on the nozzle assembly are examined visually and by PT to ensure there are no cracks. With the spray head removed, the liner can be examined with a video or fiber optic probe. For larger attemperators, it may be necessary to remove

Fig. 12 Failed attemperator spray head.

radiograph plugs before and after the attemperator to better view the critical liner welds.

High temperature piping

Damage mechanisms Damage to high temperature piping systems operating at more than 800F (427C) arises from creep, cycle fatigue, creep fatigue, and erosion-corrosion.

Most modern high temperature piping systems are designed for temperatures ranging from 950 to 1050F (510 to 566C), or higher. The American Society of Mechanical Engineers (ASME) allowable material stresses at these temperatures may produce creep rupture in approximately 30 to 40 years. Systems designed from 1950 through 1965, that used 1-1/4 Cr-1/2 Mo alloy steel, may be underdesigned by today's standards because the ASME Code has evolved, lowering the allowable high temperature stress for this material.

Fatigue damage to a piping system is caused by repeated cyclic loading, which can be the result of mechanical loads, thermal expansion and contraction, and vibration. Most piping systems are designed with some degree of fatigue resistance. This built-in flexibility comes from hangers and supports.

Creep and fatigue can occur together and interact to cause more damage than each mechanism by itself; it is not fully understood which mechanism is the primary cause. This combination of conditions is by far the most prominent because most power piping systems are highly dynamic.

Erosion-corrosion is not as prominent as the creep fatigue failure mechanisms. It is defined as wall thinning that is flow induced and occurs on the fluid side of the piping system. Factors that contribute to erosion-corrosion include bulk fluid velocity, material composition and fluid percent moisture.

Overall evaluation program When evaluating high temperature piping, condition assessment is usually necessary if the following conditions exist: piping operates above 1000F (538C); was manufactured of SA335-P11 or P22 material, or manufactured of long seam welded material; has had hanger problems; was manufactured with specific weld joint types; has a history of steam leaks; or operates above design conditions. Once a priority list is developed, the evalua-

Fig. 11 Typical attemperator assembly.

tion can begin. This evaluation program should be as complete as economically possible.

Detailed evaluation program

Phase I To determine where physical testing is required, the following preliminary steps are part of a Phase I evaluation: plant personnel interviews, plant history review, walkdowns, stress analysis, and life fraction analysis.

Plant personnel interviews are conducted to gather information that is not readily available from plant records. Significant history may only be found in recollections of experienced personnel.

Operating history reviews complement personnel interviews. They can provide problem histories and design or operating solutions.

Piping system walkdowns serve three major functions: to evaluate pipe supports and hangers, to find major bending or warpage, and to verify changes.

Pipe hangers and supports should be carefully examined. This can be done by creating a baseline inspection record of all supports.

While the data are being taken on the piping walkdown, the general appearance should also be noted. In particular, inspections may reveal the following damages: necked-down rods or yokes, spring coil fractures, deterioration of the hanger can, and deterioration of tiebacks into building steel.

Many times a walkdown reveals that a modification was performed. If the entire system was not reviewed during the modification, other problems may result.

Stress analysis of the piping system can now be performed. Typically, a computer program is used to perform the stress calculations based on design and any abnormal conditions found during the walkdown. Once a piping system is modeled, the analysis allows the engineer to pinpoint high stress locations. The objective is to limit the nondestructive examination work to these high stress areas.

Life fraction analysis (LFA) of a pipe is done if the primary failure mode is creep due to operating temperatures above 900F (482C). The LFA is based on the unit's operating history and stress levels are calculated using design conditions and minimum wall thicknesses. This analysis is discussed at length later.

Phase II Phase II of the evaluation includes all physical testing of the piping system. The majority of the testing should be nondestructive; however, some destructive testing may be required. The results from Phase I testing provide test location priority. Specific test recommendations are shown in Table 1.

The test data generated from the inspections must be evaluated to determine the remaining component life. This is known as the Phase III evaluation and is covered under *Analysis techniques*.

Typical failures The most typical steam pipe failure is cracking of attachment welds (support welds or shear lugs). These cracks are caused by thermal fatigue, improper support, or improper welding.

Radiograph plugs often have cracked seal welds. Although the plug threads are the pressure bearing surfaces, they can become disengaged over time due to corrosion, creep swelling or oxidation.

Steam pipe warping is another serious problem. If

Table 1
Typical Piping System Tests

Test Area	Test Type	Optional*
Circumferential welds	A, B, D, E, F, G, H	C, I, J
Longitudinal welds	A, B, D, E, F, G, H	C, I, J
Wye blocks	A, B, E, F, G, H	C, D, I, J
Hanger shear lugs	A, B	C, F, G, J
Hanger bracket and supports	A, B	C, F, G, J
Branch connections	A, B, D, E, F, G, H	C, I, J
RT plugs	A, B	C, F, G, I
Misc. taps and drains	A, B	C, I
Elbows/bend	A, E, F	B, C, G
A - Visual	F - Replication

E - Ultrasonic thickness	J - Metallography	

* Optional tests should be used to gather more detailed information.

the pipe has deformed, it has undoubtedly gone through a severe thermal shock. The high strain between the upper and lower sections of pipe can cause permanent deformation.

Two final common failure areas are the boiler outlet headers and turbine stop (throttle) valves. These areas should always be considered in any piping evaluation.

Low temperature piping

Low temperature piping operating at less than 800F (427C) is not damaged by creep. These systems typically fail due to fatigue, erosion or corrosion. The evaluation methods are the same as those for high temperature piping; however, a finite life is not predicted. Low temperature pipes, if maintained, last much longer than their high temperature counterparts. Typical systems are reheat inlet steam lines, extraction lines, feedwater lines and general service water lines.

Typical failures Many high temperature failure modes occur in low temperature pipes. Cold reheat lines experience thermal shock because the reheat temperature control is typically an in-line attemperator. The attemperator spray can shock the line if the liner is damaged or the nozzle is broken. Economizer discharge lines that run from the economizer outlet header to the boiler drum can be damaged during startup sequences. If the economizer is steaming and flow is initiated as a water slug, the line can experience severe shocks. This can cause line distortion and cracking at the end connections and support brackets. Other low temperature piping can be damaged by oxygen pitting caused by inadequate water treatment. Erosion due to flow cavitation around intrusion points can cause severe wall thinning. If solid particles are entrained in the fluid, erosion of pipe elbows results. General corrosion of the inside pipe surface can be caused by extended outage periods. Proper line draining is recommended unless protective materials are in place.

Tubular air heaters

Tubular air heaters are large heat exchangers that transfer heat from the boiler flue gas to the incoming combustion air, as discussed in Chapter 20. On large utility boilers, tubular air heaters can contain up to 90,000 tubes with lengths of 50 ft (15.2 m) each. These 2 in. (50.8 mm) OD tubes are densely grouped with spacings of 3 to 6 in. (76.2 to 152.4 mm) centers in two directions. Flue gas flow direction is typically opposite that of the combustion air to maximize thermal efficiency. Unfortunately, this promotes corrosion on the gas side cold end.

Condensate formation promotes acid corrosion from the flue gas which causes wall thinning. If left unchecked for several years the tubes eventually corrode through, causing air leakage from the air to gas side.

Because access to air heater tubes is limited, eddy current and acoustic technologies are used to test for blockage, holes and wall thinning. Eddy current technology is used to measure wall thicknesses of thin [< 0.065 in. (< 1.65 mm)] nonferrous heat exchanger tubing. Holes and partial and complete blockage are located using acoustic technology. When an audible sound is introduced into a tube it travels the length of the tube and exits the open end. If a hole exists in the tube, however, it changes the signal pitch in the same manner as a flutist changes a note pitch. In a like manner, partial or total tube blockage yields a pitch change. B&W uses The Acoustic Ranger® inspection probe for this test. (See Fig. 13.)

Boiler settings

The boiler components that are not part of the steam-water pressure boundary are general maintenance items that do not have a significant impact on remaining life of the unit. The nonpressure components include the penthouse, boiler casing, brickwork and refractories, and flues and ducts. Deterioration of these components results from mechanical and thermal fatigue, overheat, erosion and corrosion. In all cases, condition assessment is done by performing a detailed visual inspection. For flues, ducts and casing, it is of value to inspect the in-service boiler to detect hot spots, air leaks and flue gas leaks that can indicate a failed seal.

Fig. 13 Acoustic Ranger® schematic.

The structural members of the boiler must be reviewed during a condition assessment inspection. Normally these members, along with the support rods above the boiler and auxiliaries, last the life of the boiler. However, because nonuniform expansion can lead to boiler load movement, the support system should be examined during the boiler outage inspections. Particular attention should be given to header and drum supports that could be damaged if the vessel is distorted.

Analysis techniques

Once the testing is complete and the data are compiled, the next step in condition assessment is to decide whether to repair, replace or re-inspect certain components. For high temperature components with finite lives, this decision is aided by computers that predict failures by modeling analyses.

Component end of life is defined as the point at which failures occur frequently, the costs of inspection and repair exceed replacement cost, or personnel are at risk. Therefore, remaining life can be considered as the interval between the present time (t_p) with accumulated damage and the time at end of life (t_e). This can be written as:

$$R.L. = t_e - t_p \quad (1)$$

For waterwall tubing that is eroding at a linear rate, the remaining life is as follows:

$$R.L. = \frac{(t_e - t_r)}{e.r.} \quad (2)$$

where

- $R.L.$ = remaining life
- t_e = current wall thickness, in. (mm)
- t_r = preset replacement wall thickness, in. (mm)
- $e.r.$ = erosion rate, in./yr (mm/yr)

Remaining life of headers is calculated using modeling software due to the complexity of crack growth.

Steam-cooled tubes

Steam-carrying superheater and reheater tubes operating at temperatures above 900F (482C) are subject to failure by creep rupture. The creep life of a tube can be estimated from tabulated data, provided the applied (hoop) stress and the operating temperature are known.

When a tube is put in service, the metal contacting the steam begins to form a layer of oxide scale known as magnetite (Fe_3O_4). As the life progresses, the ID oxide layer grows at a rate that is dependent on temperature. This scale acts as a heat transfer barrier and causes an increase in the tube metal temperature as discussed in Chapter 4. The metal temperature, therefore, also gradually increases with time.

Internal oxide thickness measurements are necessary for estimating a tube's operating temperature and remaining creep life as well as for assessing the overall condition of the superheater. In the past, these

measurements have been obtained by removing tube samples for laboratory examination. To avoid destructive tests, B&W developed the NOTIS NDE technique discussed earlier.

Life prediction methodology The prediction of tube creep life begins with creep rupture data taken in short-term laboratory studies. Creep specimens, similar to cylindrical tensile specimens, are machined from various tube steels. Each specimen is heated to a temperature (T) and is pulled uniaxially at a stress (S) until failure occurs; at this point, a time to failure (t) is measured. A matrix of stress and temperature values has been tested.

The Larson-Miller parameter (LMP) is a function relating T , S , and t . This parameter is defined as:

$$LMP = (T + 460) (20 + \log t)$$

where

T = constant temperature applied to the creep specimen, F
 t = time at temperature T , h

Every tube in service has an associated LMP number that increases with time. These LMP data can be related to stress, as is illustrated in Fig. 14. This relationship between stress and LMP can then be used to predict a time to creep rupture for a superheater or reheater tube. Knowing two of the three factors affecting creep rupture, i.e., hours in service and hoop stress, the third factor, temperature history, can be estimated.

There are numerous mathematical models relating steam-side oxide thickness, time, and mean metal temperature for low chromium-molybdenum alloys. The following relationship is most widely used to calculate oxide thickness (x) in mils:

$$\log x = [0.00022 (T + 460) (20 + \log t)] - 7.25 \quad (3)$$

Although this formula works well with 1-1/4 Cr-Mo alloys, it must be modified for use with higher chromium alloys and carbon steels.

Creep life fraction analysis The life fraction is defined as the ratio of the time a tube withstands a given stress and temperature (t) to the time for creep rupture conditions (t_f).

Robinson's Rule of life fractions states that if the applied stress and temperature conditions are varied, the sum of the life fractions (or damage) associated with each set of conditions equals 1 at failure. It may also be written as follows:

$$(t/t_f)_1 + (t/t_f)_2 + \dots + (t/t_f)_n = 1 \quad (4)$$

where subscripts 1 through n indicate unique stress temperature conditions.

Example – Part I

Assume a tube operates at a hoop stress of 5 ksi (34,474 kPa) and a temperature of 1050F (566C). What is the predicted time to failure? Using these parameters and the stress-LMP curve presented in Fig. 14, the effective LMP at failure is 38,015.

From the LMP equation, the expected time to failure (t_f) can be calculated:

$$LMP = [(T + 460) (20 + \log t_f)] \quad (5)$$

$$t_f = 150,000 \text{ h}$$

If this tube has operated for 100,000 hours at these parameters, the creep life fraction expended is:

$$f_{\text{expended}} = t/t_f = \frac{100,000}{150,000} = 0.6667 \quad (6)$$

The creep life fraction remaining is:

$$f_{\text{remaining}} = 1 - t_{\text{expended}} = 1 - 0.6667 = 0.3334$$

$$t_{\text{remaining}} = f_{\text{remaining}} \times t_f$$

$$t_{\text{remaining}} = 0.3334 \times 150,000 \quad (7)$$

$$t_{\text{remaining}} = 50,000 \text{ h}$$

Example – Part II

Assume that, after operating at 1050F (566C) for 100,000 hours, tube temperature increases to 1065F (574C).

Using the same effective LMP, the LMP equation is used to calculate t_f at 1065F (574C) as follows:

$$LMP = (T + 460) (20 + \log t_f) \quad (8)$$

$$t_f = 85,000 \text{ h}$$

Therefore, a new tube operating at 1065F would have an expected life of 85,000 hours. However, from Part I, this tube has used up two-thirds of its life at 1050F and has a remaining life fraction of 0.33.

Fig. 14 Stress versus Larsen-Miller parameter (LMP).

Robinson's Rule can be applied to determine the higher temperature service life after the tube is exposed to 100,000 hours at 1050F.

Recall Robinson's Rule – the sum of the life fractions is equal to 1:

$$\begin{aligned} \left(\frac{t}{t_f} \right)_{1050} + \left(\frac{t}{t_f} \right)_{1065} &= 1 \\ 100,000/150,000 + t/85,000 &= 1 \\ t &= 28,000 \text{ h} \end{aligned} \quad (9)$$

Note that in this example, the total tube life would be 100,000 + 28,000, or 128,000 hours.

Analysis procedure The following analysis procedure is used with tube wall oxide thickness measurements from the NOTIS system.

1. The life of the tube, past and future, is broken into time intervals, each of length t :

An oxide growth rate is determined knowing the present oxide thickness and the time in service and assuming the initial oxide thickness was zero. Once a mathematical function describing oxide thickness with respect to time and temperature is defined, the thickness in each analysis interval can be calculated. The tube metal temperature in each interval, taking into account the insulating property of the oxide, is also calculated.

A linear wall thinning rate is determined for the tube, knowing the present wall thickness as measured by NOTIS, the original wall thickness, and the service time of the tube. Once a function describing wall thickness with respect to time is defined, the wall thickness in each analysis interval can be calculated. The hoop stress is calculated using the ASME Boiler Code Section I tube formula in each interval.

2. The creep life fraction used up in each interval is determined:

Given the stress, the LMP value may be found from the creep rupture database. Given the operating temperature and the LMP, the time a new tube would last at these conditions (t_f) is determined. The interval creep life fraction used up is then t/t_f .

3. Because the life fractions, summed over the analysis intervals, are equal to 1, the remaining life is obtained by subtracting the tube service time from this total life.

Accuracy of creep life prediction analysis Life fraction analysis is the most accurate and widely accepted method for estimating tube life. Although this method is straightforward and well documented, it is not precise.

Result inaccuracies are due to inherent material property variations. Additionally, during service, short excursions to higher temperatures lower the remaining life fraction.

Rather than attempting to determine the precise time of a creep rupture, the evaluation places each tube into a band of expected remaining lives. These bands take into account the shortcomings of the life fraction analysis, as well as the inaccuracy of the operating parameters for the unit being assessed. In effect, these bands are confidence limits.

Capabilities and limitations At elevated temperatures, the external and internal surfaces of boiler tubes slowly oxidize. The external scale is normally removed, whereas the internal scale usually remains intact. Typically, the multilaminated scale that is formed on the inner surface is characterized by an iron-rich inner layer and an oxygen-rich outer layer. The latter generally contains a large number of pores or voids. The ultrasonic response with the NOTIS system from the inner/outer layer interface is small compared to the signals associated with the metal/oxide and oxide/air interfaces. Therefore, a tightly adhering porous oxide does not affect the accuracy of the NOTIS system. However, if the two oxide layers become disbonded due to exfoliation processes, the NOTIS operator may only measure the oxide thickness to the disbonded area and therefore indicate that the oxide is exfoliating. Exfoliation is the flaking of scale particles off of the internal oxide layer.

Water-cooled tubes

Water-carrying tubes operate at or below saturation temperature and are not subject to creep damage. Therefore, these tubes have no defined design life as do high temperature components. However, erosion, corrosion, thermal expansion and mechanical stresses act on water carrying tubes. This limits useful practical life.

Outside tube wall thinning Erosion and corrosion are the most common causes of OD wall thinning. Erosion typically occurs on the tube outside diameter in the form of wall thickness loss. A tube's wall thickness is designed to the ASME Boiler and Pressure Vessel Code to withstand a given pressure, temperature, and mechanical load. An example is as follows:

Given: Design pressure (P)	= 2400 psi (16.5 MPa)
Design temperature (T)	= 700F (371C)
Tube outside diameter (OD)	= 3 in. (76.2 mm)
Tube material	= SA210 A1

From the ASME Code the wall thickness formula is:

$$t = \frac{PD}{2S + P} + 0.005D \quad (10)$$

where

t	= minimum wall thickness
P	= design pressure
D	= outside diameter
S	= allowable stress

By knowing the material and temperature, the allowable stress can be found in the ASME Code. In this case, the allowable stress is 14,400 psi (99,285 kPa). Solving the equation gives $t = 0.245$ in. (6.22 mm).

In the case of industrial and utility boilers, the next higher standard tube thickness would be supplied. In the case of a chemical recovery boiler used in the pulp and paper industry a much higher thickness would be used. This allows for wall thickness reduction when operated in a reducing atmosphere. (See Chapter 28.)

As a guide, the following are B&W recommendations for utility and industrial boiler tubes:

1. Water-cooled tubes should be repaired to original wall thickness or replaced if reduced to 70% of original.
2. Steam-cooled tubes should be repaired to original wall thickness or replaced if reduced to 85% of original.

Inside tube wall corrosion Internal corrosion due to hydrogen damage, caustic gouging and under-deposit corrosion is more difficult to evaluate for remaining life because it is not easily quantified.

In addition to wall thickness, other factors, such as the effect of water quality, microstructure and damaged area size, must also be considered. Internal corrosion data can be mapped similarly to that for ultrasonic wall thickness.

Internal deposits Internal deposits lead to tube failures and provide initiation sites for hydrogen damage and under-deposit corrosion as discussed in Chapter 42. The type of corrosion depends upon the nature of the deposit (dense or porous) and the composition of the chemicals beneath the deposit. Chemical cleaning of the boiler removes these deposits. The cleaning frequency depends on the type of unit, operating pressure, fuel, and water treatment program. The hours of operation and data from tube samples also determine the cleaning frequency.

Tube samples should be taken from locations with the heaviest deposits which are usually located in the high heat input burner zone areas of the furnace.

Headers and piping

High temperature headers and piping typically fail due to creep, fatigue, or a combination of the two. Although a header is more complex in geometry, it is essentially a pipe with tubes welded to it. Therefore, many of the remaining life analyses are similar to those for tubes. However, it must be noted that the root cause of damage can be different in headers.

On thick walled sections, where thermal and stress gradients can occur, remaining life is based on crack initiation and propagation. Computational methods, statistics, dimensional measurements, metallographic methods, and post service creep rupture testing are considered mainly with crack initiation and the events preceding it. When dealing with thick sections, these analytical techniques must be followed by crack growth analyses. Once a component is cracked, the pre-crack evaluation methods do not apply.

Crack growth analysis (CGA) There are three steps used in predicting crack propagation based on time dependent fracture mechanics. (See also Chapter 8.) The schematic shown in Fig. 15 illustrates the various steps.

Step 1 consists of identifying the creep growth and deformation behavior of the material. Step 2 consists of the expressions for the crack tip driving force for creep, C_t . The basic expression for C_t is:

$$\frac{da}{dt} = bC_t^m \quad (11)$$

where a is crack depth, t is time, and both b and m are material constants.

The final step is the development of results from Steps 1 and 2. These results are the remaining life or crack growth curves that are presented two ways. The first is a plot of crack versus time. This curve is exponential because the crack grows faster as it becomes larger. The second curve is the inverse of the first, plotting size versus remaining life. Remaining life is based on a critical predetermined through-wall crack size. Once the crack reaches this value, the remaining life is zero. From the previous equation, this can be written:

$$R.L. = \int_{a_i}^{a_c} \frac{da}{bC_t^m} \quad (12)$$

where a_c is the critical crack depth and a_i is the initial crack depth.

Leak before break analysis (LBBA) When evaluating cracks that are growing at a stable rate, even though they are through-wall, a condition occurs where fluid leaks through the crack but does not cause

Fig. 15 Three-step methodology for crack growth analysis.

a catastrophic rupture. If the flaw is characterized by depth a and length $2C$, then the following expression applies to leak before break:

$$R.L. = \int_{a_i}^{a_c} \frac{da}{bC_t^m} = \int_{c_i}^{c_{cr}} \frac{dc}{bC_t^m} \quad (13)$$

where C_{cr} and C_i are the critical crack and initial crack half lengths respectively. Because all variables except C_i are known or determined, the equation can be solved for C_i . B&W has developed a software code, Failure Analysis Diagram (PCFAD®), that models many crack scenarios encountered in header and piping systems. The failure assessment procedure uses a safety/failure plane diagram. The plane is defined by the stress intensity factor/fracture toughness ratio (K') as the ordinate and the applied stress/net section plastic collapse stress ratio (S') as the abscissa. If an assessment point lies within the curve (Fig. 16), the structure is safe. The distance from a point to the curve indicates the margin of safety. Chapter 8 provides further discussion. These two approaches allow the engineer to determine 1) how long a flaw will take to reach a predetermined critical size (crack growth, PC CREEP), and 2) whether the flaw will cause a leak or catastrophic failure.

Life fraction analysis Life fraction analyses (LFA) are performed on piping at temperatures above 900F (482C) in which the primary failure mode is creep. Stress levels are calculated using design conditions. To determine the minimum creep rupture life, published creep rupture data (LMP) are used. The calculation is similar to that for steam-cooled tubes, however piping is not influenced by gas stream heat flux and, therefore, operates at a fairly consistent temperature. The life fraction expended (LFE) is expressed as:

$$LFE = \frac{t}{t_m} \quad (14)$$

By using Minor's sum, an expression can be created to represent the unit's history of operating at different conditions:

$$LFE = \sum_{i=1}^z \frac{t_i}{t_{mi}} \quad (15)$$

where

- z = number of different conditions
- i = i th temperature and stress level
- t_i = time of operation at given conditions
- t_{mi} = minimum time to creep rupture (LMP)

When considering only creep rupture stress, a long remaining life results. However, most piping systems are also subjected to fatigue stress. Fatigue damage can be calculated by using standard fatigue curves. By combining the creep rupture and fatigue components, the expression becomes:

$$LFE = \sum_{i=1}^z \frac{t_i}{t_{mi}} + \sum_{j=1}^x \frac{c_j}{C_j} \quad (16)$$

Fig. 16 Sample PCFAD® failure plant diagram.

where

- x = number of different stress modes
- j = j th stress level
- c_j = number of cycles at stress level
- C_j = number of cycles to failure at stress level

This simple approach requires detailed operating history. In addition, it only provides a gross estimate of expected life.

Stress calculation The calculation of stresses for headers is complex because of tube stub geometry, tube bank loading, differential tube temperatures, and piping stresses on the outlet nozzle. Using specially developed software codes, it is possible to perform a finite element analysis for the entire header. B&W has performed finite element analysis on the tube stub ligament region and found that this area contains very high stresses, especially during temperature transients.

The total stress (S_t) applied to the flaw is equal to the sum of the primary stresses (axial or hoop) (S_p), bending stresses (S_b) and pressure stresses on the crack face (S_c):

$$S_t = S_p + S_b + S_c \quad (17)$$

The primary stress is determined by the orientation of the flaw. If the flaw is located axially along the length of the component, then the hoop stress is primary. If it is located circumferentially, then the axial stress is primary. Bending stresses are caused by dead loads, hanger spacing, thermal differentials and restraints. The pressure stresses applied to the crack face are only considered when the crack is open to the pressure. When this is the case, the applied stress is equal to the internal pressure.

BLESS Code analysis BLESS is an acronym for Boiler Life Evaluation and Simulation System. The complete BLESS code considers crack initiation and growth in headers as well as crack growth in pipes. The BLESS Code can also perform leak before break analysis (LBBA) of axial cracks in pipes. The Code was developed for EPRI by B&W as a subcontractor to General Atomics. The BLESS Code was derived from B&W's previous software codes for failure analysis

(PCFAD) and crack growth analysis (PC CREEP). Because stress calculations in headers and piping require difficult finite analysis due to complex geometries, simplifying assumptions were made in the development of the BLESS Code to allow for analysis.

The BLESS Code greatly facilitates the life assessment of elevated temperature headers and piping by eliminating the need for finite element thermal and stress analysis and utilizing developments in nonlinear creep-fatigue crack growth. The evaluation includes both crack initiation and crack growth. The Code permits the evaluation of the effects of extremely detailed thermal and mechanical load histories on headers with very complicated geometric details. The estimated remaining life is calculated by BLESS either as a single value (when re-run in the deterministic mode) or a statistical distribution. This distribution is obtained when BLESS is run in the probabilistic mode and defines the probability of failure as a function of time. Such information can be useful in making run/repair/replace and re-inspection decisions for aging or cracked headers and piping.

Flaw characterization Flaws found in headers and piping must be characterized prior to crack growth, LBBA, or BLESS analysis. This characterization involves accurately determining the flaw's length and depth. Through-wall depth is considered the most critical. The most common characterization methods include standard NDE techniques such as MT, PT, RT and UT.

Destructive samples

Destructive sampling is frequently done when data from nondestructive evaluations are inconclusive. Material properties, damage and deposits can be quantified. Tube samples and boat samples are discussed earlier under *Destructive examinations*.

Leak detection

Leaks in boilers, piping and feedwater heaters are major contributors to power plant unavailability and performance losses. In their early stages, leaks are often undetected because they are inaudible and/or concealed by insulation.

In the early 1980s, acoustic monitoring equipment began to be used for leak detection. By using a piezo-

electric pressure transducer to detect acoustic energy emitted by a leak, the detection of smaller leaks became possible. Leak noise is transmitted by air and by the structure. Boiler tube leaks are best detected through an airborne sensor because of the large boiler structure volume. Feedwater heaters, headers and piping leaks are best detected through a structural sensor. Because these components are small and self-contained, direct contact monitoring is used.

Leak noise is caused by a fluctuating pressure field associated with turbulence in the fluid. Turbulence is a condition of flow instability in which the inertial effects are highly dominant over the viscous drag effects. Once turbulence is established, the acoustic energy radiated from a leak increases strongly with pressure and flow rates.

Acoustic leak detection technology has been demonstrated through laboratory work, field testing and operational experience. The sensitivity of the sensor depends on three factors: sound radiated from the leak, attenuation of sound between the leak and the sensor, and background noise. Leak noise occurs in a broad band, ranging from below 1 kHz to above 20 kHz. Because of the low frequency background noise and the greater attenuation of high frequencies, most airborne systems operate in the range of 1 to 25 kHz. This is important because the acoustical signal diminishes in amplitude as it travels away from the source. Therefore, in designing a system, there is a tradeoff between sensor spacing and minimum detectable leak.

Table 2 shows typical leak monitor signals for boiler tubes, feedwater heaters, steam piping, and crack detection acoustic emissions.⁷

Boiler leak detection The background noise in a boiler is primarily due to combustion in the furnace. Direct measurement of background noise is needed to determine the spectral characteristics. In addition, the background noise level must be stable. The magnitudes of background noise from different parts of the boiler are similar; a large component is due to soot-blower operation.

Using background noise and leak characterization data, full scale tests have been run to optimize sensor listening distances, sensor orientation, and signal processing equipment. A typical 500 MW utility boiler can

Table 2
Typical Acoustic Monitoring Signals⁸

	Boiler Tubes	Leak Detection Feedwater Heaters		Steam Lines	Crack Detection Steam Lines/Headers
Acoustic path	Gasborne	Waterborne	Metalborne	Metalborne	Metalborne
Detection band	0.5 to 25 kHz	5 to 25 kHz	100 to 400 kHz	200 to 500 kHz	100 to 500 kHz
Background noise frequency	Below 2 kHz	Below 8 kHz	Below 125 kHz	Below 200 kHz	Below 200 kHz
Background noise amplitude*	20 to 30 dB	40 to 60 dB	30 to 50 dB	40 to 60 dB	40 to 60 dB

Number of sensors	12 to 18	1 to 2 per heater	1 per heater	Every 20 ft (6.1 m)	Every 10 to 20 ft (3 to 6.1 m)

* Reference 1 μ bar

be monitored using 16 to 24 sensor channels. Fig. 17 shows a typical airborne sensor and waveguide arrangement.

Waveguides are installed through the boiler enclosure at various locations. A typical sensor has a detection range of approximately 50 ft (15.2 m).

Header and piping leak detection Headers and piping are monitored with structural sensors similar to those of feedwater heaters. The sensors are placed approximately 15 to 20 ft (4.6 to 6.1 m) apart.

These sensors can also be used to detect crack growth. When a crack grows, it emits acoustic energy that can be detected. The processing of crack growth signals from leak detection sensors requires different, more powerful computing hardware than the systems required for leak detection. With structural leak detection sensors installed, and the proper fitting and signal processing hardware, periodic monitoring for crack growth can be performed.

Cycling effects and solutions

In assessing a boiler's ability to withstand cycling, those components most vulnerable to cycling are reviewed first. These components are discussed from two standpoints: the operating methods which minimize cyclic damage, and design modifications which permit the component to better withstand cycling conditions.

Cycle definition

Two types of cycling service are usually considered: load cycling and on/off cycling. The on/off type has also been called *two shifting*.

A cycle is considered to start at full load, full temperature steady-state conditions. It goes through a load change, then returns to the initial conditions. A typical load cycle is then composed of three phases:

- 1) load reduction,
- 2) low load operation, and
- 3) reloading.

A typical on/off cycle has four phases:

- 1) load reduction,
- 2) idle,
- 3) restart, and
- 4) reload.

The phase that is often ignored, the idle period, can offer the greatest potential for reducing cyclic damage.

Economizer thermal shock

On boilers that are on/off cycled, economizers often show more cyclic damage than the other components. The economizer receives water from the extraction feedwater heater system, and the inner metal surfaces follow the feedwater temperature with practically no time delay. As a result, high rates of metal temperature change can occur with resulting high local stresses.

Fig. 18 shows economizer inlet temperatures during an overnight shutdown cycle. The first two hours are for load reduction, followed by eight hours of idle or banked condition. Next, the boiler is fired in preparation for restart. The rates of temperature change

Fig. 17 Typical airborne noise sensors.

during the load decrease and increase are usually not excessive, but would represent load cycling conditions for the economizer.

During the banked period, there is some air leakage through the boiler with a resulting decay in boiler pressure. As this happens, the drum water level decreases. At the same time, the leaking air passing through the boiler is heated to near saturation temperature, and that air then heats the economizer. An economizer metal temperature can increase at 30 to 50F/h (17 to 28C/h) during this period and can approach saturation temperatures. When the drum level drops, the operator usually refills the boiler so that it is ready for firing. Because there is no extraction steam available, the feedwater temperature is low. This slug of cold water quickly chills the economizer, causing thermal shock as indicated by the solid lines in Fig. 18. The inlet header and tubes receive the greatest shock.

When the boiler is fired in preparation for turbine restart, rollup, and synchronization, the economizer heats up rapidly, often nearing saturation temperature. Feedwater is started when the initial load is applied to the turbine. Because little extraction heating is available, feedwater temperature is low. A severe shock occurs at this point, as the temperature can increase 300F (167C) in a few minutes.

Typically, early damage consists of cracks initiating in the tube holes of the inlet header which are closest to the feedwater inlet connection (Fig. 19).

Other damage has also been seen from this cyclic service. Outlet headers have shown damage similar to inlet headers. Furthermore, some tube bank support systems can not accommodate the high temperature differences between rows.

Fig. 18 Economizer temperatures during overnight shutdown cycles.

Solutions are available to reduce the frequency and magnitude of thermal shocks. These have taken two forms and address the out of service and restart conditions.

The first solution is called trickle feed cooling. Very small quantities of feedwater are frequently introduced during the shutdown and restart periods. This prevents the inlet header from reheating and reduces the cooling rate during feedwater introduction. Because feedwater introduction is controlled to limit economizer temperature rise, some drum blowdown may be necessary to prevent a high water level.

Fig. 19 Cracking in economizer inlet header occurs first in bore holes nearest water inlet.

A second method of reducing thermal shock is to permit the economizer to reheat during the idle period and then to provide higher temperature feedwater for restart. This can occur by pressurizing a high pressure heater with steam from an auxiliary source or from the drum of the unit. The quantity of steam required is low because it only heats the initial low flow of feedwater.

Furnace subcooling

Several drum boilers that have been subjected to on/off cycling have developed multiple cracks in lower furnace wall tubes where the tubes are restrained from diameter expansion or contraction. Typical cracking areas have been at the lower windbox attachment where filler bars or plates are welded to the tubes (Fig. 20).

Investigation of these failures indicated that, during the shutdown or idle period, relatively cold (cooled below saturation temperature) water settled in the lowest circuits of the furnace bottom. When circulation was started by initial firing or the circulating pump, the cold water interface moved upward through the walls, rapidly cooling the tubes. As the interface moved, its temperature gradient decreased and the rate of cooling decreased, therefore reducing damage higher in the furnace. Experience indicates that if the subcooling can be limited to 100F (56C), there is a low probability of damage.

An out-of-service circulating pump system may be used to limit the subcooling (Fig. 21). This is a low capacity pump that draws from the bottom of the downcomers and discharges water to the drum, therefore

Fig. 20 Lower windbox attachment cracking due to subcooling.

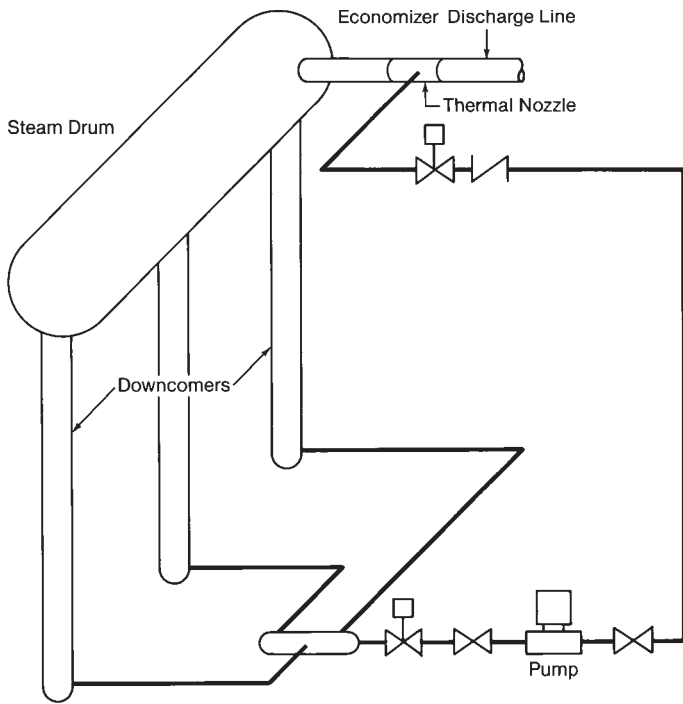

Fig. 21 Out-of-service circulating pump system.

preventing the stratification temperatures of water within the unit.

Tube leg flexibility

The enclosure walls of most boilers are water- or steam-cooled. The water-cooled circuits carry boiling water, and the steam-cooled circuits carry steam from the drum. As a result, they operate near the saturation temperature corresponding to the drum pressure. Whether the boiler is being fired or shut down, considerable heat absorption or loss is necessary to change the temperature of the walls. As a result, they change temperature more slowly than the other components.

The economizer, superheater and reheaters penetrate these walls; the penetrations are designed to be gas-tight. At the point of penetration the expansion then follows saturation temperature. However, the header that forms the inlet or outlet of the other circuits expands with the temperature of the steam or water that it is handling. Fig. 22 shows the motions of the header end and the outermost connecting leg for a superheater or reheater outlet. Note that the greatest deflection is when the header temperature is at a maximum.

In the case of economizers and the reheater inlet, the deflection is in the opposite direction because these headers operate below saturation temperature. For these components the greatest temperature difference, and therefore the greatest deflection, is at low loads.

Regardless of the direction, the greatest temperature difference produces the maximum differential expansion and the maximum bending stresses in the connecting legs. The stress range and amplitude dictate component fatigue life.

Consider the superheater outlet and the drum (penetration point) temperature differences at constant

and variable drum pressures, as shown in Fig. 23. In this example, for constant drum pressure, the maximum differential occurs at 50% load (hour 1) and is:

$$1000\text{F} - 685\text{F} = 315\text{F} \quad (538\text{C} - 363\text{C} = 175\text{C})$$

The minimum difference is at the end of the idle period (hour 10) and is:

$$655\text{F} - 570\text{F} = 85\text{F} \quad (346\text{C} - 299\text{C} = 47\text{C})$$

This is a stress range proportional to:

$$315\text{F} - 85\text{F} = 230\text{F} \quad (157\text{C} - 29\text{C} = 128\text{C})$$

For variable drum pressure, the maximum difference occurs at 35% load and is:

$$1000\text{F} - 540\text{F} = 460\text{F} \quad (538\text{C} - 282\text{C} = 256\text{C})$$

The minimum temperature difference at the end of the idle period is:

$$655\text{F} - 400\text{F} = 255\text{F} \quad (346\text{C} - 204\text{C} = 142\text{C})$$

producing a stress range proportional to:

$$460\text{F} - 255\text{F} = 205\text{F} \quad (238\text{C} - 124\text{C} = 114\text{C})$$

The variable drum pressure mode of operation is then slightly less severe for the superheater and reheater outlets and much less severe for the reheater inlet.

In considering operational changes, it should be noted that the steam temperature characteristics shown are the maximum available at a given load.

Fig. 22 Superheater tube leg flexibility.

Fig. 23 Overnight shutdown temperatures.

Lower temperature differences of 50 to 75°F (28 to 42°C) may be obtained in practice.

The first indications of cyclic damage are external cracks on the tube to header welds or the stub to tube welds of the outermost header legs. This damage is relatively easy to inspect and repair. Successive damage is also usually limited to closely adjacent legs because they have experienced similar stress levels. Most sensitive are high temperature headers which are a short distance from the penetration seal on wide units.

Drums

It is important to limit the rate of saturation temperature change in a steam drum. When operating in a variable drum pressure mode, considerable overfiring or underfiring is necessary to quickly change the drum pressure. These firing effects on steam temperature control also prevent rapid drum pressure changes.

Top to bottom drum temperature differences must also be limited. Only small differences result when pressure changes are made under load. The greatest

differences develop during pressure reduction, when little or no steam is being taken from the drum.

If drum pressure is rapidly lost during the idle period, top to bottom differentials develop and the drum *humps*. Because most drums have two point supports, the humping is unrestrained and causes little change in the drum or support stress levels. However, the drum acts as a stiff beam, and connected parts move with it (Fig. 24). If those parts do not have sufficient flexibility they can experience unacceptably high stresses.

While most recent units were designed with flexibility in the drum connections, there are some older units where the front furnace wall tubes are routed directly to the drum and are supported by the drum. In such cases, it is difficult to add flexibility by rerouting and the humping must be limited.

Developments

Symptoms of advanced creep and fatigue have been found in some older superheater and reheater outlet headers. Diametral swelling has been observed. Interior cracking around the header ID tube holes and along the length has also been present. To better understand the failure mechanism, finite element stress analyses have been performed. These analyses consider steady-state temperature differences between individual tubes and the bulk header and transient temperature changes of both.

Advances in nondestructive examinations

Innovative techniques are being developed to replace or enhance existing NDE methods. Some are becoming viable due to advancements in microprocessor technology. Others are relatively new and may replace current methods. Advanced techniques include: 1) infrared scanning,⁸ 2) automated Phased Array UT, 3) pipe and wall scanners which automatically cover large areas, and 4) through-insulation radiography. EMAT technology is being refined and studied for further applications in the NDE field.

Fig. 24 Drum humping.

Section VIII

Steam Generation from Nuclear Energy

Nuclear power generation provides a critical element in the energy supply of virtually all developed nations today, and offers the promise to address growing power needs in an environmentally acceptable and safe manner in the future. This section describes the application of steam generation fundamentals to the design of nuclear steam supply systems (NSSS) in which steam is generated by heat released from nuclear fuels.

This section begins with an overview of nuclear installations, concentrating on the pressurized water reactor. Principles of nuclear reactions and the nuclear fuel cycle are then explored in Chapter 47. Chapter 48 is dedicated to nuclear steam generators. Operating experience indicates that this component is a particularly challenging and important part of the NSSS. As nuclear power plants age, the steam generators are increasingly being replaced to optimize plant performance and extend the operating plant life.

Chapter 49 explores the key service, maintenance and operating characteristics of a nuclear steam system that can optimize life and performance. The section concludes in Chapter 50 with an overview of the highly specialized manufacturing requirements and capabilities that are necessary for successful component fabrication.

Chapter 46

Steam Generation from Nuclear Energy

Since the early 1950s, nuclear fission technology has been explored on a large scale for electric power generation and has evolved into the modern nuclear power plants. (See frontispiece and Fig. 1.) Many advantages of nuclear energy are not well understood by the general public, but this safe, environmentally benign source of electricity is still likely to play a major role in the future world energy picture. Nuclear electric power generation is ideally suited to provide large amounts of power while minimizing the overall environmental impact.

First generation power plants

The concept of an energy generating plant using nuclear fission was first considered by nuclear physicists in the 1930s. However, peaceful use of the atom was delayed until after World War II. The United States (U.S.) had a head start on nuclear technology because of its work in the atomic weapons program. The U.S. Atomic Energy Commission (AEC) took the lead in research and development for a controlled chain reaction application to energy generation. Many concepts were hypothesized and several promising paths were explored, but the real momentum developed when U.S. Navy Captain Hyman G. Rickover established a division in the AEC to develop a nuclear power plant for a submarine. This program, established in 1949, was to become the forerunner of commercial generating stations in the U.S. and the world. Rickover's design succeeded in 1953. Technology and materials developed by his team became the cornerstone of future U.S. nuclear plants. Concurrently, the AEC established a large testing site in Arco, Idaho where, in 1951, the fast neutron reactor produced the first electricity (100 kW) generated by controlled fission.

The world's first civil nuclear power station became operational in Obninsk in the former Soviet Union (FSU) in mid-1954, with a generating capability of 5 MW. This was about the same energy level produced in the U.S. submarine design.

In 1953, the Navy canceled Captain Rickover's plans to develop a larger nuclear power plant to be used in an aircraft carrier. However, he subsequently transformed this project into a design for the first U.S. civilian power stations. Duquesne Light Company of Pittsburgh, Pennsylvania agreed to build and operate the conventional portion of the plant and to buy steam from the nuclear facility to offset its cost of operation. On December 2, 1957, the Shippingport, Pennsylvania reactor plant was placed in service with a power output of 60 MW. This event marked the beginning of the first generation U.S. commercial nuclear plants.

Several basic concepts were being explored, developed and demonstrated throughout the world during this period. The U.S. submarine and Shippingport plants were pressurized water reactors (PWR) that used subcooled water as the fuel coolant and moderator. The FSU developed enriched uranium, graphite-

Fig. 1 Indian Point Station, New York.

moderated, water-cooled designs. British and French engineers explored natural uranium, graphite-moderated, carbon dioxide-cooled stations. In all these designs, the coolant (gas, liquid metal or pressurized water) transferred heat to a heat exchanger, where secondary water was vaporized to provide steam to drive a turbine-generator. The other major competing approach in the U.S. was the boiling water reactor (BWR). This was similar to the PWR except that the need for a heat exchanger to transfer heat from the coolant to the secondary steam cycle was eliminated by boiling the water in the reactor core and by using this slightly radioactive steam to drive the turbine. (See also Chapter 1.)

Two main classes of reactor fuel evolved: enriched and natural uranium. In the early stage of nuclear power development, only the two major nuclear powers, the U.S. and the FSU, had sufficient fuel production capacity for civilian power generation using enriched uranium. Therefore, natural uranium was chosen as the principal fuel in the United Kingdom (U.K.), France, Canada and Sweden. While the enriched uranium-fueled plants could be smaller and therefore required a lower initial investment, higher costs of the enriched fuel over the life of the plant made its use economically equivalent to that of natural uranium. All six countries launched programs to build civil, commercial nuclear power stations. Other countries collaborated with one of these six for construction technology.

In the U.S., the emerging technology focused on the enriched uranium light water reactor (LWR) that used regular water for the coolant and moderator. This had been the technology selected by the Navy programs and, as a result, the civilian sector gained from the experience of naval applications. The AEC also financed construction of the nuclear-powered merchant ship *N.S. Savannah*, which used this technology in a PWR designed and constructed by The Babcock & Wilcox Company (B&W).

In 1955, the AEC began the Power Reactor Demonstration Program to assist private industry. However, by 1963, only one demonstration plant had started up, and two others had been privately financed. Yankee Rowe in Massachusetts, Indian Point Unit 1 in New York, and Dresden 1 in Illinois operated successfully and demonstrated the viability of this technology for larger plants.

Second generation power plants

From these beginnings, the second generation of nuclear plants began in 1963, when a New Jersey public utility (Jersey Central Power & Light) invited bids for a nuclear power station to be built at Oyster Creek. A comprehensive study showed that it was economically attractive to operate, and the utility was ready to proceed. This bid was won with a turnkey proposal to deliver a plant at a fixed price. The suppliers were expected to absorb initial losses in expectation of profitably building a series of similar plants in the near future. From this study and resulting order came the realization that nuclear power stations could be competitive with other electricity sources.

Enthusiasm spread and, in the following years, more new nuclear generating capacity than conventional fossil fuel capacity was ordered. By the mid-1970s, nuclear plants, including new orders, totaled a significant portion of the nation's electric generating capacity. The second generation nuclear plants were comparable in size or larger than contemporary fossil-fueled plants. While nuclear plant capital costs were generally higher than those of the current fossil-fueled plants, the lower fuel cost of the nuclear plant offered a reduction in total generating cost.

The U.S. designs were also attractive for export. U.S. PWR designs were ordered in Japan, South Korea, the Philippines, Spain, Sweden, Switzerland, Yugoslavia, Taiwan, Italy, Brazil, Belgium and Germany, while Italy, Mexico, Spain, India, the Netherlands, Switzerland, Taiwan and Japan ordered BWRs of U.S. design.

In parallel with the rapid U.S. growth in nuclear electric generation capacity, the rest of the economically developed countries also began development and construction. In France, early efforts using natural uranium and gas-cooled reactors could not compete with oil-fired plants and enriched uranium light water reactors. After France developed uranium enrichment capability, the country's national utility, Electricité de France, in conjunction with heavy component designer and manufacturer Framatome, ordered PWR and BWR designs based on U.S. technology. An innovative concept applied by the French was to build a series of nearly identical plants of each design, thereby achieving economies of scale. Subsequently, the PWR design was selected by the French for their standardized series of plants. The basic designs developed were also eventually exported to Belgium, South Korea and South Africa.

In the U.K., initial designs for weapons production reactors were applied to generate commercial power from natural uranium-fueled, graphite-moderated, gas-cooled reactors. In the early 1960s, an advanced gas-cooled reactor (AGR), which used enriched uranium, was designed and subsequently built. Italy and Japan also built versions of these British designs.

The FSU developed a graphite-moderated, boiling water-cooled, enriched uranium reactor from its early Obninsk power station design. A major difference in this reactor from similar Western designs was that it did not include a sturdy reactor containment building. The FSU also developed naval propulsion reactors based upon the PWR concept that were then applied to civilian use. This PWR design was exported to several former Soviet bloc countries and Finland. The FSU PWR was similar to the U.S. designs except it generally provided significantly lower electrical output.

The excellent moderator characteristics of deuterium oxide (heavy water) became the basis for the Canada Deuterium Uranium (CANDU) reactor systems. These natural uranium-fueled reactors were first operated in 1962 (25 MW Nuclear Power Demonstration reactor at Rolphton, Ontario), and subsequent designs increased output to 800 MW.

In Japan, electric utilities experimented with sev-

eral types of imported nuclear generation plant designs. They ordered gas-cooled reactors from the U.K., and BWR and PWR designs from the U.S. The Japanese government also sponsored a breeder reactor design.

Germany was actively involved in designs primarily associated with high temperature gas reactor concepts. In 1969, the formation of Kraftwerk Union introduced German PWR and BWR designs based on U.S. technology. The intent was to construct a series of these plants to achieve economies of scale. However, unlike the French program, few plants were constructed. Several German PWRs were exported to Brazil, Spain, Switzerland and the Netherlands.

The energy crisis of the mid-1970s caused significant reductions in worldwide electric usage growth rates, and electric utilities began canceling and delaying new nuclear generating capacity construction. Cost increases caused by a number of factors also contributed to this construction decline. The delay of schedules due to slower load growth and/or regulatory hurdles greatly increased financing costs and drove unit costs higher. The high inflation of the period further increased construction costs. In addition, continually changing safety regulations increased costs as changes in design of plants already under construction were required.

PWR installations

By 1978, nine second generation nuclear units designed by B&W were placed into commercial operation, each generating 850 to 900 MW. The first unit was one of three built at Duke Power Company's Oconee Nuclear Station located near Seneca, South Carolina. The chapter frontispiece shows the three units of this station. The three vertical, cylindrical concrete structures are the reactor containment buildings. Although some equipment is shared among units, each is operationally independent. The rectangular building at the right contains the turbine-generators. The control room, auxiliary systems and fuel handling facilities for Units 1 and 2 are located in a structure between reactor buildings 1 and 2. Corresponding equipment for Unit 3 is located separately. The following general description applies to Oconee Unit 1, although it is generally applicable to all U.S. B&W plants; the concepts are applicable to all PWRs.

Containment building

Figs. 2 and 3 show a vertical section and plan of the reactor containment building. The structure is post-tensioned, reinforced concrete with a shallow domed roof and a flat foundation slab. The cylindrical portion is pre-stressed by a post-tensioning system consisting of horizontal and vertical tendons. The dome has a three way post-tensioning system. The foundation slab is conventionally reinforced with high strength steel. The entire structure is lined with 0.25 in. (6.3 mm) welded steel plate to provide a vapor seal.

The containment building dimensions are: inside diameter 116 ft (35.4 m); inside height 208 ft (63.4 m); wall thickness 3.75 ft (1.143 m); dome thickness 3.25 ft (0.99 m); and foundation slab thickness 8.5 ft (2.59

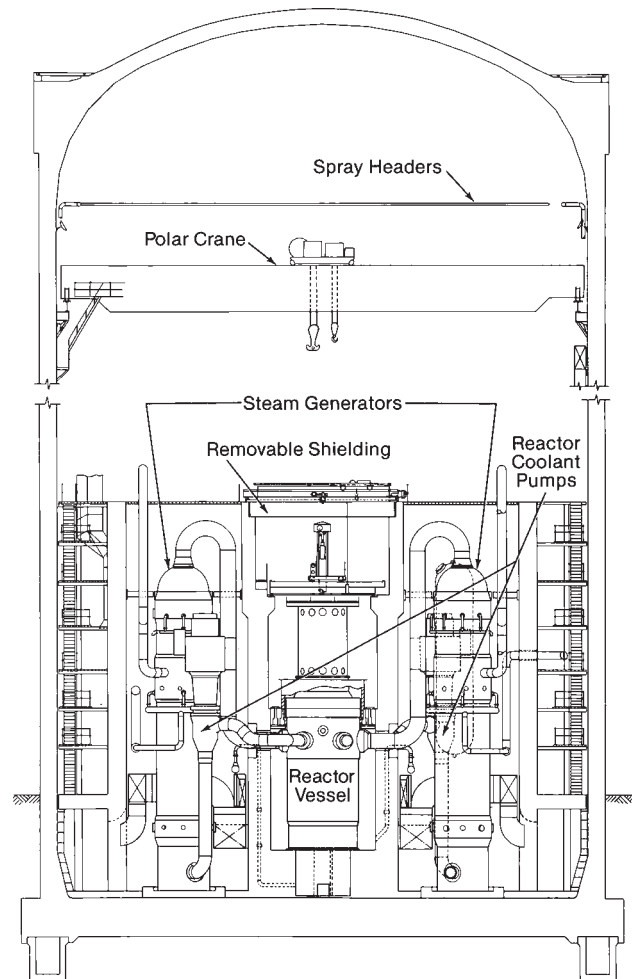

Fig. 2 PWR containment building, sectional view.

Fig. 3 Reactor containment building, ground floor plan view.

m). The building encloses the nuclear steam supply system and portions of the auxiliary and safeguard systems. The interior arrangement meets the requirements for all anticipated operating conditions and maintenance, including refueling.

The building is designed to sustain all internal and external loading conditions that may occur during its design life. In the event of a major loss-of-coolant accident, the building is designed to sustain the pressure caused by the release of the high-pressure water. To protect against external accidents, extensive tests and analyses have been conducted to show that airplane crashes or objects propelled by tornadoes will not penetrate the wall of the containment.

Nuclear steam supply system (NSSS)

B&W PWR system The major components of the B&W pressurized water reactor NSSS, shown in Fig. 4, include the reactor vessel, two once-through steam generators (OTSGs), pressurizer, primary reactor coolant pumps and piping. As shown in the simplified diagram in Fig. 5 (one of two steam generators shown), the NSSS is comprised of two flow circuits or loops.

The primary flow loop uses pressurized water to transfer heat from the reactor core to the steam generators. Flow is provided by the reactor coolant pump. The pressurizer maintains the primary loop pressure high enough to prevent steam generation in the re-

Fig. 4 B&W nuclear steam supply system.

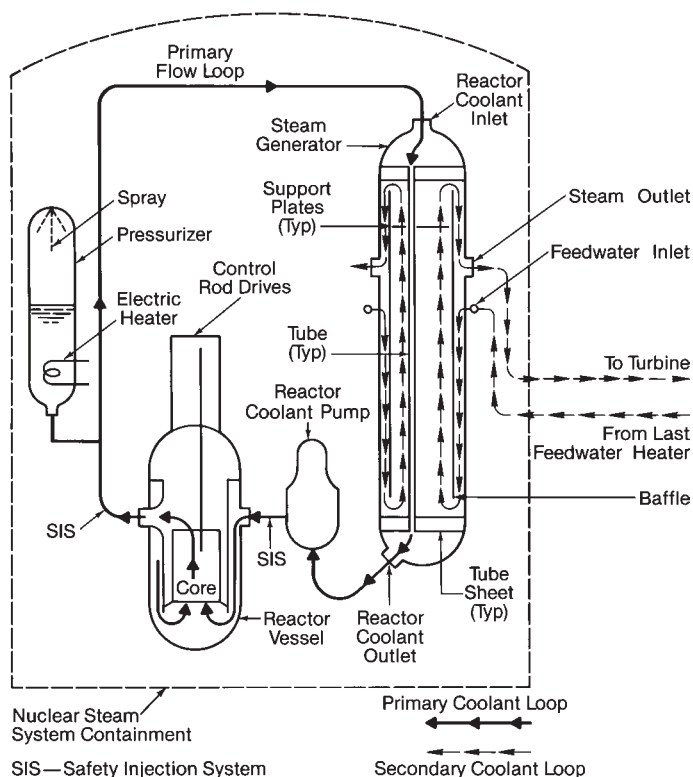

Fig. 5 Simplified schematic of primary and secondary loops.

actor core during normal operation. The steam generators provide the link between the primary coolant loops and the power producing secondary flow loop. In the B&W design, subcooled secondary side water enters the steam generator and emerges as superheated steam, which is sent to the steam turbine to produce power. The primary side water is cooled as it flows vertically downward through the straight tubes and supplies the energy to generate the steam. Table 1 in Chapter 47 of Reference 1 provides a listing of the important design parameters for the 900 MW Oconee type NSSS as well as for a larger 1300 MW system. The first 1300 MW design went into operation in 1987 at Muelheim Kaerlich power station in Germany.

Other PWR systems Fig. 6 shows a PWR system using the recirculating steam generator design. The key components remain the same as the B&W design except that two to four recirculating steam generators replace the OTSGs in providing the link between the primary coolant loop and the power producing secondary side flow loop. In the recirculating steam generator (RSG) design (Fig. 7), the primary coolant passes inside of the U-tubes while the secondary side water passes over the outside of the tubes where it is partially converted to steam. Steam separation equipment then removes residual water which is recirculated back to the bundle for further evaporation. The moisture-free steam is sent to the steam turbine to produce power.

CANDU The CANDU system uses natural uranium fuel and heavy water as the reactor coolant and moderator. The calandria (Fig. 8) is a low-pressure, thin-walled vessel containing the moderator and provides support for the horizontal fuel channel assemblies, shielding, and control mechanisms. In a CANDU 6 sys-

tem, there are 380 fuel assemblies traversing the entire width of the calandria. Heavy-water coolant flows through the fuel assembly with a full-power flow rate of 1.98×10^6 lb/h (249.5 kg/s) at an operating pressure of 1450 psi (10 MPa) and a mean temperature of 553F (289C). From the calandria, reactor coolant is piped to four inverted U-tube recirculating steam generators with design and layout similar to that shown in Fig. 6. In the CANDU system, each of the fuel assemblies can be isolated from the feedwater system, thereby allowing on-line refueling at full-power operation.

The balance of the following discussion focuses on B&W system components as the key concepts are generally applicable to all PWRs.

PWR reactor and fuel

Reactor vessel and internals

The reactor vessel, which houses the core, is the central component of the reactor coolant system (RCS). The vessel has a cylindrical shell with a spherical bottom head and a ring flange at the top. A closure head is bolted to this flange.

The vessel is constructed of low alloy steel with an internal stainless steel cladding to protect the vessel from corrosion. The vessel with closure head is almost 41 ft (12.5 m) tall and has an inside diameter of 171 in. (4343 mm). The minimum thicknesses of the shell wall and inside cladding are 8.4 and 0.125 in. (213 and 3.18 mm), respectively. Reflective metal (mirror) insulation is installed on the exterior surfaces of the reactor vessel.

The vessel has six major nozzles for reactor coolant flow (two outlet hot leg and four inlet cold leg). The coolant water enters the vessel through the four cold leg nozzles located above the midpoint of the vessel. Water flows downward in the annular space between the reactor vessel and the internal thermal shield, up

Fig. 6 Four steam generator loop configuration for a pressurized water reactor with recirculating steam generators.

Fig. 7 Simplified recirculating steam generator (RSG) with water preheating configuration.

through the core and upper plenum, down around the inside of the upper portion of the vessel and out through the two hot leg nozzles. Fig. 9 shows a reactor vessel being installed at a nuclear power plant site.

The core, containing the fuel bundle assemblies, is the primary component of the reactor vessel. The remaining major components are the plenum and the core support assemblies (see Figs. 10 and 11).

Plenum assembly The plenum assembly, located directly above the core, includes the plenum cover, upper grid, control rod guide tube assemblies, and flanged plenum cylinder. The plenum cylinder has multiple openings for reactor coolant outlet flow. These flow openings are arranged to form the coolant pro-

file leaving the core. The plenum cover is attached to the top flange of the plenum cylinder. It consists of a square lattice of parallel flat plates, a perforated top plate and a flange. The control rod guide tube assemblies are positioned by the upper grid. These assemblies shield the control rods from coolant crossflow and maintain the alignment of the rods.

Core support assembly The core support assembly consists of the following components:

1. core support shield,
2. core barrel,
3. lower grid assembly,
4. flow distributor,
5. thermal shield,
6. surveillance specimen holder tubes,
7. in-core instrument guide tubes, and
8. internals vent valves.

The core support shield is a flanged cylinder that mates with the reactor vessel opening. The forged top flange rests on the circumferential ledge in the reactor vessel top closure flange, while the core barrel is bolted to the vessel's lower flange. The cylindrical wall of the core support shield has two nozzle openings. These openings form a seal with the reactor vessel out-

Fig. 8 CANDU 6 reactor assembly.

Fig. 9 Reactor vessel placed into position between steam generators.

let nozzles by the differential thermal expansion of stainless and carbon steel. The core support shield also has eight holes in which the internals vent valves are mounted.

The core barrel supports the fuel assemblies, lower grid, flow distributor and in-core instrument guide tubes. This cylinder is flanged at both ends. The upper flange is bolted to the core support shield assembly and the lower flange is bolted to the lower grid assembly. A series of horizontal spacers is bolted to the inside of the cylinder and a series of vertical plates is bolted to the inside surfaces of the horizontal spacers to form walls enclosing the fuel assemblies. Coolant flows downward along the outside of the core barrel cylinder and upward through the fuel assemblies. Approximately 90% of the coolant flow traverses the heat transfer surfaces of the core fuel assemblies. Of the remaining 10% flow, some is directed into the gap between the core barrel and thermal shield primarily to cool the thermal shield. The remainder of the flow bypasses the core through various leak paths in the internals.

Core guide lugs are welded to the inside wall of the reactor vessel. In the event of a major internal component failure, these lugs limit the drop of the core barrel to 0.5 in. (12.7 mm) and prevent its rotation about the vertical axis.

The lower grid assembly, consisting of two lattice structures surrounded by a forged flanged cylinder, supports the fuel assemblies, thermal shield and flow distributor. The top flange is bolted to the lower flange of the core barrel. Pads bolted to the top surface of the upper lattice structure provide fuel assembly alignment. A perforated plate midway between the lattice structures aids the uniform distribution of coolant flow to the core.

The flow distributor is a perforated, dished head that is bolted to the bottom flange of the lower grid. The distributor supports the in-core instrument guide tubes and shapes the inlet flow to the core.

The thermal shield is a stainless steel cylinder located in the annulus between the core barrel and the reactor vessel. It is supported and positioned by the

Fig. 10 Cross-sectional view of reactor vessel internals.

top flange of the lower grid. The thermal shield and intervening water annuli reduce the radiation exposure and internal heat generation of the reactor vessel wall by attenuating neutron and gamma radiation.

The surveillance specimen holder tubes are installed on the outer wall of the core support assembly, at approximately mid-height of the core.

The in-core instrument guide tube assemblies guide the in-core assemblies between the penetrations in the bottom head of the reactor vessel and the instrument tubes in the fuel assemblies.

Eight co-planar internals vent valves are installed on the core support shield; they are 42 in. (1067 mm) above the centerlines of the reactor vessel inlet and

Fig. 11 Plan view of reactor vessel internals.

outlet nozzles. The valve seats are inclined 5 deg (0.087 rad) from vertical and the valve discs naturally hang closed. During normal operation, the valves are forced closed by the differential pressure, approximately 43 psi (296 kPa), between the outer annulus of the reactor vessel and the core outlet region. During a severe accident, such as a large break loss of coolant accident (LBLOCA), however, the differential pressure reverses and the internals vent valves open, permitting steam to be vented directly from the core region to the upper downcomer.

Reactor vessel closure head The closure head is an integral part of the reactor vessel pressure boundary. The head provides access for the replacement of spent fuel, and Alloy 600 penetration nozzles for control rod drive mechanisms and instrumentation. The closure head is typically made of low alloy steel and clad with stainless steel like the rest of the reactor vessel. Recently, many reactor closure heads in existing PWR systems have experienced corrosion damage and are being replaced (see summary in box on the following page.)

Fuel assemblies

In the reactor core, 177 fuel bundle assemblies rest on a lower grid attached to the core barrel. Each fuel bundle assembly contains 208 fuel rods (Fig. 12). Each

fuel rod is made up of enriched uranium oxide pellets contained in zircaloy-4 tubing/cladding (Fig. 13). Fuel pellets (Fig. 14) are made up primarily from uranium dioxide (UO_2) powder. The powder is pressed and sintered in a dry hydrogen atmosphere to produce the required pellet size. Final machining of the pellet is done under water. Within the rods, the fuel pellets are spring loaded at both ends to ensure contact between the pellets. The rod is pressurized with dry helium to improve heat transfer across the gap between the pellets and cladding. End caps are laser welded to seal the rods and ensure integrity of the fuel/coolant boundary.

Spacing of the fuel rods in the assembly is maintained with spacer grids at several locations along the length of the bundle (Fig. 15). These grids are formed from strips (Inconel® for the end spacers and zircaloy for the intermediate spacers) that are stamped to form the detailed configurations necessary to ensure adequate contact points with the fuel rods. The strips are welded together to form the square-shaped spacer grid that holds the rods in correct spacing and alignment. Stainless steel end fittings complete the bundle assembly (Fig. 16).

Each fuel assembly is fitted with an instrumentation tube at the center and with 16 guide tubes, each accommodating 16 control rods. (See Fig. 17.) Each group of 16 control rods is coupled together to form a

Fig. 12 Nuclear fuel assembly.

Fig. 13 Typical fuel rod assembly.

Reactor vessel closure heads

In recent years, discovery of cracked and leaking closure head Alloy 600 penetration nozzles, mainly the Control Rod Drive Mechanism (CRDM) nozzles, has raised concerns about the structural integrity of the closure heads. The CRDM nozzle is attached to the reactor vessel closure head and provides access to the core for the CRDMs.

Background

The problem was first discovered at the French Bugey Unit 3 power plant in 1991, when primary water leakage was observed on the vessel closure head at the CRDM nozzle region. Investigation of other French units showed cracking in the CRDM nozzles and the associated welds, and the cause was identified as primary water stress corrosion cracking (PWSCC).

This early French experience prompted examination of some PWR nozzle penetrations in the U.S. Detailed nondestructive examinations showed similar damage. Because the cracks were not through-wall and were within the approved acceptance criteria, the Nuclear Regulatory Commission (NRC) allowed continued plant operation contingent upon increased monitoring. However, in 2001, visual inspections of Oconee Unit 3 CRDM nozzles identified boric acid crystals at 9 of the 69 head penetrations, indicating that some primary water leakage had occurred. Further investigations revealed PWSCC initiated cracks that propagated from the weld radially and axially into the nozzle, allowing primary water leakage.

Evaluation of PWSCC effects has been completed at many of the PWR plants in the U.S. with subsequent decisions to replace some of the heads. These decisions to replace, rather than to follow a monitor and repair strategy, are strongly influenced by the expense of inspection and repair activities, which are challenging to perform in the hostile radioactive environment. It has proven desirable to avoid repairs and replace reactor vessel closure heads in their entirety, as quickly as possible, rather than bear the cost and schedule implications of difficult inspections and time-consuming repairs. In 2001, B&W received the first replacement head order in the U.S. to provide heads for Oconee Units 1, 2 and 3.

Closure head replacement requirements

The principal requirement for replacement closure heads is to provide a *form, fit and function* replacement that is compatible with the original equipment configuration and that provides enhanced reliability suitable for at least a 40 year design life. A form, fit and function replacement design ensures proper and efficient integration of a new closure head into the existing plant, thereby simplifying the safety assessments required to show

compliance with NRC 10CFR 50.59 regulations. However, enhanced reliability can only be achieved by having a sound understanding of the cause of the degradation, and by optimizing all aspects of the design that are related to known degradation mechanisms.

Replacement head features

The conditions that induce PWSCC, and that are present in the current CRDM-to-head-attachment region, are:

1. the corrosive environment with primary borated water,
2. the presence of tensile stresses, and
3. the use of materials susceptible to corrosion.

Accepting the presence of the primary water environment, the major focus of the replacement head design has been to provide superior materials and to control the stresses induced at all stages of manufacture.

Materials The material for the CRDM nozzles has been changed from Alloy 600 to thermally treated Alloy 690TT. Similarly, the weld consumables for the CRDM nozzle-to-head weld have been changed from Alloy 182 to Alloy 52 and/or Alloy 152, both having material compositions compatible with the Alloy 690 base material. All of these replacement materials have demonstrated superior resistance to PWSCC if they are specified and procured under a carefully controlled and monitored program.

Fabrication In addition, optimum resistance to PWSCC requires control of mechanical factors such as cold work and residual stresses. Materials for fabrication will start in the annealed condition, essentially free of bulk cold work and residual stress. Some manufacturing steps can reintroduce cold work and stresses which can negatively affect PWSCC resistance (both internal and surface conditions are important). Fabrication sequence and welding methods are important in minimizing internal residual stresses; finishing methods for both individual parts and completed assemblies are important in controlling surface cold work and related residual stresses.

Nozzle-to-head welds The original equipment nozzle-to-head welds were made with a manual shielded metal arc welding (SMAW) process. The replacement units use an automated gas tungsten arc welding (GTAW) process which improves weld quality, and minimizes residual as-welded stresses. To address concerns regarding the effect of as-manufactured surface condition on PWSCC resistance, B&W has employed an electropolishing process for both the CRDM nozzle prior to installation and the finished weld after surface conditioning. This process, unlike abrasive honing or other surface treatments, entirely removes the cold worked surface layer associated with machining and grinding.

Fig. 14 Nuclear fuel pellets.

control rod assembly as shown in Fig. 18. At any given time, 69 of the 177 fuel assemblies contain a control rod assembly. Because all fuel assemblies are identical and can be used anywhere in the core, the 108 remaining fuel assemblies have their guide tubes partially filled at the top with an orifice rod assembly. This restricts excessive coolant flow through the unused control rod guide tubes and equalizes coolant flow among the fuel assemblies.

The control rod assemblies regulate the reactor reactivity and, therefore, the power output. Each control rod consists of an absorber section made from a neutron absorbing material such as stainless steel with silver-indium-cadmium cladding, and an upper and lower stainless steel end piece. The rods regulate relatively fast reactivity phenomena such as Doppler, xenon buildup and decay, and moderator temperature change effects. The slower reactivity effects, such as fuel burnup, fission product buildup, and hot-to-cold moderator reactivity deficit, are controlled by a soluble

Fig. 15 Spacer grid coordinate measuring machine.

Fig. 16 Final visual inspection of fuel assemblies.

neutron absorbent (usually boron) in the reactor coolant. The concentration of the absorbent is monitored and adjusted by the plant operators.

Refueling

Most U.S. power reactors operate for a planned period of between one and two years before the reactivity of the nuclear fuel is reduced and the unit must be reloaded with fresh fuel. Because only part of the fuel is replaced during the shutdown, this is referred to as *batch refueling*. In some reactors, such as the CANDU design, a continuous refueling mode that does not require reactor shutdown is used.

Most PWRs were designed for annual refueling, replacing approximately one-third of the core at each outage. As operating experience has been gained, the trend has shifted to 18-month refueling cycles. Although fuel costs are higher, the longer refueling cycle is cost-effective.

Fig. 17 Diagrammatic cross-section of fuel assemblies showing instrumentation tube and control rod guide tube locations.

Fig. 18 Control rod assembly.

tive due to reductions in the number of refueling outages, licensing submittals, and replacement power cost. Furthermore, the burnup capability of the fuel has increased, permitting subsequent batch size reductions.

As nuclear fuel is continually consumed in the reactor, the fuel bundle assemblies are subjected to temperature and irradiation effects that change some of their characteristics. Dimensional and structural changes in the assemblies include growth of the fuel rods, spring relaxation, and fuel rod bow. Some corrosion of the cladding takes place on the coolant side. This corrosion effect liberates hydrogen from the coolant, some of which is absorbed by the cladding, and can subsequently decrease cladding mechanical properties. Fission gas release in the fuel rod can cause high internal pressure. The coolant is continually monitored during operation to detect any leakage of these fission gases. While these various effects have been considered and monitored over the years of reactor operation, they have not been found to limit operation of the nuclear systems.

Extreme care and detailed handling procedures are required to remove the spent fuel assemblies for disposition. During their removal from the reactor core and near-term storage in spent fuel pools, water serves as both a shielding and as a cooling medium. The spent

fuel assemblies are kept in the spent fuel pool at the reactor site until the radioactive decay and heat generation have declined sufficiently for safe transportation and processing.

Energy transport

Each fission of uranium-235 (U-235) produces approximately 200 MeV, predominantly in the form of kinetic energy of the fission products. This energy dissipates to thermal energy of the fuel. The core heat transfer process involves the fuel, fuel-cladding gap, cladding and coolant. A typical temperature profile is shown in Fig. 19. The mode of heat transfer from cladding to coolant is subcooled forced convection. Film boiling is avoided by maintaining a DNBR above 1.3. DNBR is the ratio of local heat flux at the departure from nucleate boiling (DNB) to actual local heat flux. (See Chapter 5.) The coolant enters the core at approximately 557F (292C) and exits at 607F (319C), thereby establishing the sink temperature for fuel to coolant heat transfer. The cladding to coolant convective and cladding conductive heat transfer rates are relatively high, therefore the fuel temperatures primarily depend on the gap and fuel conductances and the rate of energy deposition. The heat transfer calculation methods are described in Chapters 4 and 5. The melting temperature of unirradiated uranium dioxide (UO₂) is 5080F (2804C). This temperature decreases with burnup at the rate of approximately 58F (32C) per 10,000 MWd/t_m U, due to the accumulation of fission products. A design overpower maximum fuel centerline temperature of 4700F (2593C) has been selected to preclude melting at the fuel centerline.

Fig. 19 Radial temperature profile for a fuel rod at 11 kW/ft.

Instrumentation

The reactor vessel instrumentation consists of the nuclear instrumentation and in-core monitoring system.

Nuclear instrumentation Neutron flux levels are monitored using a combination of source, intermediate and power range detectors. Each of these detectors is located at core mid-height, outside the reactor vessel but inside the primary shield. The distribution and types of detectors are:

Range	Detector Type	Number
Source	BF ₃ Proportional	2
Intermediate	Compensated ion chamber	2
Power	Uncompensated ion chamber	4

These measurements are supplied to the reactor operator, safety parameter display system, reactor control portion of the integrated control system and reactor protection system. Additionally, the source and intermediate range readings are differentiated to provide startup rate, and the outputs of each pair of power range detectors are differenced to provide top to bottom flux imbalance.

In-core monitoring system Core performance is monitored using 52 in-core detector assemblies. These assemblies are arranged in a spiral fashion outward from the center of the core. Each assembly consists of seven local flux detectors, one background detector and one thermocouple, arranged as shown in Fig. 20. The seven local flux detectors, distributed over the axial core length, indicate the axial flux shape and provide fuel burnup information. The background detector indicates the integrated axial flux. These flux detectors are self-powered rhodium-103 instruments. The thermocouple indicates the exit coolant temperature.

Steam generators

Nuclear steam generators are particularly significant components in the NSSS and are discussed in more detail in Chapters 48 and 50.

The steam generators in PWR systems transfer heat from the primary coolant loop to the secondary flow loop, effectively functioning as heat sinks for the reactor core. The decrease of primary coolant temperature through the steam generators is virtually the same as the increase of primary coolant temperature through the core. Any difference is attributable to the fluid energy supplied by the reactor coolant pumps, less heat losses to ambient.

A variety of steam generator designs have been used in nuclear reactor systems.² However, two have been primarily used on second generation NSSS: the once-through steam generator (OTSG) and the more prevalent recirculating steam generator (RSG).

The OTSG is a straight tube counterflow heat exchanger where the primary coolant flows vertically downward inside the tubes and the secondary side water flows upward changing from slightly subcooled liquid to superheated steam at the outlet.

The RSG uses an inverted vertical U-tube bundle to transfer the energy and generate steam. The primary coolant passes through the U-tubes. The

Fig. 20 Instrument tube cross-section.

subcooled secondary side water mixes with water from the steam separators and passes up over the outside of the U-tube bundle as it is partially converted to steam. The steam-water mixture passes through multiple levels of steam separation equipment which returns the water to the U-tube bundle for further heating and evaporation and passes the saturated steam to the power-producing system.

Pressurizer

Description

The pressurizer (Fig. 21) is a tall, cylindrical tank connected at the bottom to a reactor coolant loop hot leg through 10 in. (254 mm) diameter surge line piping. Spray is introduced near the top of the pressurizer through a nozzle and 4 in. (102 mm) diameter line from a cold leg. Three replaceable heater bundles are installed over the lower portion of the pressurizer. Pressure relief devices are mounted at the top of the unit; these include two code safety valves and the power operated relief valve (PORV).

Function

The pressurizer controls primary system pressure. During normal operation, the pressurizer volume of 1500 ft³ (42.5 m³) contains equal portions of saturated liquid and saturated steam. Should the primary system liquid expand, such as through an increase of coolant temperature due to a load reduction, the excess volume displaces liquid into the surge line, raising the pressurizer level. This evolution is termed an *insurge*. The pressurizer steam is compressed, raising the primary system pressure and causing some of the steam to be condensed. The specific volume of liquid is much less than that of steam, therefore the steam condensation counteracts the ongoing pressure rise. The opposite occurs during an *outsurge*, the displacement of pressurizer liquid toward the hot leg through

the surge line. In this case, the primary system pressure decreases, saturated pressurizer liquid flashes to steam and the net increase of specific volume through the change of phase suppresses the depressurization.

The pressurizer liquid volume is sized to maintain liquid above the pressurizer heaters and to maintain pressure above the HPI actuation point during the outsurge due to a reactor trip. The pressurizer steam volume is sized to retain a steam bubble during the insurge due to a turbine trip. Operation without a pressurizer steam bubble is termed solid plant operation. The pressurizer is sized to avoid this mode in which pressure control is encumbered.

Heaters

The pressurizer heaters maintain the pressurizer liquid at the saturation temperature, replacing the heat losses to ambient. They also raise and/or restore primary system pressure by elevating the saturation temperature of the pressurizer fluid. The three bundles of heaters are divided into five banks. There are two essential banks and three nonessential banks. The essential banks are energized automatically, based on primary system pressure. Essential bank no. 1 is energized below 2150 psig (14.82 MPa) and is subsequently de-energized above 2160 psig (14.89 MPa); the corresponding pressures for essential bank no. 2 are 2145 and 2155 psig (14.79 and 14.86 MPa). Nonessential bank no. 3 is sized to maintain the pressurizer fluid temperature during normal, steady-state operation. Banks no. 4 and no. 5 provide additional heater capacity that can be used during system startup or load changes.

Fig. 21 Nuclear steam system pressurizer.

Spray

The pressurizer spray system lowers primary system pressure and counters an increasing pressure transient. The actuation of pressurizer spray introduces 550F (288C) cold leg fluid into the pressurizer steam space. The resulting condensation decreases the pressurizer fluid volume, thereby decreasing pressure.

The spray enters the pressurizer through the spray nozzle. This nozzle imparts rotational motion to the fluid, generating a downward directed, hollow spray cone. This pattern enhances steam condensation efficiency while minimizing contact of the cold spray with the pressurizer vessel walls. Between the pressurizer wall and the spray nozzle, the spray line makes a bend in the vertical plane. This loop seal line configuration is designed to maintain liquid in the spray line, thereby alleviating the temperature changes experienced by the spray nozzle.

The spray line is attached to the cold leg piping just downstream of the reactor coolant pump. The spray is driven by the RCS fluid pressure drop across the reactor vessel, and the full spray flow rate at normal operating conditions is approximately 170 GPM (10.7 l/s). The spray flow control valve is normally operated in a modulated rather than on/off mode. When in automatic mode, the spray flow control valve opens 40% when the primary system pressure increases to 2200 psig (15.17 MPa) and closes when pressure decreases to 2150 psig (14.82 MPa). The 40% open setting permits a spray flow rate of approximately 90 GPM (5.68 l/s).

A continuous flow rate of approximately 1 GPM (0.063 l/s) is maintained to minimize the thermal transients of the spray nozzle; this is accomplished by a bypass line around the spray flow control valve. An auxiliary system provides pressurizer spray when the reactor coolant pumps are inactive, such as during decay heat removal cooling of the RCS.

Pressure control devices

Pressure increases are countered by pressurizer steam condensation through compression and by pressurizer spray actuation. Should pressure continue to rise, the PORV opens at 2450 psig (16.89 MPa). A pressure actuated solenoid operates the pilot valve, which actuates the PORV. The PORV discharges into the pressurizer quench tank and can be isolated by closing the PORV block valve. A hypothetical continuous rod withdrawal accident from low power would cause core power generation to greatly exceed steam generator heat removal. The two code safety valves are sized to prevent RCS pressure from exceeding the 2750 psig (18.96 MPa) limit. These valves open at 2500 psig (17.24 MPa) and also discharge to the pressurizer quench tank.

Pumps and piping

Description and function

Coolant is transported from the reactor vessel to the two steam generators through hot leg piping. The coolant is returned to the reactor vessel from the generators through four cold legs, two per generator. Fluid

circulation is provided by four reactor coolant pumps, one per cold leg. The arrangement of the piping and pumps is shown in Figs. 2, 3 and 4.

The hot leg and cold leg piping is fabricated from carbon steel and is clad on the inside with type 304 or 316 stainless steel. The inside diameters of the hot leg and cold leg piping are 36 and 28 in. (914 and 711 mm) and their nominal wall thicknesses are 2.75 and 2.5 in. (69.9 and 63.5 mm), respectively. The other piping attached to the RCS is either fabricated from stainless steel or clad with stainless steel.

Thermal sleeves are used to minimize the thermal stresses generated by rapid fluid temperature changes; they are installed on the four high pressure injection (HPI) nozzles and two core flood nozzles.

Pump characteristics

The reactor coolant pumps are vertical suction, horizontal discharge, centrifugal units. They are further characterized as diffused flow, single stage, single suction, constant speed, vertical centrifugal, controlled leakage pumps having five-vane impellers. The pumps are driven by constant speed, vertical squirrel cage induction motors. Pump sealing is accomplished using three-stage mechanical seals. The pump and motor are just over 27 ft (8.2 m) tall (see Fig. 22). The motor develops approximately 9000 hp (6714 kW) at cold conditions and 1185 rpm (124 rad/s) using a 6600 volt, three-phase power supply. The locked rotor starting current is approximately 3800 amperes. At normal operating conditions, the motor develops approximately 8300 hp (6192 kW), drawing a current of 685 amperes. Each unit's rotational moment of inertia is in excess of 70,000 lbf ft² (28,928 Nm²). This rotational inertia is sufficient to sustain rotation for approximately 45 seconds following a power interruption. Each reactor coolant pump has a nominal capacity of 92,400 GPM (5829 l/s) with a discharge head of 403.5 ft (122.99 m) at operating RCS conditions.

Integrated control system

Function

The integrated control system (ICS) simultaneously controls the reactor, steam generators and turbine to obtain a smooth, rapid response to load changes. The ICS operates the control rods to regulate core power, adjusts the feedwater flow to control the rate of steam production, and operates the turbine throttle valves to control electrical power output. This control method combines the advantages of two alternative approaches.

The NSSS responds inherently to load changes without an ICS, but this response causes undesirable system variations. Consider the response to an increased load demand without integrated control. The increased electrical load causes the turbine throttle valves to open to maintain turbine speed. The increased steam demand lowers steam pressure at the turbine and within the steam lines and steam generators. Feed flow rate is increased to match the increased steam flow rate. The increased steam generator heat

transfer lowers the temperature of the reactor coolant returning to the core. Core power gradually increases due to the reactivity gained from the negative temperature coefficient. This means that the increased reactor coolant density enhances the moderation of neutrons, thereby increasing the thermal neutrons available to cause thermal fissions. Also, the control rods are withdrawn to maintain the average primary fluid temperature. These primary system interactions would be reversed as the core and steam generator stabilized at the new, higher power level. This method of feedback control has the advantage of immediately supplying the required electrical load.

An extremely stable but slow method of NSSS control is termed the turbine-following method. The turbine output is varied only as the steam pressure is adjusted for the revised conditions. Again consider the response to an increased load demand. The control rods are withdrawn to increase reactor power and the feed flow rate is increased to support a higher rate of steam generation. As the turbine throttle pressure begins to increase, the throttle valves are gradually opened, allowing the turbine output to respond to the increased load demand.

The ICS operates all three systems: turbine, feed-water flow and control rods, to combine the rapid response of the unregulated system with the stability of the turbine-following system. The key to ICS operation is the turbine header pressure setpoint. The turbine governor valves maintain turbine speed and turbine header steam pressure. Because of the thermal inertia of the NSSS, the steam production rate can not be changed as rapidly as the steam demand varies in response to a turbine load change. This time delay is handled by temporarily changing the turbine

Fig. 22 Reactor coolant pump arrangement.

header pressure setpoint. For example, again consider a load increase. The ICS causes the control rods to be withdrawn and the feedwater flow rate to be increased. Simultaneously, the ICS temporarily reduces the turbine header pressure setpoint. The turbine governor valves open to maintain turbine speed and to reduce the header steam pressure to the new setpoint. As core power, primary to secondary heat transfer and steam flow rate gradually increase, the turbine header pressure recovers and its set point is returned to the steady-state value. In this fashion, the ICS obtains a rapid response and a smooth transition between turbine loads.

Limits and controls

The ICS recognizes a variety of limiting conditions, such as a reactor coolant pump trip, a feed pump trip or an asymmetric control rod fault. It imposes the appropriate load and load change limits corresponding to these conditions.

Special ICS signals are imposed below 15% of full power. During system startup, the reactor and steam generator power levels are increased to approximately 10% power by steaming through the turbine bypass valves. The turbine-generator is rolled, synchronized with the electrical distribution system and gradually loaded. The turbine control station is placed in automatic mode at approximately 15% turbine load. The reactor is then controlled to maintain a constant average coolant temperature of 582F (306C) above 15% power, using the RC subsystem. From 0 to 15% power, manual control is used to increase the average coolant temperature from 532F to 582F (278 to 306C).

Reactor protection system

Function

The reactor protection system (RPS) trips the reactor when limiting conditions are approached. These limits prevent boiling of the reactor coolant, limit the local core power generation rate (the linear heat rate) and minimize challenges to the PORV.

Multiple independent RPS channels monitor critical reactor trip functions. If any two of these channels detect single or multiple trip functions outside normal parameters, the control rod drive breakers are opened, tripping the reactor. Depending upon the NSSS design, the trip functions can include:

1. ARTS (anticipatory reactor trip system) main feedwater pump trip,
2. ARTS turbine trip,
3. overpower trip,
4. high outlet temperature trip,
5. high pressure trip,
6. reactor building high pressure trip,
7. pressure/temperature trip,
8. low pressure trip,
9. power/imbalance/flow trip, and
10. power/reactor coolant pumps trip.

The two ARTS trip functions trip the reactor before the RCS pressure rises to the reactor set point, thereby

minimizing the activation of the PORV (power operated relief valve). The reactor can also be manually tripped from the control room.

Safety features actuation system

The safety features actuation system (SFAS) engages the emergency core cooling system (ECCS) in the event of a breach of the primary system boundary. The two SFAS signals are low RCS pressure and high reactor building pressure. A schematic of the various systems is shown in Fig. 23. The SFAS operates the following systems:

1. high pressure injection,
2. low pressure injection,
3. reactor building cooling, and
4. reactor building spray.

In addition, the SFAS activates the two emergency diesel generators.

Each of the three independent measurements of RCS pressure is fed to a trip bistable. This input is combined with the output of a reactor building pressure bistable; the trip of either pressure bistable trips the output. This output signal, combined with those of the other two pressure logic signals, engages the SFAS should two out of three trip. Reactor building spray is also initiated using two out of three logic, but is based only on reactor building pressure. In addition, the reactor building spray is delayed five minutes from the time of actuation.

Certain features are bypassed when the system is normally depressurized. These include high pressure injection, low pressure injection, reactor building isolation and reactor building cooling. Bypass must be initiated at an RCS pressure of less than 1850 psig (12.76 MPa); the system is automatically reinstated when the pressure exceeds 1850 psig (12.76 MPa).

High pressure injection system

The high pressure injection (HPI) system provides water to the RCS during a loss of coolant accident (LOCA). It is designed to prevent core uncover in the event of a small RCS leak, during which the RCS pressure remains elevated, and to delay core uncover in the event of an intermediate size break. The HPI system is activated by the SFAS signal when RCS pressure decreases to 1600 psig (11.03 MPa) or when reactor building pressure increases to 4 psig (27.6 kPa).

The HPI system consists of three pumps, a common discharge header and four lines that are equipped with motor operated isolation valves leading to the four cold legs. One HPI pump operates continuously to provide water for the reactor coolant pump seals. Two pumps are always available for automatic safety injection. The SFAS signals activate both pumps and their auxiliary equipment. The system also opens the four isolation valves to preset throttled positions to produce 125 GPM (7.89 l/s) per line using either of the two HPI pumps.

The HPI system is designed redundantly. Either pump is sufficient to meet the system requirements. The pumps are located in separate rooms and draw

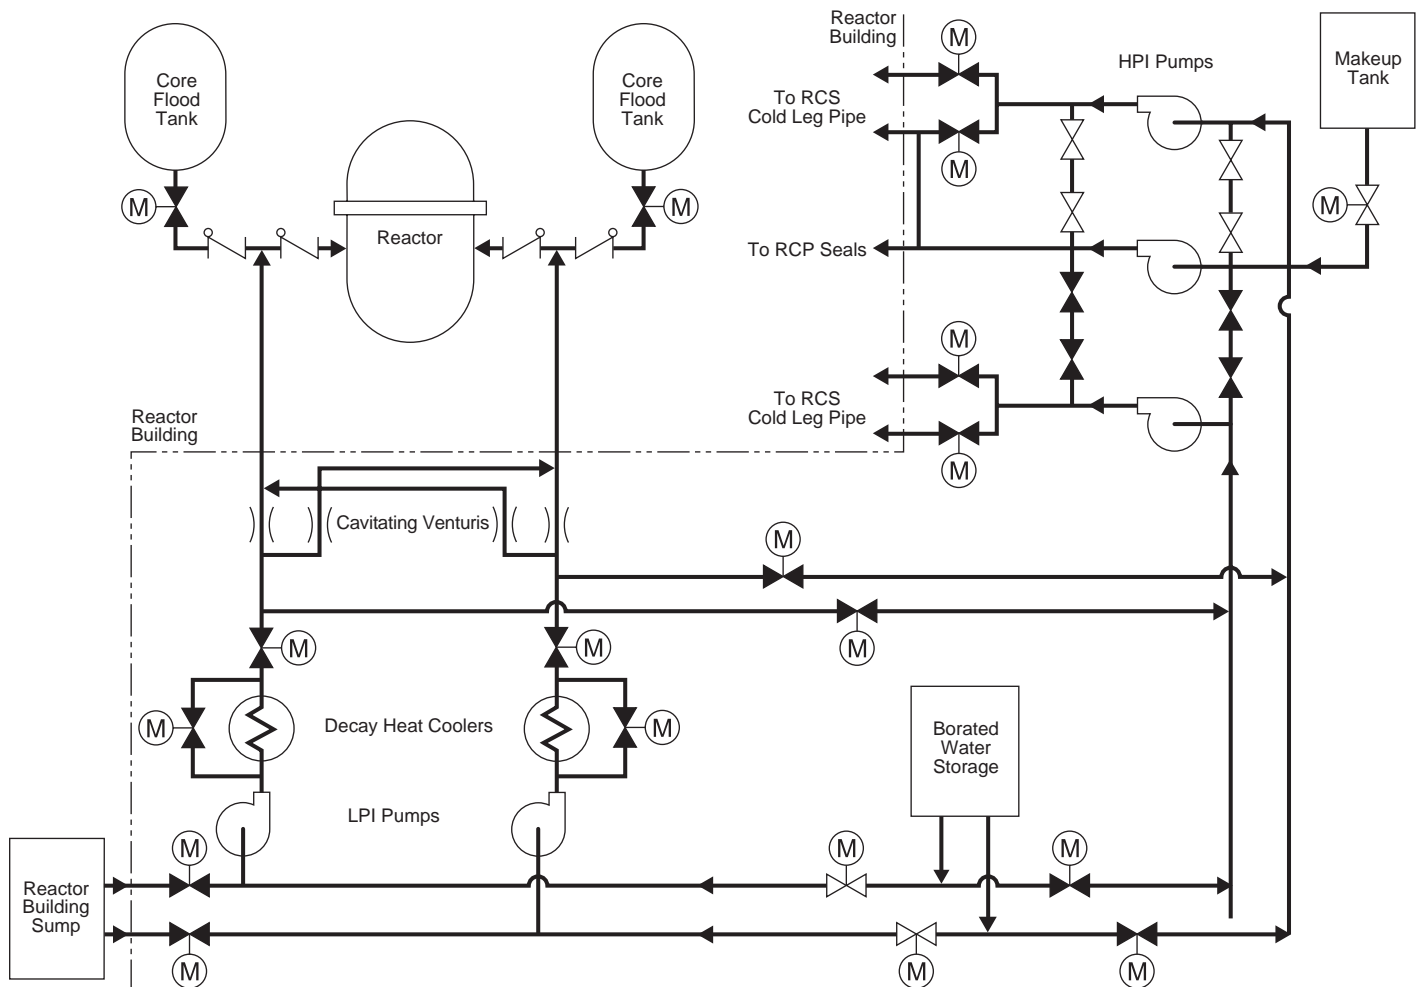

Fig. 23 Emergency core cooling/injection system.

water from the borated water storage tank (BWST) through separate lines. The SFAS channels are physically separated. The HPI pump and valve power supply lines are independent, physically separated and energized from independent power sources. The SFAS also activates the emergency diesel generators that provide backup power to the HPI system.

HPI fluid enters each RCS cold leg midway in the down-sloping piping run at the reactor coolant pump discharge. The fluid enters horizontally at the side of the cold leg pipe. The HPI nozzles are equipped with sleeves to minimize the thermal stress caused by the cold water injection.

The HPI system can be used during normal operation as part of the makeup and purification system. Either HPI pump can supply RCS makeup and seal injection flow to the reactor coolant pumps; these functions are normally performed by the makeup pump.

Low pressure injection system

The low pressure injection (LPI) system provides water to the core in the event of a large LOCA which depressurizes the RCS. The two LPI pumps discharge 3000 GPM (189.2 l/s) each at a rated head of 350 ft (106.7 m). [Shutoff head is 435 ft (132.6 m).] The borated water storage tank (BWST) supplies the LPI

pumps. The pumps are actuated independently and automatically by the SFAS signal, as are the four motor operated isolation valves. They discharge to the reactor vessel upper downcomer through two core flood nozzles.

The two BWSTs have a capacity of 450,000 gal (1,703,430 l) each. The boron concentration is maintained above 1800 ppm at 80F (27C). The storage tank inventory provides at least 30 minutes of operation of all ECCS pumps. When the BWST inventory is depleted, the LPI pumps are manually transferred to the reactor building emergency sump, which collects water lost from the RCS. In the event that the HPI pumps are still required, such as with RCS pressure higher than the LPI pump shutoff head, the HPI pumps can be realigned to draw from the discharge of the LPI pumps. This is referred to as piggy-back operation.

Core flood system

The core flood system provides a passive water supply to the core in the event of a large break loss of coolant accident. The system consists of two tanks, associated piping and valves. Each tank has a volume of 1410 ft³ (39.9 m³). Approximately two-thirds of this volume, or 7500 gal (28,391 l), is borated water; the remainder is nitrogen gas pressurized to 600 psig (4.14 MPa). Should the RCS depressurize to less than

600 psig (4.14 MPa) in the event of an LBLOCA, the nitrogen cover gas forces the core flood tank (CFT) water into the RCS. The boron concentration of the CFT water is maintained between 2270 and 3490 ppm.

Each CFT discharges through 14 in. (356 mm) lines, dual check valves and a core flood nozzle into the upper downcomer of the reactor vessel. The two CFTs use separate piping and nozzles. Each tank is equipped with a motor operated isolation valve to prevent tank discharge when the RCS is normally depressurized. These valves are open when the RCS is pressurized.

Reactor building cooling and spray systems

The reactor building emergency cooling and spray systems are actuated in the event of a loss of coolant accident. The spray system also reduces the post accident level of fission products in the reactor building atmosphere through chemical reaction. The systems are designed such that either one can offset the heat released by the escaping reactor coolant.

The systems are activated by the SFAS signals. The emergency cooling system is actuated within 35 seconds after the RCS pressure decreases to 1600 psig (10.03 MPa) or the reactor building pressure increases to 4 psig (27.6 kPa). The emergency spray system is actuated 5 minutes after the reactor building pressure reaches 30 psig (206.8 kPa). Both systems can also be actuated manually.

The reactor building emergency cooling system includes four units, each consisting of an air circulator and a cooling coil. The 40,000 ft³/min (18.9 m³/s) circulators draw air from a point high within the reactor building dome and discharge downward toward the cooling units. Two of the four units are equipped with activated charcoal filters for removing fission products. The cooling units reject heat to the nuclear service cooling water system.

The reactor building emergency spray system includes two spray trains, each consisting of a pump, spray header, spray additive tank and eductor and associated isolation valves, piping and controls. The pumps are supplied from the BWST and, later in an accident, from the reactor building emergency sump.

The 300 hp (224 kW), 1500 GPM (94.6 l/s) spray pumps discharge through the spray additiveeductors, drawing in sodium hydroxide. The spray additive concentration is sufficient to bring the entire post-accident inventory of reactor building water to a pH of 9.3. The spray discharge is distributed through 100 spray nozzles per header that are arranged to provide a uniform spray throughout the reactor building, above the operating floor.

Decay heat removal system

The RCS is periodically cooled and depressurized for maintenance and refueling. The first portion of the cooldown is accomplished by circulating the primary coolant using reactor coolant pumps and by removing heat using the steam generators. This method becomes impractical as the RCS pressure is reduced towards the net positive suction head (NPSH) of the reactor coolant pumps and as the primary to secondary system temperature difference diminishes.

The decay heat removal system (DHRS) is used to complete the RCS cooldown below 225 psig (1.55 MPa) and 290F (143C). The DHRS also performs the following functions:

1. purifies the reactor coolant during cold shutdown,
2. refills the RCS following maintenance,
3. cools and adds boron to the spent fuel pool, and
4. transfers water between the borated water storage tank and the fuel transfer canal during refueling.

The DHRS also functions as the low pressure injection system during a loss of coolant accident.

The DHRS is activated approximately six hours after reactor shutdown. It can reduce the RCS temperature from 280F to 140F (138 to 60C) within 14 hours. The DHRS pumps draw reactor coolant from the hot leg piping, just beyond the reactor vessel, through a 12 in. (305 mm) decay heat drop line. The DHRS fluid is discharged through coolers to the reactor vessel upper downcomer through the core flood nozzles. The injected DHRS fluid then follows the usual flow path down the reactor vessel downcomer, up through the core and out the hot leg to the DHRS inlet, thereby completing the flow circuit. The DHRS flow rate and rate of RCS cooling are controlled by bypassing a portion of the DHRS flow around coolers. The flow rate per cooler is limited to approximately 3000 GPM (189.2 l/s). The heat transferred in the coolers is removed by the nuclear service cooling water (NSCW) system, and the temperature difference between the RCS and the DHRS cooler outlet is maintained at approximately 30F (17C). The decay heat removal suction header temperature is measured to monitor RCS cooldown and the return header flow rates are also measured and remotely indicated. The DHRS suction block valve is interlocked to prevent inadvertent actuation at RCS pressures above 225 psig (1.55 MPa).

A portion of the DHRS flow rate can be diverted to the makeup and purification system for purifying the reactor coolant. This flow path is from the discharge of a DHRS pump; through the letdown filter, purification demineralizers and makeup filters; and back to a DHRS pump inlet header. The purification demineralizers are limited to a maximum fluid temperature of 135F (57C).

Makeup and purification system

The functions of the makeup and purification system are as follows:

1. control RCS inventory,
2. purify and degasify the reactor coolant,
3. maintain coolant boron concentration,
4. add chemicals to the reactor coolant for pH control,
5. supply seal injection flow to the reactor coolant pumps and handle seal return flow, and
6. add borated water to the core flood tanks.

The makeup and purification system can also function as part of the high pressure injection system.

The makeup and purification system consists of the letdown, purification and makeup portions. The letdown portion draws reactor coolant from the cold leg suction through a 2.5 in. (63.5 mm) line. The effluent

is cooled using one of the three letdown coolers. Radioactive nitrogen-16 is allowed to decay in the letdown delay line, a 15 ft (4.6 m) length of 12 in. (305 mm) piping. Depressurization and flow control are provided by the letdown orifice; the nominal flow rate of 45 GPM (2.83 l/s) may be increased to 140 GPM (8.83 l/s) by bypassing the orifice.

The flow rate of 45 GPM (2.83 l/s) processes one RCS volume daily. Letdown flow rate, temperature and pressure are measured. Multiple motor operated valves are used to isolate the system in the event of SFAS operation.

The purification portion of the system consists primarily of the letdown filters, mixed bed demineralizers and makeup filters. The demineralizers are provided temperature protection by temperature actuated isolation valves. The purified effluent may be directed to the makeup tank or diverted to the bleed tanks when reducing the RCS fluid inventory.

The 4400 gal (16,657 l) makeup tank is central to the makeup and purification system. It receives purified letdown flow and seal return flow. It also serves as the point of boron and hydrogen addition to the RCS. Boron is used for reactivity control, lithium hydroxide provides pH control and hydrogen or hydrazine is used for oxygen control. The makeup tank acts as a surge tank to accommodate temporary changes of RCS inventory and provides water for the makeup pump. Finally, it can be used to degasify the reactor coolant.

A 4 in. (101.6 mm) line connects the makeup tank to its pump, with cross connects to the HPI pumps. The pump discharges are recombined and a 2.5 in. (63.5 mm) diameter flow line is routed back to the seal return coolers to cool the operating pumps. The makeup flow rate is measured and remotely indicated and is controlled by the pressurizer level control valve. Makeup is injected into the RCS through the cold leg HPI nozzle at the reactor coolant pump discharge, thereby completing the flow circuit.

During power operation, the makeup and purification system operates continuously to regulate RCS inventory. The makeup flow control valve is adjusted automatically to maintain pressurizer level. The flow rate of the makeup pump is the sum of the makeup flow rate (to the RCS), the seal injection flow rate to the reactor coolant pumps and the makeup pump recirculation flow rate. The net makeup system flow rate to the RCS is the sum of the makeup and the seal injection flow rates, less the seal return flow rate.

Abnormal transient operating guidelines

The abnormal transient operating guidelines (ATOG) represent a symptom-oriented response to plant transients. These guidelines provide the operator with a clear and effective method of correcting abnormal conditions. ATOG involves the identification and correction of key upset conditions, regardless of their cause. These actions alone are sufficient to ensure core cover and cooling and to ensure plant safety.

The three key symptoms of ATOG are loss of subcooling margin, inadequate heat transfer and excessive heat transfer.

The subcooling margin refers to the difference between the saturation temperature at RCS pressure and an RCS temperature. A positive subcooling margin ensures that the core is covered and therefore cooled. A loss of subcooling margin, on the other hand, indicates steam generation within the RCS and may indicate core uncover. The operator must take action to restore the subcooling margin, such as by activating HPI pumps or a primary system heat removal process.

Subcooling margin is the key ATOG indicator. However, inadequate or excessive heat transfer indications must also be remedied. Inadequate heat transfer is countered by restoring primary to secondary system cooling and/or by initiating HPI-PORV cooling. In the latter method, core decay heat is removed by actuating full HPI and the PORV. The HPI fluid flows into the cold leg discharge piping leading to the reactor vessel. It flows through the core, out the hot leg, into the pressurizer through the surge line and out the PORV. Excessive heat transfer is remedied by reducing the rate of primary to secondary system heat transfer. This can be done by throttling the flow of auxiliary feedwater to the steam generators, restoring steam generator secondary pressure and reducing the primary to secondary temperature difference.

Exclusive among the events that can give rise to abnormal ATOG symptoms is the steam generator tube rupture (SGTR) accident. This event is readily identified using radiation indications and alarms and indications of steam generator conditions: pressure, temperature and level. Event oriented operator actions are taken to minimize radiation release and to ensure core cooling.

NSSS design: today and in the future

There are currently 103 operating, fully licensed nuclear power reactors in the United States representing 97.5 GW of capacity and generating 780 billion kWh in 2002, or 20% of the total U.S. generation.^{2,3} These 103 NSSS units fall into one of three categories:

	No.	MW
Pressurized Water Reactor (PWR)		
Recirculating Steam Generator (RSG)	62	59,793
Once-Through Steam Generator (OTSG)	7	5,915
Boiling Water Reactor (BWR)	34	31,792
Total	103	97,500

As of May 2004 there were 440 operating nuclear power systems worldwide with a capacity of 362 GW producing approximately 16% of global electricity generation.^{4,5} More than 30 new plants are under construction.⁶ As discussed in the introduction to this chapter, commercial NSSS designs outside of the U.S. fall into one of six general categories:

1. PWR – RSG
2. PWR – OTSG
3. BWR
4. PHWR (pressurized heavy water reactor, including the Canadian CANDU design)
5. GCR (gas-cooled reactor)
6. FBR (fast breeder reactor)

As with the PWRs, the PHWR, GCR and FBR also include steam generators to provide a heat sink for the

primary side reactor coolant system and to generate steam for the secondary side power cycle. The PHWR system steam generators are very similar in design to the PWR recirculating steam generators. (See Chapter 48.) In particular, 33 Canadian CANDU PHWR systems with 21 GW of capacity are in operation in Canada, India, Pakistan, China, Argentina, Romania and South Korea. An additional 18 units (48 GW) in India are based upon the CANDU technology.

The current (second) generation of nuclear power plants in the U.S. has demonstrated decades of safe and reliable performance. Continual improvements have been made in maintenance and operation. In the past 20 years, the average capacity factor has increased from about 60% to more than 90%. This significant increase translates into an additional 23,000 MW of power to the grid – the equivalent of 23 new plants. Production costs (fuel, operations and maintenance) of most plants are less than US\$0.02/kWh, and in the best plants about \$0.01/kWh. The proven reliability has resulted in 25 of the current operating plants being granted licenses to continue operations for another 20 years beyond their original license period.

Despite this excellent performance, no new nuclear plants have been ordered in the U.S. for the past 26 years, although design of a third generation of nuclear systems, commonly designated Generation III, has proceeded. The key attributes of these new designs are:

1. simple and more rugged making these more resistant to upsets and easier to operate,
2. standardized to reduce cost and schedule,
3. increased availability,
4. extended design life (approximately 60 years),
5. reduced possibility of core meltdown accidents,
6. minimized environmental impact,
7. enhanced fuel burn-up to reduce waste, and
8. extended fuel life.

The most significant change has been the incorporation of passive or inherent safety features which do not require operator or control system intervention to avoid accidents if equipment malfunctions. These systems may include gravity assisted flow, natural circulation within and between components, and resistance to deterioration at elevated temperatures. Most of these NSSS designs (including PWRs, BWRs, PHWR/PWR hybrid, high temperature GCR) are evolutionary from the existing second generation systems. These systems are being introduced in other countries with two in operation by 2003 and others being built or ordered.

Beyond the Generation III designs, a number of countries including the U.S. have formulated a general agreement to explore the potential of several more revolutionary designs, designated Generation IV. Introduction of these new designs may be feasible starting around 2020. In addition to further improving the key attributes of the Generation III designs, the Generation IV designs will try to offer some radical new approaches to solve future energy needs and resolve environmental concerns. The new designs will employ fast cores and coolants that allow a marked increase in operating temperatures. The high temperatures

can be used for chemical processes, including production of low cost hydrogen. The advanced fuel cycles can be arranged to extract more energy from the spent fuel and also to drastically reduce the toxicity of high level waste.

Nuclear ship propulsion

Nuclear power for propulsion has been applied to both commercial and naval vessels beginning with the U.S.S. *Nautilus*, the world's first nuclear ship (see Fig. 24). The development of nuclear ship propulsion also formed the basis for commercial pressurized water reactors (PWR) for land-based electric power generation. For submarines, nuclear propulsion has proven to be the greatest single advancement in post-World War II technology. This dramatic achievement virtually abolished range limitations and enabled the submarine to become a true submersible, freed from the need to make regular forays to the surface to recharge batteries.

Nuclear power has also proven extremely valuable for naval surface ships such as aircraft carriers and escort vessels. While the advantages are not as readily apparent as for submarines, the unlimited, sustained power available with nuclear propulsion allows the ship commander to devote his full attention toward effectively executing his mission without the continuous logistical concern for fuel oil supplies.

While any type of reactor system may be used for ship applications, only the PWR and the sodium-cooled reactor have been used. Of these, the PWR is the predominant system. A typical PWR schematic arrangement for shipboard application is shown on Fig. 25.

Fig. 24 Launching of the U.S.S. *Nautilus*, the world's first nuclear powered ship.

Fig. 25 Pressurized water reactor system – naval type.

There are important differences between shipboard reactors and land-based installations. These differences involve weight and space limitations, plant reliability and on-board maintenance, plant safety, and problems inherent with a moving platform. While the weight and size of the nuclear reactor itself does not present a problem, the weight and size of the radiation shielding around the NSSS is significant. These considerations usually dictate a more compact arrangement of the major components, as compared to land installations. However, the need to account for maintenance requirements forces the designer to balance compactness against access needs. Because access to ship units is more limited, reliability of shipboard components assumes even greater importance.

Safety is, of course, a major consideration. Shipboard nuclear plants are more subject to external hazards than land-based plants, particularly for naval units that may be exposed to extreme battle shock conditions. In the early stages of development, com-

mercial ships showed promise. However, the public fear of accidents, especially with ships in harbor, essentially has prevented any further exploration of commercial ship installations. On the other hand, the U.S. Navy has maintained an excellent performance and safety record over the years, and U.S. naval ships are welcomed in major ports throughout the world.

Commercial nuclear ships

In the 1950s, several countries became interested in applying nuclear power to commercial shipping. These efforts resulted in the launching of the U.S. ship *N. S. Savannah* and the soviet ice-breaker *Lenin*. Later in the 1970s, Germany launched the *N. S. Otto Hahn* and Japan launched the cargo ship *N. S. Mutsu*. Fig. 26 is a schematic diagram of a typical marine propulsion plant.

Nuclear merchant ship *Savannah*

A nuclear merchant ship was first proposed by President Dwight D. Eisenhower in 1955, as evidence of the U.S.'s interest in promoting the peaceful use of atomic energy. After Congress approved the funding in 1956, the President directed the AEC and the Maritime Administration (MARAD) to design and construct the vessel that was subsequently named the *Savannah*.

The program's major objectives were to demonstrate the peaceful use of nuclear energy and resolve the problems of commercial marine reactor operation. Plant requirements included a conservative design with a long core life, use of commercially available materials and equipment wherever practical, and safety of operation.

The *Savannah* (Fig. 27) was a single-screw, geared turbine vessel, 595 ft (181.4 m) long, with a beam of 78 ft (23.8 m), draft of 29.5 ft (9 m), and a displacement of 21,900 t (19,867 t_m). The ship had a design speed of 22 knots (40.7 km/h) at 22,000 shaft hp (16,412 kW), accommodations for 60 passengers and 652,000 ft^3 (18,463 m^3) of cargo space.

Fig. 26 Shipboard nuclear propulsion system.

Fig. 27 N.S. *Savannah* – first nuclear merchant ship.

B&W supplied the PWR nuclear propulsion plant and auxiliaries (see Fig. 28) for the *Savannah* and trained the operating crew. Pertinent design data for the power plant are given in Table 1.

The keel of the *Savannah* was laid in 1958, and the ship was launched 14 months later. In 1962, the ship was delivered to the operating agent, and port visitations began. The *Savannah*'s reactor was fueled by 15,653 lb (7100 kg) of uranium enriched to an average of 4.4% uranium-235. On her first fuel core, the *Savannah* traveled approximately 330,000 mi (531,089 km) and developed 15,000 full power hours with no shuffling of fuel. By late 1970, the *Savannah* had traveled more than 450,000 mi (724,205 km), visited 32 different U.S. ports in 20 states and 45 different foreign ports in 27 countries, and had been visited by more than 1,500,000 people.

The operation of the *Savannah* provided technology for future development of nuclear ships, and established standards for the design of the ship and reactor, operating practices and safety. After completing her mission, the *Savannah* was retired and is now a museum ship located in Charleston, South Carolina.

Nuclear merchant ship *Otto Hahn*

After building the N.S. *Savannah* reactor, B&W developed an improved nuclear marine plant known as the Consolidated Nuclear Steam Generator (CNSG). The CNSG was designed to achieve more economic nuclear propulsion systems for merchant ships, and has potential application for small- to medium-sized land-based plants.

The CNSG design incorporates the reactor and once-through steam generators within a single pressure vessel, achieving a compact arrangement and eliminating some of the auxiliary equipment.

The CNSG design was used successfully for the nuclear plant of the German N.S. *Otto Hahn* (Fig. 29). This ship was a single-screw geared turbine ore carrier 565 ft (172.2 m) long, with a beam of 77 ft (23.5 m), a draft of 30 ft (9.1 m), dead weight of about 15,000 t (13,608 t_m) and a design speed of 16 knots (30 km/h) at 10,000 shaft hp (7460 kW).

The nuclear plant for this ship was designed and

constructed by the German-Babcock Interatom consortium with the assistance of B&W. A cross-section of the pressure vessel for the power plant is shown in Fig. 30. Pertinent design data for the power plant at normal load are given in Table 2. The *Otto Hahn* began commercial service in 1970, and was decommissioned in 1978.

Naval nuclear ships

U.S. naval nuclear propulsion program

Background In 1946, the U.S. Navy's Bureau of Ships recognized that atomic energy might ultimately be developed for ship propulsion. Under the direction of Captain (later Admiral) Hyman G. Rickover, a team was established to transform existing theory and concepts into practical engineering designs.

The basic requirements for applying nuclear power to shipboard propulsion were clear. The reactor would have to produce sufficient power so that the ship would have military usefulness, and it would have to produce that power safely and reliably. The reactor plant would have to be rugged enough to meet the stringent requirements of a combatant ship, and be

Fig. 28 N.S. *Savannah* nuclear steam supply system arrangement.

Table 1
N.S. Savannah

Power plant design data:	
Maximum shaft power	22,000 hp (16,412 kW)
Reactor power	70 MW
Total steam flow	226,000 lb/h (28.5 kg/s)
Turbine inlet pressure	430 psi (2.96 MPa)
Feedwater temperature	340 F (171C)
Reactor coolant data:	
Pressure in reactor	1735 psi (11.96 MPa)
Temperature in core	508 F (264C)
Flow	9,400,000 lb/h (1184.4 kg/s)

designed for operation by a Navy crew. A suitable reactor would require new corrosion resistant metals that could sustain prolonged periods of intense radiation, effective shielding to protect personnel from radiation, and the development of new components that would operate safely and reliably for prolonged time periods.

These problems were even more difficult for submarine applications because the reactor and associated steam plant had to fit within the confines of a small hull, and be able to withstand extreme battle shock. Although the application of nuclear power to submarines was a major challenge, success would revolutionize submarine warfare. No longer limited to submerged operation on battery power, a true submarine was possible, one that could travel submerged at high speed for long periods. Because of the immense challenge posed by this revolutionary approach, the Navy established extremely rigorous guidelines covering design, fabrication, quality, testing, and training for the suppliers and Navy personnel. These new guidelines demanded significant improvements in performance from all involved parties and established the design and engineering philosophy which underlies the basis of the commercial and Naval nuclear industry today.

Three reactor concepts were initially considered for naval nuclear propulsion. A study of a gas-cooled reactor showed that this concept was not then suitable. The pressurized water reactor and liquid metal-cooled

Fig. 30 Reactor vessel cutaway (N.S. Otto Hahn) (courtesy of Gesellschaft für Kernenergieverwertung in Schiffbau und Schifffahrt mbH).

reactor approaches were found promising and carried through to full scale prototype plants, and thereafter to shipboard applications. B&W became actively involved in both designs.

U.S.S. Nautilus

In 1949, the U.S. Navy's Chief of Naval Operations issued a formal requirement for the development of a nuclear powered submarine. The following year, the U.S. Congress authorized funds for a land-based prototype of the pressurized water reactor that would power the world's first nuclear powered ship. B&W was

Fig. 29 N.S. Otto Hahn (courtesy of Gesellschaft für Kernenergieverwertung in Schiffbau und Schifffahrt mbH).

Table 2
German N.S. Otto Hahn

Power plant design data:	
Shaft power	10,000 hp (7460 kW)
Reactor power	38 MW
Total steam flow	141,000 lb/h (17.8 kg/s)
Superheater outlet press.	440 psi (3.03 MPa)
Superheater outlet temp.	523 F (273C)
Feedwater temp.	365 F (185C)
Reactor coolant data:	
Pressure in reactor	918 psi (6.33 MPa)
Temp. in reactor core	523 F (273C)
Flow	5,280,000 lb/h (665.3 kg/s)

selected to provide major reactor system components. Just three years later, the prototype began operation and for the first time, a reactor produced sufficient energy to drive power machinery.

On January 17, 1955, the *Nautilus* (Fig. 31) put to sea for the first time and radioed her historic message: “underway on nuclear power.” On her shakedown cruise, the *Nautilus* steamed submerged more than 1300 mi (2092 km) in 84 hours – a distance that was 10 times greater than had been traveled continuously by a submerged submarine.

Within months, the *Nautilus* would break virtually every submarine speed and endurance record. Her global odyssey carried her under the seven seas, and on the first voyage in history across the top of the world, passing submerged beneath the North Pole.

On her first fuel core the *Nautilus* steamed more than 62,500 mi (100,584 km), more than half of which were totally submerged. During 25 years of service, she traveled a total of 600,000 mi (965,606 km) on nuclear energy, making the dream of Jules Verne come alive. The *Nautilus* is now a historic museum ship and is located in New London, Connecticut.

The *Nautilus* was the first application of a reactor power plant using pressurized water both as the primary coolant and as the heating fluid for converting the secondary water into steam. The recirculating steam generator (Fig. 32) was comprised of a straight tube and shell heat exchanger with riser and downcomer pipes connected to a separate steam drum. B&W designed and fabricated the prototype test steam generator, and the reactor vessel and pressurizer for the *Nautilus*.

U.S.S. *Seawolf*

The U.S.S. *Seawolf*, the second U.S. nuclear submarine, was launched in 1955, and her liquid metal-cooled reactor attained initial criticality in 1956. To help ensure tube integrity, the *Seawolf*'s sodium-heated steam generators (Fig. 33) utilized sodium-potassium as a third or monitoring fluid in the annulus of the double-tube design. Although the ship operated satisfactorily for almost two years on its sodium-cooled reactor, overriding technical and safety considerations (mainly the potential for violent reaction between sodium and water) led to the abandonment of this type of reactor for propelling U.S. naval ships.

Fig. 31 U.S.S. *Nautilus*.

Fig. 32 U.S.S. *Nautilus* steam generator.

While liquid sodium is a much more efficient heat transfer medium than water, it can be very troublesome in service. Two problems are particularly noteworthy: the sodium has to be kept molten at all times or it will solidify and can damage primary system piping, and the sodium must be kept isolated from water to prevent a violent reaction.

In 1958, the *Seawolf* entered a shipyard where her sodium-cooled plant was replaced with a pressurized

Fig. 33 Sodium-heated steam generator for U.S.S. *Seawolf*.

water reactor similar to that in the *Nautilus*. When her sodium plant was shut down for the last time, the *Seawolf* had steamed a total of 71,611 mi (115,247 km) of which 57,118 mi (91,923 km) were fully submerged.

U.S.S. Skipjack

The U.S.S. *Skipjack* attack submarine class combined the PWR plant with a streamlined *Albacore* hull shape to provide increased speed and reduced flow noise. In 1956, B&W received a contract for the design and fabrication of steam generators for the *Skipjack*. These were the first vertical recirculating PWR steam generators with integral steam separators and were the forerunner to the recirculating steam generator designs in current commercial PWR (non-B&W) plants and in CANDU reactor plants.

Technological advancements

Each new naval propulsion plant is a balance between the desire to make technological advances and a commitment to deliver a reliable fighting ship on schedule. Each new design can incorporate only a portion of all the potential improvements in technology. The ultimate success of any power plant design will depend on how well that balance is achieved.

In developing power plant components for modern naval vessels, improvements have been made in thermal hydraulic design, materials, structural design, and fabrication. Significant improvements in the art of steam-water separation have contributed greatly to the performance and compactness of naval steam generators.

Significant advances have also been made in reactor fuel technology. Reactor fuel lifetime has been extended from 2 years for the first *Nautilus* core, to more than 15 years for cores delivered in the 1980s. Efforts have been underway to develop reactor fuel that will last the life of the ship, making expensive and time consuming refueling unnecessary.

While much research has been done in the U.S. and in other countries on alternate forms of submarine power production, such as magnetohydrodynamics and fuel cells, nuclear power has proven to be highly reliable, safe and cost effective, and continues to be the system of choice for the U.S. Navy and other international fleets for the foreseeable future.

International naval nuclear programs

All of the principal maritime nations have studied the application of nuclear power to naval ship propulsion. The U.S., Great Britain, France, the People's Republic of China, and the FSU have built nuclear vessels. These nations all have naval nuclear fleets that rely primarily on pressurized water reactor technology. However, the Soviet Navy reportedly utilizes liquid metal cooled reactors in at least one attack submarine class for higher power output and greater operational speeds.

The Soviet *Typhoon*-class ballistic missile submarine (Fig. 34) is the largest submarine type ever built with a length of 563 ft (171.6 m) and a submerged

displacement of 26,500 t (24,041 t_m). The Soviets' titanium-hulled *Alfa*-class attack submarines are reportedly the world's fastest and deepest diving with a speed of 45 knots (83 km/h) and an operational depth of 2500 ft (762 m).

Nuclear ship development is proceeding in other countries. The FSU is continuing development of new attack and missile submarines. The overall picture is somewhat unclear due to the economic conditions in the FSU and also because of continued safety issues, particularly in the aftermath of the sinking of the *Kursk* submarine in 2000. Both issues have led to a marked downturn in Soviet ship deployment. China has been developing new attack and ballistic missile nuclear submarines based on early Soviet designs. India is trying to develop a nuclear ballistic missile submarine.

Future U.S. Navy

The U.S. Navy has the largest nuclear fleet in the world, comprising 72 submarines and 10 aircraft carriers. In line with the ever changing situation in the world, the naval strategies and ship requirements are constantly evolving to meet the perceived global issues. Ship designs and power propulsion systems are constantly upgraded to meet the navy needs and to incorporate the newest technological advances.

Submarines

With the demise of the Cold War, the need for a large contingent of ballistic missile submarines has greatly diminished and strategy is now more focused on providing multi-purpose submarines with a broad range of missions. The U.S.S. *Virginia* (SSN774) is the first of a new class of attack submarines intended as a more cost-effective follow-on to the current *Seawolf* class. The ship is capable of both deep ocean

Fig. 34 Soviet *Typhoon*-class ballistic missile submarine.

warfare and shallow water operations of all types. Missions of the new ship include anti-submarine warfare, covert operations, personnel delivery, intelligence gathering, convert mine warfare, and Battle Group Support. The Virginia displaces 7800 tons and is 370 feet long. Fig. 35 shows a Virginia-class submarine under construction.

Aircraft carriers

In 2006, the U.S.S. *George W. Bush* will be the last of the Nimitz-class carriers to be built (see Fig. 36). Construction of a new class of carrier, the CVN 21 with 100,000 ton displacement, will begin at Newport News Shipbuilding in 2007 for delivery in 2014. The

new ship will incorporate a new design of nuclear power plant, expanded flight deck, and a new electrical power distribution system. The new power plant will greatly increase the electrical power supply enabling the deployment of an electromagnetic aircraft launch system and offering scope for advancements in new electromagnetic weapons systems. The power plant and related equipment are designed to reduce maintenance and provide substantial reduction of personnel required to operate and staff the ship.

Fig. 35 Virginia-class submarine nears completion.

Fig. 36 U.S.S. *Nimitz* and U.S.S. *Ronald Reagan* are part of the current Nimitz-class aircraft carrier group.

Chapter 47

Fundamentals of Nuclear Energy

Fundamental particles and structure of the atom¹

In the fifth century B.C. Greek philosophers postulated that all matter is composed of indivisible particles called *atoms*. Over the next 24 centuries there were many speculations on the basic structure of matter but all theories lacked any experimental basis. It was not until late in the nineteenth and early twentieth centuries that the existence of fundamental particles, the *proton*, *neutron* and *electron*, was confirmed.

The discovery of nuclear fission, credited to Otto Hahn, Lise Meitner and Fritz Strassman, was made possible through an accumulation of knowledge on the structure of matter beginning with Becquerel's 1896 detection of radioactivity.

As shown in Fig. 1, the structure of an atom is pictured as a dense, positively charged nucleus surrounded by an array of negatively charged electrons. Each proton, the equivalent of a hydrogen atom nucleus, carries an elemental positive charge of electricity. The number of protons determines the type of chemical element of the atom. Each neutron is an electrically neutral particle with a mass slightly greater than the proton. Because of their association with the nucleus of the atom, protons and neutrons are also referred to as *nucleons*. Each electron shown orbiting around the nucleus has an elemental negative charge and a mass about 1/2000 that of a proton. The nucleus of an atom with a characteristic number of neutrons and protons is called a *nuclide*.

Despite the minute size of the atom, there is a relatively great distance between the nucleus and the orbiting electrons. This distance, approximately 10^5 times the dimension of the nucleus, accounts for the ability of various radiations to pass through apparently dense materials.

Fig. 1 also indicates the relationship of the positively charged protons in the nucleus and the negatively charged electrons. In the un-ionized state, the number of protons is balanced by an equal number of electrons. An atom becomes ionized by gaining or losing one or more electrons. A gain of electrons yields negative ions and a loss results in positive ions. An atom in an ionized state can interact with other elements to form various compounds.

When an atom has more than two electrons, their orbits are located in a series of separate and distinct groupings of energy levels or *shells*. Each shell is capable of containing a specific number of electrons. In

general, an inner shell fills to its maximum number of electrons before electrons begin to form in the next shell. An x-ray is a quantum of electromagnetic energy that is emitted when an electron transitions from an outer shell to an inner shell or between energy levels within the same shell.

The number of electrons in the outermost shell determines certain chemical properties of the elements. The properties are similar for elements which have similar electron distributions in the outer shell regardless of the number of inner shells. This accounts for the repetition of chemical properties in the Periodic Table of the Elements. (See Appendix 1.)

Nuclides and isotopes

A nuclide is characterized by its atomic number Z (number of protons in the nucleus) and the mass number A (total number of protons plus neutrons). When nuclides are described by chemical symbol, the atomic

Fig. 1 Structure of the atom (Z = atomic number; A = mass number).

number is the left hand subscript and the mass number the right hand superscript. For example, the α particle can be represented as α , ${}_2\alpha^4$, or ${}_2\text{He}^4$. With most chemical elements there are several types of atoms having different mass numbers, i.e., different numbers of neutrons in the nucleus but the same number of protons. An isotope is one of two or more nuclides of the same chemical element having different mass numbers.

Two isotopes of hydrogen and two isotopes of oxygen are depicted in Fig. 1. An ordinary hydrogen atom ${}_1\text{H}^1$, contains one proton and no neutrons. Its atomic number Z and mass number A are 1. It combines with oxygen to form H_2O or regular or light water. The deuterium atom, ${}_1\text{H}^2$ or ${}_1\text{D}^2$, has one proton and one neutron; Z is 1 and A is 2. It combines with oxygen to form D_2O or heavy water. A third isotope of hydrogen, tritium, ${}_1\text{H}^3$ or ${}_1\text{T}^3$, has one proton and two neutrons.

Heavier nuclides are also identified by chemical name and mass number. Oxygen-16 and oxygen-17 (Fig. 1) have 16 and 17 nucleons respectively, although each has eight protons. For example, symbols for the two isotopes of oxygen described above are ${}_8\text{O}^{16}$ and ${}_8\text{O}^{17}$.

Although either the atomic number or the chemical symbol could identify the chemical element, subscripts sometimes are useful in accounting for the total number of charges in an equation.

Mass

It is customary to list the mass of atoms and fundamental particles in atomic mass units (AMU). This is a relative scale in which the nuclide ${}_6\text{C}^{12}$ (carbon-12) is assigned the exact mass of 12 AMU by agreement at the 1962 International Union of Chemists and Physicists. One AMU is the equivalent of approximately 1.66×10^{-24} grams, or the reciprocal of the presently accepted Avogadro number, 0.602214×10^{24} atoms per gram-atom. A gram-atom of an element is a quantity having a mass in grams numerically equal to the atomic weight of the element.

Table 1 lists the masses of the fundamental particles and the atoms of hydrogen, deuterium and helium in atomic mass units.

Mass defect

The mass of the hydrogen atom ${}_1\text{H}^1$ listed in Table 1 is almost but not quite equal to the sum of the masses of its individual particles, one proton and one electron. However, the mass of a deuterium atom ${}_1\text{H}^2$ is noticeably less than the sum of its constituents – a proton, neutron and electron. Measurements show that the mass of a nuclide is always less than the sum of the masses of its protons, neutrons and electrons. This difference, the *mass defect* (MD), is customarily calculated as:

$$MD = Zm_h + (A - Z)m_n - m_e \quad (1)$$

where

- MD = mass defect, AMU
- Z = number of protons in the nucleus of the nuclide
- m_h = mass of the hydrogen atom, AMU
- $A - Z$ = number of neutrons in the nucleus

Table 1
Masses of Particles and Light Atoms

Isotope or Particle Mass, AMU	
Electron	0.000549
Proton, ${}_1\text{p}^1$	1.007277
Neutron, ${}_0\text{n}^1$	1.008665
Hydrogen, ${}_1\text{H}^1$	1.007825
Deuterium, ${}_1\text{H}^2$	2.01410
Helium, ${}_2\text{He}^4$	4.00260

m_n = mass of neutron, AMU

m_e = mass of the nuclide including its Z electrons, AMU

Binding energy

Although most nuclei contain a plurality of protons with mutually repulsive positive charges, the nucleus remains tightly bound together, and it takes considerable energy to cause disintegration. This energy, called *binding energy*, is equivalent to the mass defect. From the equivalence of mass and energy, as defined by Einstein's equation $E = mc^2$, one AMU equals 931 million electron volts (*MeV*). An electron volt is the energy gained by a unit electrical charge when it passes, without resistance, through a potential difference of 1 volt. Therefore,

$$\begin{aligned} &\text{Binding energy (MeV)} \\ &= \{ Zm_h + (A - Z)m_n - m_e \} \times 931 \end{aligned} \quad (2)$$

This represents the amount of radiant or heat energy released when an atom is formed from neutrons and hydrogen atoms. It also represents the energy which must be added to fission an atom into its basic nucleons, i.e., neutrons and protons.

Dividing Equation 2 by A , the number of nucleons in the nucleus, yields the binding energy per nucleon. This in turn can be plotted as a function of A , the mass number as shown in Fig. 2. The result shows that the binding energy per nucleon rapidly increases for low mass numbers, reaches a maximum for mass numbers in the range of 40 to 80, and then drops off with an increasing slope. On the rising portion of this curve, *fusion* or joining of nucleons to atoms of higher mass number means that there is an increased binding energy per nucleon and consequently a release of energy. On the falling portion of this curve, the *fission* process or splitting of an atom results in nuclides of lesser mass numbers and greater binding energy per nucleon. Again, energy is released because of the increased mass defect.

Radioactivity and decay

Nuclear radiations

Nuclides that occur in nature are stable in most cases. However, a few are unstable, especially those of atomic number 84 and above. The unstable nuclides

undergo spontaneous change at specific rates by radioactive disintegration or decay. Many nuclides decay into other unstable nuclides, resulting in a decay chain that continues until a stable isotope is formed.

There are generally three types of radiation commonly arising out of the decay of specific nuclides: alpha (α) particles, beta (β) particles and gamma (γ) rays.

Alpha particle The α particle is equivalent to the nucleus of a helium atom comprising two neutrons and two protons. It results from radioactive decay of an unstable nuclide and, with very few exceptions, is observed only in the decay of heavy nuclides.

Beta particle The β particle results from radioactive decay and has the same mass and charge as an electron. It is believed that the nucleus of an atom does not contain electrons and, in radioactive β decay, the β radiation arises from conversion of a neutron into a proton and β particle; therefore:

In some instances a positive β particle (called a *positron*) is produced from the conversion of a proton to a neutron.

Gamma ray Gamma rays are electromagnetic radiation resulting from a nuclear reaction. They can be treated like particles in many nuclear reactions and are included among the fundamental particles. Although γ rays have physical characteristics similar to x-rays, their energy is greater and wave length shorter. The only other difference between the two rays is that γ rays originate from within the nucleus while x-rays originate from within the shell structure of the atom.

Biological effects of radiation

The organs of the human body are composed of tissue which is composed of atoms. When electrons are knocked out of or added to atoms (ionized), the chemical bonds which bind atoms together to make molecules are broken. This process is called *ionization*. The recombination of these broken molecules can result in changes in the molecular structure of a cell which may affect the way the cell functions, its growth characteristics and its interaction with other cells. In cases

Fig. 2 Binding energy per nucleon versus mass number.

of high radiation exposure, cancer may result. The term used to describe the effects of radiation on humans is *biological damage*.

Ionization is a direct result of alpha and beta particles interacting with human tissue. These particles produce a continuous path of ionization as they travel throughout the body. Gamma radiation produces ionization indirectly in matter by the photoelectric effect, the Compton effect and pair production. All three processes yield electrons which in turn produce most of the ionization which occurs within the body.²

In the photoelectric effect, the γ ray transfers all its energy to the electron that it strikes. The electron then causes ionization in the medium. In the Compton effect, only part of the γ ray's energy is transferred to the electron as kinetic energy. The remaining energy gives rise to a lower energy γ ray. Pair production occurs when the γ ray has an energy greater than 1.02 MeV. All of its energy is given up and two particles, an electron and a positron, are produced. (All three processes produce electrons which then ionize the absorbing matter.)

Although ionization causes biological damage, the seriousness of the damage is determined by many factors such as the types of cells effected (how radiosensitive they are), the age of the person receiving the exposure (young cells are more radiosensitive) and whether the dose is received over a short (acute exposure) or long (chronic exposure) period of time.

Acute exposure is more detrimental because a large amount of damage is incurred rapidly and the cells do not have an adequate amount of time to repair themselves. Under chronic exposure, cells are very effective in repairing injury. The effects of chronic exposure and the amount required to produce damage have been extrapolated primarily from known cases of acute radiation exposure. More recent radiobiology laboratory and other studies have developed data which assess the effects of chronic exposure. As the nuclear industry continues, the database for low level occupational exposure grows and it becomes more evident that the associated risks are low. The data available suggest that the body can tolerate low doses of radiation received over long periods of time with little risk. This is supported by the exposure and health history of x-ray technicians, physicians and radiation workers. In many laboratory and historic exposure studies, beneficial effects of low level radiation are demonstrated. These studies certainly counter the argument that no level is low enough and that allowable levels must be endlessly reduced in the pursuit of safety.

Radiation protection

Alpha particles, due to their large mass and double positive charge, travel very short distances. Their range in air is only a few centimeters. Fig. 3 illustrates the penetration ranges of various types of radiation. Alpha particles are seldom harmful when the source is located outside the human body because an α particle of the highest energy will barely penetrate the outer layer of skin. If emitted inside the body, however, α radiation can be serious. It is important, there-

fore, to prevent the ingestion or inhalation of α emitting nuclides. Particular care is required to keep the air in working spaces free of dust containing α emitters. Fabrication of α emitters such as plutonium normally takes place inside gloveboxes that remain under a slight negative pressure. The boxes discharge air effluent through a filter designed to prevent α bearing dust from entering the working spaces and the atmosphere in general. The air is continuously monitored and analyzed.

Beta particles penetrate up to an inch of wood or plastic material and travel several yards in air. The skin and the lenses of the eye are most vulnerable to external β radiation. However, clothing and safety glasses provide adequate protection for external exposure to β radiation. The β particle is not as great an internal hazard as the α particle. The β particle, due to its smaller mass and lower charge, will travel farther than the α particle through tissue and will deposit less energy in a localized area.

Gamma rays penetrate deeply and deposit their energy throughout the entire body. They have great ranges in air and may present a hazard at large distances from the source; however, they do not present as large an internal hazard as α particles.

Neutrons, like gamma radiation, are an external hazard and their damage extends throughout the body. In addition, the effectiveness of neutrons to produce biological damage is 2.5 to 10 times greater than γ rays. The concrete and water shielding provide the primary protection against neutrons and gamma rays.

Decay rate

The rate at which a radioactive nuclide emits radiation is a characteristic of the nuclide and is unaffected by temperature, pressure or the presence of other elements that may dilute the radioactive substance. Each nucleus of a specific radioactive nuclide has the same probability of decaying in a definite period of time at a rate characterized by its radioactive decay constant. The rate of decay at any time, t , always remains proportional to the number of radioactive atoms existing at that particular instant. The decay is calculated by:

$$N(t) = N(0) e^{-\lambda t} \quad (3)$$

where

$$\begin{aligned} N(t) &= \text{the number of atoms per cm}^3 \text{ at time } t \\ N(0) &= \text{the number of atoms per cm}^3 \text{ at time zero} \\ \lambda &= \text{radioactive decay constant} \end{aligned}$$

Half life

Decay is usually expressed in terms of a unit of time called radioactive half life, $T_{1/2}$. This represents a measurable period of time, the period it takes for a quantity of radioactive material to decay to one half of its original amount. The relationship between half life and decay constant can be determined by substituting $(T_{1/2})$ for t and $N(0)/2$ for $N(t)$ in Equation 3 and solving for λ . The result is:

$$\lambda = \frac{0.693}{T_{1/2}} \quad (4)$$

Decay constants for radioactivity isotopes are easily obtainable with a listing of measured half lives.³

If $N(t)$ represents the number of radioactive atoms present at time t , then $\lambda N(t)$ becomes the number of radioactive nuclei that decay per unit of time at time t . This is referred to as the *radioactivity*, or more simply the *activity*, of the atoms and is expressed in *curies*. A curie is 3.70×10^{10} disintegrations per second. $N(t)$ can be converted directly to curies by the relation $N(t)/(3.70 \times 10^{10})$. Fig. 4 shows on a relative scale how the activity decreases during several half lives. This curve applies to all radioactive substances.

It is sometimes difficult to distinguish between stable and radioactive nuclides. All nuclides heavier than bismuth-209 (Bi-209) are unstable. However, the specific nuclides thorium-232 (Th-232), uranium-235 (U-235) and U-238 have half lives of 10^8 to 10^{10} years and can be considered stable. In fact, they are generally referred to as the stable isotopes of the heavier chemical elements. Table 2 shows half lives of some nuclides of high atomic number.

Induced nuclear reactions

By providing sufficient energy, all of the fundamental particles can be made to react with various nuclei. In this procedure, the particle strikes or enters an atomic nucleus causing a transfiguration or change in structure of the nucleus and the release of a quantity of energy. Particles which activate these reactions include neutrons, deuterons, α , β , protons, electrons and γ . Many reactions produce artificial radioactive nuclides.

Charged particles such as alphas, betas and protons do not have great penetration power in matter because the interaction with the existing electrical field within the atoms either slows or stops them. Collisions between like charged particles require exceedingly high kinetic energy. Electrical fields, however, can not deflect electrically neutral neutrons; therefore, they collide with nuclei of the material on a statistical basis. The neutron is therefore the most effective particle for inducing nuclear reactions including fission.

Reactions of principal interest in the design of nuclear reactors are those that involve neutrons and those that involve the interaction of the particles pro-

Fig. 3 Ranges of various types of radiation in materials.

Fig. 4 Exponential decay of radioactive nuclides.

duced by fission and other nuclear processes within the reactor and surrounding materials.

The expression:

is generally used to denote a nuclear reaction and is the short form for:

The X^* notation indicates formation of a compound nucleus which is generally unstable. Terms P_1 and P_2 represent incident and resultant particles respectively. The individual sum of the Z s (atomic numbers) and the sum of the A s (mass numbers) on the left side of the equation always equals, respectively, the sum of the Z s and the sum of the A s on the right side of the equation. (See Table 3).

Nuclear reactions always conserve total mass-energy on the two sides of the equation in accordance with Einstein's equation for the equivalence of mass and energy. However, there is usually an energy difference and

a mass difference. A good statistical probability for the reaction to occur exists when energy is released as a result of reaction. The more probable reactions generally can be initiated by lower energy particles. The less probable ones, those that require significant energy addition, can be initiated only by high energy particles. Table 3 gives some typical induced nuclear reactions.

In a nuclear reactor, many heavy nuclides with mass numbers greater than 238 are produced by a series of neutron captures accompanied by β and/or α decay. These artificially produced nuclides have many uses – some are readily fissionable, some are fertile because they absorb a neutron and then transmute to a fissionable nuclide, some have high energy α decay modes that can be used in neutron sources, and some are used as sources in medical procedures.

Probability of nuclear reactions – cross-sections

The probability of a nuclear reaction between a neutron, or other fundamental particle, and a particular nuclide is expressed as the *cross-section* for that reaction. The probability is dependent on the energy of the interacting particle. Because neutron interactions are most important in a nuclear reactor, the following discussion is directed toward neutron cross-sections; however, the concepts can be directly applied to all particle interactions.

Two types of nuclear cross-sections are defined:

1. The microscopic cross-section or interaction probability is an intrinsic characteristic of the nuclei of the material. It has dimensions of an area and is normally expressed in *barns* where one barn equals 10^{-24} cm².

Table 3
Typical Induced Nuclear Reactions

Table 2
Half Lives of Heavy Elements

	Decay Mode	Half Life
Naturally occurring nuclides:		
Thorium-232	α	1.39×10^{10} yr
Uranium-238	α	4.51×10^9 yr
Uranium-235	α	7.13×10^8 yr
Artificial nuclides:		
Thorium-233	β	22.1 min
Protactinium-233	β	27.4 d
Uranium-233	α	1.62×10^5 yr
Uranium-239	β	23.5 min
Neptunium-239	β	2.35 d
Plutonium-239	α	2.44×10^4 yr

- The macroscopic cross-section is a probability of interaction per centimeter of neutron path and takes into account the density of the material. It has the dimensions cm^{-1} .

The symbol σ represents the microscopic cross-section. In the case of a neutron approaching a fissionable atom it becomes possible to consider a total cross-section σ_T in which:

$$\sigma_T = \sigma_c + \sigma_s + \sigma_f = \sigma_a + \sigma_s \quad (6)$$

where

- σ_c = the capture cross-section, a measure of the probability for absorption without fission
- σ_s = the scattering cross-section, the probability that the nucleus will scatter the neutron
- σ_f = the fission cross-section (present in only a few of the many nuclei), the probability for a neutron to strike and cause a fission to occur
- σ_a = the absorption cross-section, the sum of the probabilities for capture and fission

The macroscopic cross-section can be obtained from:

$$\Sigma = N_0 \rho \sigma / M \quad (7)$$

where

- Σ = macroscopic cross-section, cm^{-1}
- N_0 = Avogadro's number, 0.602214×10^{24} atoms/gram-atom
- ρ = density of the material, grams/cm^3
- σ = microscopic cross-section, cm^2/atom
- M = atomic weight, grams/gram-atom

Experimental measurements determine microscopic cross-sections for each element. Total cross-section measurements are generally made by transmission techniques. For example, placing a material of known density and thickness in front of a neutron source permits measuring the intensity of neutrons at a particular energy on each side of the material. The difference represents the loss or attenuation of neutrons by the material. The cross-section required to obtain this attenuation is derived by calculation.

Isotopes of the same element can have very different cross-sections. For example, the isotope xenon-134 (Xe-134) has a microscopic cross-section for neutron absorption of about 0.2 barn, yet Xe-135 has a microscopic cross-section of 2.7×10^6 barns. U-235 is fissionable at any energy, and U-238 only at high energy.

Cross-sections of some nuclides also contain abrupt peaks called *resonances* at certain energy bands (Fig. 5). Because a cross-section is really a function of relative energy of the neutron and the nucleus, an effective change in the cross-section results when the energies of the neutron and the nucleus increase or decrease as a result of temperature changes.

Where the curve of cross-section versus energy is fairly smooth, the effect of a temperature change of the target nucleus is relatively small. However, the effect of a temperature change is large and important in the vicinity of a resonance. An increase in temperature results in increased vibration of the nucleus with

a corresponding increase in the number of probable collisions between the nucleus and neutron occurring at energies in the vicinity of the resonance. Therefore, an increase in the temperature of the nucleus results in an apparent broadening of the energy width of the resonance. This in turn results in a very effective increase in resonance neutron absorption, i.e., capture and fission. Conversely, a decrease in temperature of the nucleus results in narrowing the resonance width and decreasing resonance absorption. The change in resonance energy width with temperature, known as the *Doppler effect*, is important in reactor control.

Fig. 5 illustrates a typical cross-section curve showing the neutron capture cross-section of U-238 as a function of neutron energy. Below 10^2 eV the height of the resonance peaks is about 10^3 barns. Between 10^2 and 4×10^3 eV the great number of resonances makes it impractical to show the cross-section as a curve, although the resonance parameter data are available for use on a computer. Between 4×10^3 and 10^5 eV the curve represents a statistical average of the measurements which have been made.

The fission process

Nuclear fission is the splitting of a nucleus into two or more separate nuclei accompanied by release of a large amount of energy. In the fission of an atom due to a neutron, the mass of the neutron plus its energy must be equal to or greater than the mass defect associated with the two fission products. U-235 is the only naturally occurring nuclide that is capable of undergoing fission by interaction with low energy or slow neutrons. Some of the artificially produced heavy nuclides are also fissionable with slow neutrons, including plutonium-239 (Pu-239) and U-233. Other nuclides such as U-238 and Pu-242 require higher energy neutrons to cause fission.

This difference in fission capability occurs because the binding energy of a nucleus is not only determined by its mass number but also by whether the number of protons and neutrons is even or odd. A nuclide with an even number of neutrons and protons, such as U-238, has the highest binding energy per nucleon and requires the most added energy to fission. Fission only occurs with high energy or fast neutrons ($> 1\text{MeV}$). A nuclide with an odd number of protons and an even number of neutrons or an even number of protons and an odd number of neutrons, such as U-235, Pu-239 and U-233, has a lower binding energy per nucleon. Nuclides with both an odd number of protons and neutrons have the lowest binding energy per nucleon for essentially equivalent mass numbers. U-235 and Pu-239 are fissionable with slow or thermal neutrons (~ 0.025 eV). The term *thermal neutron* refers to a neutron energy distribution that is in thermal equilibrium with the temperature of the surrounding materials.

Fission occurs when the fissionable nucleus absorbs a neutron. In the case of U-235 the reaction is:

Fig. 5 Capture cross-section of uranium-238.

As previously noted, the asterisk in ${}_{92}\text{U}^{236*}$ indicates an unstable nuclide. The value 2.43 applies to U-235 fission by a thermal neutron and is the statistical average of the number of neutrons produced per reaction. X and Y represent the fission products which are distributed as shown in Fig. 6.

Energy from fission

Fission also produces γ rays, neutrons, β particles and other particles. The energy release per fission amounts to about 204 MeV for U-235 and is distributed as shown in Table 4. Release of approximately this amount of energy per fission can be predicted by examination of Fig. 2 for binding energy, considering that two fission products are formed as shown in Fig. 6. Table 4 also includes data for Pu-239.

Neutrons from fission

The fact that additional neutrons are born or generated by a fission event makes it possible to establish a *chain reaction*, as depicted in Fig. 7, that can sustain itself as long as sufficient fissionable material and neutrons are present. The neutrons produced per fission event, ν , and the average number of neutrons produced per neutron absorbed in the fuel, η , vary with the different fissionable isotopes and with the energy of the neutron producing the fission. Statistical averages for these quantities are given in Table 5. There are individual fission reactions that produce only one neutron, possibly none, or as many as five. Because some of the neutrons are absorbed without producing fission, η becomes a more meaningful quantity in reactor design than ν . The values in the table are for fission by low energy or thermal neutrons at room temperature [0.025 eV neutron energy or 7218 ft/s (220 m/s) neutron velocity]. To maintain a chain reaction, the average number of neutrons per absorption must be significantly greater than 1 because some of the neutrons will be lost to absorption in the moderator and structural materials, to absorption in control materials, and to leakage from the core. Control materials such as boron and silver-indium-cadmium are used to maintain a steady-state chain reaction by

absorbing any additional neutrons over that needed for steady-state operation.

Fission neutron energy distribution

Neutrons released from fission vary in initial energy over a wide range up to 15 MeV and above. The distribution of neutrons produced by fission as a function of energy has been determined from several experimental measurements, and typical results for U-235 and Pu-239 are shown in Fig. 8. Based on these measurements, the average energy of fission neutrons is about 2 MeV; the peak of the energy distribution occurs at about 0.8 MeV.

Fig. 6 Mass distribution of fission products from fission of U-235.

Table 4
Energy Produced in Fission (MeV/fission)

	U-235	Pu-239
Instantaneous		
Kinetic energy of fission products	169	175
γ ray energy	8	8
Kinetic energy of fission neutrons	5	6

Delayed		
β particles from fission products	8	8
γ rays from fission products	7	6
Neutron-capture γ s*	7	10
	<u>22</u>	<u>24</u>
Total	204	213

* Energy produced depends on reactor composition.

Burnup

As a mass of uranium undergoes fission it produces energy. The term *burnup* is used to represent the amount of energy produced per unit mass of the material. The units of burnup are megawatt days per metric ton (MWd/t_m) of initial heavy metal, i.e., uranium. One megawatt day represents about 2.6×10^{21} fissions. A nuclear fuel assembly is typically discharged from the reactor when it has achieved a burnup of about 50,000 MWd/t_m. In commercial power reactors that are fueled with uranium comprising mainly the isotope U-238, with 4% or less U-235, most of the energy produced comes from the fissioning of U-235. At burnups of 50,000 MWd/t_m only about 5% of the initial uranium content of the fuel assembly has fissioned. Even when the other nuclear reactions that cause loss of the original uranium atoms are considered, there is still more than 90% of the initial uranium remaining in the fuel assembly when it is discharged.

Fission products

When a nucleus undergoes fission, experimental measurements have shown that predominantly two fission products or fragments are generated. The distribution of these fission products for U-235 fissions has also been measured and is shown in Fig. 6. In fission, as in any nuclear reaction, there is always conservation of

Table 5
Neutrons from Fission

Fuel	Avg. Neutrons per Fission, ν	Avg. Neutrons per Absorption in Fuel, η
Uranium-233	2.51	2.28
Uranium-235	2.43	2.07
Natural uranium	2.43	1.34
Plutonium-239	2.90	2.10
Plutonium-241	3.06	2.24

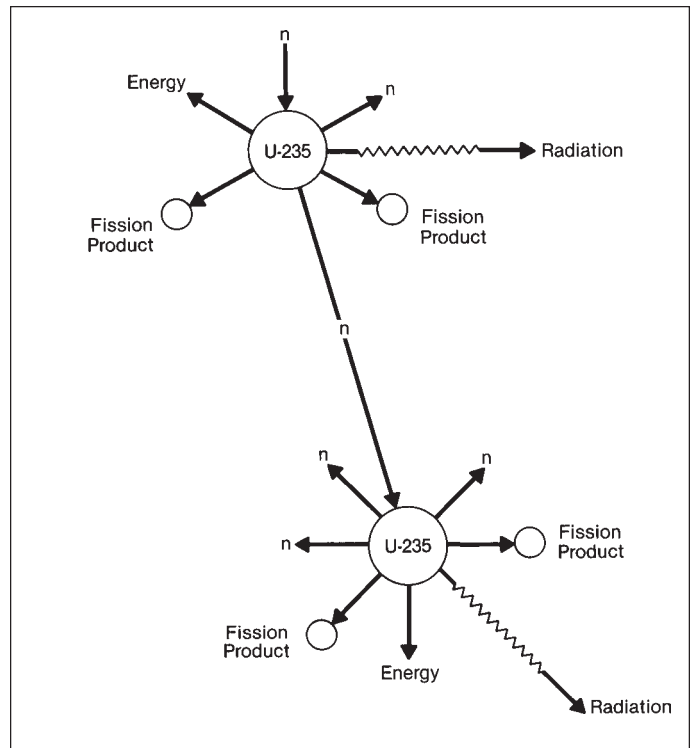

Fig. 7 Chain reaction.

total mass-energy so that one of the two fission products will come from each hump of the distribution.

Examination of Fig. 6 reveals that mass number of the fission products ranges from about 70 to 170 with two plateaus at approximately 95 and 135. Curves are shown for fission caused by thermal energy neutrons and by 14 MeV neutrons. The higher the neutron energy causing fission the more uniform the fission product distribution.

Many fission products interact with neutrons, absorbing them so that they are not available to the chain reaction. As these fission products build up (see Fig. 9), they act as absorbers to retard the chain reaction. All long lived fission products except samarium build up as the core is operated, reaching a maximum effect at the end of core life.

Fig. 8 Fission neutron energy distribution.

After discharge from the reactor and sitting in storage for a few years, most of the fission products will have decayed due to their relative short half lives. However, some of the long half life fission products will contribute significantly to the γ ray source that must be shielded against in handling the fuel during its ultimate disposal. These isotopes include strontium-90 (Sr-90), ruthenium-106 (Ru-106), cesium-134 (Cs-134) and 137 (Cs-137), cerium-144 (Ce-144) and europium-154 (Eu-154). These isotopes will either be bound in the fuel pellets or on the inside surface of the cladding. Other isotopes important to fuel handling are the artificially produced nuclides in the fuel pellet that decay by spontaneously fissioning. These isotopes include Pu-238, americium-241 (Am-241), and curium-242 (Cm-242) and 244 (Cm-244). In addition, the γ emitting isotope cobalt-60 (Co-60) is produced in the structural steels and Inconel® through neutron activation and must be shielded against.

Fission product behavior with time

Certain fission products, specifically Xe-135 and samarium-149 (Sm-149), both of which have very high cross-sections for absorption of thermal neutrons, are not only produced directly from fission but also are the decay products of other fission products.

Essentially all initial products of fission are highly radioactive and decay rapidly to less active isotopes with somewhat longer half lives. There are usually several isotopes in the chain before a stable end product is reached. The most significant such decay chain is the following:

In this chain, tellurium-135 (Te-135) with a one minute half life decays to iodine-135 (I-135) with a 6.7 hour half life and then to Xe-135. This xenon isotope, which fortunately has only a 9.2 hour half life, has a macroscopic cross-section for thermal neutron absorption approximately $100,000 \text{ cm}^{-1}$, as great as all the long lived fission products together. Unfortunately, the nuclides of this chain occur abundantly as fission products – a predictable happening, because the mass number 135 occurs at a peak in the fission product distribution (Fig. 6). The Xe-135 absorbs an appreciable

Fig. 9 Fission product chain.

fraction of available neutrons as long as the reactor is operating. This changes some of the Xe-135 to Xe-136 (which has negligible neutron absorption). As a result, when a water reactor operates at constant power level, the Xe-135 builds up to its equilibrium value in 36 to 48 hours.

When reactor power lessens and, particularly, when the reactor is shut down, the I-135 formed at the original power level continues for a time to generate Xe-135 at a rate corresponding to the original power level. Therefore, the Xe-135 builds up rapidly after shutdown because fewer neutrons are available for conversion to Xe-136. The buildup reaches a peak 4 to 12 hours after shutdown and then slowly decays. The time behavior of Xe-135 must be addressed in reactor control.

Sm-149, the second important fission product in the reactor core during operation, is generated as follows:

In the chain, neodymium-149 (Nd-149) decays (1.7 hour half life) into promethium-149 (Pm-149), which in turn decays (47 hour half life) into Sm-149. Although Sm-149 is a stable isotope it is destroyed so rapidly by neutron absorption that it reaches an equilibrium value when the reactor operates at constant power. Typically, Sm-149 reaches equilibrium in a pressurized water reactor after 50 to 100 days. Buildup after shutdown is slower and less extensive than for Xe-135.

Decay after shutdown has little consequence for all other fission fragments because of their long lives and comparable capture cross-sections between parent and daughter nuclide.

Nuclear reactor composition

A reactor core is composed of fuel, structural and control materials, and a moderator and/or coolant. Typical pressurized water reactor (PWR) fuel assembly and control component designs are shown in Fig. 10. A depiction of the interactions that take place within a fuel assembly is shown in Fig. 11. Neutrons react not only with uranium, but also with the nuclei of most other elements present. Therefore, many materials which have high neutron absorption properties should not be used for structural purposes. Fortunately, a few materials such as aluminum and zirconium have low neutron absorption cross-sections. Inconel, steel and stainless steel also can be used to a limited extent.

The choice of coolants includes water, helium and liquid sodium. Thermal reactor design, where the neutron energy distribution is essentially in thermal equilibrium with its surroundings, requires a moderator (a material containing atoms of a light element such as hydrogen, deuterium or carbon) in the core to reduce the kinetic energy of the neutrons. Hydrogen is the ideal moderator because its nucleus is as light as a neutron and, therefore, it can absorb the energy of the neutron in a single direct collision. Hydrogen is normally present in the form of water. The heavier the

atom the less energy it absorbs per collision, and the less slowing effect on the neutron. Carbon, in the form of graphite, is about the heaviest atom that can be used practically as a moderator. Carbon has the additional advantage of absorbing very few neutrons, even less than hydrogen. Other low weight atoms can be used, but they are less practical because of excess neutron absorption or high material cost. Because the helium nucleus absorbs essentially no neutrons, it would be an ideal moderator except that helium is a gas at reactor operating temperatures. In this state it would be impossible to provide the core with a sufficient number of atoms to be an effective moderator.

All thermal reactors contain some fast (high energy) neutrons because only fast neutrons result from fission. The amount of moderator provided determines the degree of thermalization (energy reduction) or the percentage of thermal neutrons present in the reactor. Perhaps the greatest advantage of the thermal reactor is its compatibility with the water coolant. Water has proven to be the most practical and economical coolant.

The low neutrons per fission available with natural uranium makes it difficult to design a natural uranium (0.71% U-235) reactor. However, it can be accomplished if all materials are of especially high purity and if discrete sections of fuel are placed in a heterogeneous array such that the neutrons can slow down in the moderator and then re-enter the fuel material as slow neutrons. Under these conditions, there is a relative high probability of causing fission. The normal moderators used in natural uranium re-

Fig. 11 PWR neutron moderator/coolant-fuel interactions.

actors are either graphite or deuterium oxide (heavy water). The absorption cross-section of normal hydrogen makes it less desirable than the other moderators. Also, minute quantities of any high neutron absorbers can prevent a chain reaction. Nevertheless, all early reactors used natural uranium and many still operate, notably the large plutonium producing reactors and the Canadian CANDU pressurized heavy water reactors. (See Chapter 46.)

Physical description of nuclear chain reactions⁴⁻⁷

To use fission as a continuous process for power production, it is necessary to initiate and maintain a fission chain reaction at a controlled rate or level which can be varied with power demand. Obtaining a steady-state chain reaction requires the availability of more than one neutron for each fission produced because non-fission reactions absorb some neutrons and others leak from the reactor. For a reactor as a whole, the neutrons born in each instant of time constitute one generation of neutrons. The term *effective multiplication factor*, k_{eff} , is defined as the ratio of the number of neutrons in one generation to that in the previous generation. With a multiplication factor of less than one, the system is a decaying one and will never be self-sustaining. With a multiplication factor greater than one, a nuclear system produces more neutrons than it uses, and power increases. For a steady-state chain reaction, $k_{eff} = 1$.

The steady-state equation for neutron balance in a chain reaction can also be written as:

$$\text{Production} = \text{Absorption} + \text{Leakage} \quad (8)$$

When this condition is obtained, the reactor has gone *critical* meaning that the necessary amount of neutron production has been achieved to balance the leakage and the absorption of neutrons. The mass of fissionable material required to achieve this condition is called the *critical mass*.

Production, absorption and leakage all depend heavily on interactions of neutrons with nuclei of the various materials in the reactor. Production depends

Fig. 10 Typical PWR fuel assembly and control components.

primarily on those interactions with U-235 nuclei which result in fission. Absorption depends on interactions of neutrons with any nuclei in the core that result in absorption of neutrons with or without fission. Leakage depends on the scattering effect of collisions between neutrons, nuclei and other particles, which results in transport of neutrons toward the boundaries of the chain reacting system and ultimate escape from the system.

Table 5 indicates that each fission of a U-235 atom by a thermal neutron makes available an average of 2.43 neutrons. However, only 2.07 neutrons are produced per thermal neutron absorbed in U-235 as also indicated in Table 5. The other 0.36 neutrons are absorbed in non-fission reactions. If natural uranium is used, the number of neutrons produced per thermal neutron absorbed is reduced to 1.34 because of the neutron absorption in U-238. Most of this absorption results in the ultimate production of fissionable Pu-239. However, neutrons used in this manner are no longer available to help maintain the chain reaction.

A neutron chain reaction is possible because each fission event on the average produces more than one neutron. If the process is controlled such that just one of the neutrons produced from fission causes another fission reaction then a steady state process is maintained and a constant power level is achieved. To best understand the process, a general description of the lifetime of a neutron follows. It must be realized that for a power reactor the number of neutrons crossing a 1 cm² surface (neutron flux) near the center of the reactor is on the order of 10¹³ neutrons/cm²/s. The lifetime of a neutron is on the order of 10⁻⁹ seconds. Therefore, this description is only representative of what happens in an instant of time.

As described previously, a neutron produced by the fission process has an average energy of about 2 MeV and is termed a fast neutron. At this energy, elastic or inelastic scattering reaction with the moderator, the fuel or with the structural materials are most probable. However, about 2% of the fast neutrons cause a fission in U-238 and produce an even higher number of neutrons than produced from thermal fission.

In an elastic scattering reaction some of the neutron energy is transferred to the nucleus with which it collides in the form of kinetic energy; this can cause the nucleus to be displaced from its normal lattice position in the material. In an inelastic collision a compound nucleus is formed in an excited state and it reduces its energy by releasing a lower energy neutron and a γ ray. Some of the original neutron's energy is also deposited as the kinetic energy on the nucleus. The net impact of the scattering reactions is to cause the neutron to lose energy or slow down into the energy range where resonance interactions with various materials (especially U-238) can take place. In the resonance range, neutrons will have a high probability of being captured if their energy coincides with any of the resonances associated with the uranium fuel or the fission products and will not be available to react with the U-235 to help sustain the chain reaction. The resonance escape probability is the fraction of neutrons that escape capture while slowing

down to the thermal energy range. The term *resonance escape* refers particularly to U-238 because in the intermediate range of neutron energy there are several resonance peaks of absorption cross-section for this isotope. These resonances are useful in the production of plutonium; however, to maintain criticality in a thermal reactor, sufficient neutrons must escape absorption in the resonance region.

In contrast, collisions with hydrogen atoms in the moderator can slow down the neutron very rapidly, and therefore the resonance escape probability is high for water moderated systems. Once past the resonance range the neutron is said to become thermalized and becomes part of a Maxwellian energy distribution with an average energy of about 0.2 eV. As the fission cross-sections for U-235 and Pu-239 are the highest in the thermal energy range, most fission reactions take place in this range.

The probability of having a fission reaction is referred to as the *thermal utilization* and is the ratio of the fission cross-section to the absorption cross-section (capture plus fission) averaged over the moderator plus the fuel and structural materials.

The other mechanism for loss of neutrons is leakage from the system. This is dependent on the size of the system and the length of the path neutrons travel between source and capture. For a thermal reactor this length is approximately 2.95 in. (75 mm). Today's power reactors are on the order of 13.1 ft (4 m) in diameter and therefore only neutrons born in the fuel assemblies on the periphery of the core have a significant probability of being lost from the system.

Control of the chain reaction

More than 99% of neutrons produced in fission are *prompt* neutrons; that is, they are produced almost instantaneously. About 0.73%, in the case of U-235, are released by the decay of fission products rather than directly from fission. The average half life for these delayed neutrons from fissioning of U-235 is about 13 seconds. This provides time for the reactor operator to respond to small changes in either power demand by the system or reactor system parameters.

The chain reaction can be regulated by placing materials with high neutron absorption capability in the reactor and providing a means of varying their amounts. These materials tend to stop the chain reaction and include boron, cadmium-silver-indium, hafnium and gadolinium. One or more of these materials usually goes into the reactor in the form of control rods that can be withdrawn to start up the reactor or to increase power level and reinserted to reduce power or to shut down the unit. To assure accurate control of power, at least some of the rods must be capable of fine regulation.

Reactivity

The first step in establishing a chain reaction is to bring the reactor to critical condition at essentially no thermal power or zero power level. The reactor power is gradually increased up to the desired level by the removal of a control material and maintained there. The objective in each step of this procedure is to obtain and hold a constant value of $k_{eff} = 1.0$. In view of

the changes that continually occur in a nuclear system, it is never possible to keep $k_{eff} = 1.0$ for more than a short period of time without adjustments to compensate for variations. Operating a reactor at any constant power level at an effective multiplication factor of unity corresponds to steering a ship on a compass course. It takes a continual effort, either automatic or manual, to hold the ship on the exact course.

If a reactor operates at a specific power level with $k_{eff} = 1.0$, and if anything changes to increase or decrease the multiplication factor, a reactivity change is said to have occurred. It may be of positive or negative change depending upon the direction of change in k_{eff} . Reactivity, represented by the symbol ρ , is defined as the ratio:

$$\rho = (k_{eff} - 1) / k_{eff} \quad (9)$$

Reactivity has been given units of dollars (\$) and cents (¢) or inhours. It is usually expressed in the units of pcm (per cent milli) which corresponds to a ρ of 1×10^{-5} . As will be shown, most processes in the reactor, except for control rod insertion, generate reactivities of 1 to 10 pcm which constitute a very small change from a k_{eff} of 1.

Calculation of reactor physics parameters⁴⁻⁷

The calculation of a chain reaction (or the design of a nuclear reactor) requires solution of the steady-state equation:

$$\text{Production} = \text{Absorption} + \text{Leakage}$$

or its counterpart for nonsteady-state (transient) conditions:

$$\text{Production} - \text{Absorption} - \text{Leakage} = dn/dt \quad (10)$$

where dn/dt is the variation of the neutron density with time.

The production rate is evaluated as:

$$\text{Production} = \nu \Sigma_f n v \quad (11)$$

where

- ν = neutrons per fission
- Σ_f = macroscopic fission cross-sections, cm^{-1}
- n = neutron density, neutrons/ cm^3
- v = neutron velocity, cm/s

If the neutron flux is defined as the product of the neutron density and neutron velocity, then the production rate can be defined as:

$$\text{Production} = \nu \Sigma_f \phi \quad (12)$$

where

$$\phi = nv = \text{neutron flux}$$

Similarly, the absorption rate is defined as:

$$\text{Absorption} = \Sigma_a \phi \quad (13)$$

where

$$\Sigma_a = \text{macroscopic absorption cross-section, cm}^{-1}$$

Leakage is a complicated function of the gradients in the neutron flux at boundaries of the region under consideration.

In performing reactor calculations, the core is divided into discrete spatial regions or nodes, and the continuous neutron energy range is divided into a number of groups. The above equations then become a coupled set of partial differential equations that are solved in both the space and energy domains to find the neutron flux and reaction rates in each node.

In the design of the early reactors, most calculations of reactor physics parameters were done by hand using homogeneous models of the core components. Neutron cross-sections were obtained from experimental plots of total, absorption, scattering and fission cross-sections. Critical experiments were performed mocking up the fuel designs and modeling both the fuel and control rods. From these experiments, modeling adjustments were developed to ensure high accuracy predictions of reactor performance parameters. As with most other disciplines, the advent of more powerful computers has permitted the designer to perform detailed calculations in both space and energy. The following sections describe some techniques that have been used in calculations for commercial PWR fuel cycle design and licensing.

Cross-sections

Basic neutron and gamma cross-sections are compiled and verified as part of the industry effort to maintain the cross-section libraries. These libraries provide the basic data needed to calculate the cross-section of each isotope as a function of incident neutron energy. Typically two major energy groups, each containing subgroups, are used by the designer. The first, the fast and epithermal group, spans energies from 1.85 eV to 20 MeV and is composed of 40 or more subgroups. The second, the thermal energy group, covers energies from 0.00001 eV to 1.85 eV and is composed of 50 or more subgroups. In the fast and epithermal energy range, only scattering reactions that decrease neutron energy are used in the calculations. In the thermal energy range, the neutron energies are in thermal equilibrium with the moderator, and energy can be imparted to the neutron during scattering collisions. Therefore, scattering reactions, which can increase or decrease neutron energy, are permitted in the calculations for this group.

When designing a reactor core, specific cross-sections are calculated using the total multigroup cross-section set (40 epithermal plus 50 thermal groups) for each material present. Each cell type in the fuel assembly can then be modeled (Fig. 12). This calculation determines the neutron flux distribution in each energy group and cell. The resulting neutron flux is then used to average the cross-sections over the two major energy groups and over various regions of the fuel assembly. A full core representation, indicating the position of fuel assemblies and control components, is shown in Fig. 13.

The important quantities that describe the reactor core and its performance include critical boron concentration, core power generation distribution, control rod reactivity worths, and the reactivity coefficients associated with changes in reactor conditions.

Critical boron concentration

There is sufficient U-235 in a commercial power reactor to power the unit for 12 to 24 months before refueling. Without additional absorbers present in the system, the k_{eff} would be greater than 1. It is impractical to provide the absorption using control rods. Therefore, for long-term control $k_{eff} = 1$ is maintained by soluble boron in the moderator (boron dissolved in water) and/or burnable absorbers. Burnable absorbers contain a limited concentration of absorber atoms such that, as neutrons are absorbed, the effectiveness of absorption decreases and essentially burns out with time. Burnable absorbers may be in the fuel rods or in fixed absorber rods that are placed in fuel assembly guide tubes. The boron concentration in the coolant can be near 1800 ppm at the beginning of a fuel cycle. This concentration can decrease to near zero at the end of the cycle, when a significant portion of the

Fig. 12 Cross-sectional view of fuel assembly.

Fig. 13 Cross-sectional computer modeling of PWR core.

uranium is depleted and fission products have built up. The critical boron concentration is the boron level required to maintain steady-state reactor power levels. The burnable absorber limits the amount of soluble boron that is used at the beginning of the cycle.

Power distribution

The primary factor governing acceptable reactor operation is the energy production rate at every point in each fuel rod. If the rate is too high, the fuel can melt and cause rod failure. Excessive energy rates can also cause coolant steaming, which results in poor heat transfer and can lead to cladding burnout.

The energy production rate, or power, at each fuel rod location is referred to as the core power distribution. This has typically been calculated by forming a three-dimensional model of the reactor and representing each fuel assembly as a homogenized region over an axial interval. A more recent method for power calculations involves reconstructing the power production in each fuel rod based on detailed fuel assembly calculations. This method is more accurate because it provides a better fuel assembly model that can include water, burnable absorbers or guide tube control rods. With proper fuel assembly placement, the core power distribution can be optimized to limit power peaks in fuel rod segments. As part of this primary analysis, initial enrichments of the fuel and burnable absorbers can be determined, as well as the necessary soluble boron concentration in the coolant over the cycle.

Control rod worths

Control rods are used in a pressurized water reactor to change power levels and to shut down the reactor. Approximately 48 rods, divided into banks of 8, are commonly used and core reactivity is changed by sequentially moving the banks. The control rod banks are grouped into shutdown and control (or regulating) banks. The shutdown banks provide negative reactivity to bring the reactor from hot to cold conditions. During a shutdown, the core temperature decreases

and its reactivity increases. The shutdown control rod banks counteract this increase. The controlling banks are used in conjunction with variations in the soluble boron concentration to take the reactor from hot zero power to full power. These banks also provide the reactivity to handle rapid power changes. The negative reactivity caused by the buildup of xenon in the core following a shutdown is offset by a combination of control rod removal and decreases in the coolant boron concentration.

The reactivity *worth* of a control rod is a measure of its ability to reduce core reactivity. Control rod worths are calculated by first calculating the core with the control rod inserted to determine its k_{eff} . The core is then similarly calculated with the rod withdrawn. Control rod worth is defined as:

$$\frac{k_{eff(i)} - k_{eff(w)}}{k_{eff(w)} k_{eff(i)}} \quad (14)$$

where

$k_{eff(w)}$ = multiplication factor, control rod withdrawn
 $k_{eff(i)}$ = multiplication factor, control rod inserted

Bank worths are similarly calculated.

Reactivity coefficients

Reactivity coefficients define the rate of core reactivity change associated with the rate of change in reactor conditions. These coefficients indicate the relative sensitivity of the core operation to changes in operating parameters.

In determining a coefficient, the core is first modeled with a given power and/or temperature distribution, and k_{eff} is calculated. The reactor is then similarly modeled at a different power or temperature distribution. The coefficient is defined as the reactivity change per unit of power or temperature. Fig. 14 shows the impact of various core parameter changes on core reactivity.

There are three basic reactivity coefficients that are important to reactor operation: 1) the moderator temperature, 2) Doppler, and 3) power coefficients. The moderator temperature coefficient is defined as the change in reactivity associated with a change in moderator temperature. It includes the effects of moderator density changes and the changes in nuclear cross-sections. The Doppler coefficient is defined as the change in reactivity associated with changes in fuel temperature that occurs primarily because of fuel nuclides with large resonances. The power coefficient is defined as the change in reactivity associated with a change in power level. It is a combination of the moderator and Doppler coefficients and is based on the change in temperature as power changes.

When the coolant temperature increases, the associated density reduction normally decreases its moderating capability. A net decline in core reactivity, i.e., a negative moderator temperature coefficient, occurs. Similarly, when the fuel temperature increases, core reactivity decreases. Both mechanisms provide an inherent safety response for the system. However, if the soluble boron concentration is too high, a positive moderator temperature coefficient can occur, and core

Fig. 14 Core reactivity as a function of operating parameters.

reactivity could increase. For this reason boron concentration is limited to ensure a negative moderator coefficient at full power.

Neutron detectors

When operating a nuclear chain reaction system, neutron detectors are used to measure the intensity of the neutron radiation (flux). This radiation is a direct indication of nuclear reaction intensity. Neutron detectors can be counters or ionization chambers. Counters, which detect neutrons by sensing the individual ionizations they produce, are most useful when the neutron flux is low. Ionization chambers are more useful at high neutron fluxes. They measure the electrical current that flows when neutrons ionize gas in a chamber. These two types of detectors, placed on the exterior of the pressure vessel, only measure neutrons leaking from the reactor.

Two other types of detectors, a self-powered neutron detector and a miniature fission chamber, can be used to measure the neutrons inside the instrument tube of operating fuel assemblies. Self-powered detectors are usually arranged in strings and are positioned to continuously measure the neutron reactions at up to seven axial locations in the fuel assembly. The miniature fission chamber contains uranium, and fission events are detected by the electronics. The fission chamber is moved into and out of the core on a periodic basis, normally monthly, and measures the neutron level along the entire length of the fuel assembly.

Neutron source

During the start of the chain reaction, it is essential that the operator monitor nuclear instrumentation that is counting neutrons and not gamma rays. The mass of fuel in the core is much greater than the critical mass required to sustain a chain reaction. Control rods and soluble boron dissolved in the reactor coolant keep the core subcritical when no power output is required.

When the core is to be brought to criticality, control rods are withdrawn to initiate the chain reaction. However, if the control rods are withdrawn before a measurable neutron flux is available, a reaction could be initiated by a stray neutron and build up to a high power level before the control rods could be reinserted to maintain the desired core output.

To control the rate of buildup of the reaction, it is necessary to have a neutron source present in the core for startup. With a neutron source available, it is possible to measure neutron flux before moving control rods and help ensure a safe reactor startup.

Several types of neutron sources are available. One is an americium-beryllium-curiu source rod. The radioactive isotopes americium and curium emit α particles which react with the beryllium to produce neutrons.

Fast reactors

It is possible to design for a chain reaction to occur predominantly with either fast (high energy) neutrons or slow (thermal energy) neutrons. In fast reactors the chain reaction is maintained primarily by fast neutrons. Thermal reactors are those in which the chain reaction occurs primarily from thermal neutrons. Today's commercial water reactors are thermal reactors.

Fertile material such as U-238 can be used as a fuel by first converting it to plutonium in a reactor. Fast reactors and particularly fast breeder reactors accomplish this conversion most effectively. Liquid sodium, which has essentially no moderating effect, is the coolant most often considered for fast breeders. Helium is used as a coolant in high temperature gas-cooled reactor designs.

Conversion and breeding

Most important of the conversion reactions is the capture of a neutron by a U-238 nucleus, resulting in a nucleus of fissionable Pu-239:

The U-238 nucleus absorbs a neutron and becomes U-239, which decays with a half life of 23 minutes, into neptunium-239 (Np-239). Again this nuclide, with a half life of 2.3 days, is transmuted to Pu-239 by β decay. This is the nuclear process by which the most useful isotope of plutonium is formed.

There are other reactions during operation which form different isotopes of plutonium. Some of these isotopes, including Pu-241, are fissionable, and others, including Pu-240, are converted to fissionable isotopes by neutron absorption. These isotopes can not be separated economically from Pu-239, and therefore must be taken into account when plutonium is used in a reactor.

The large commercial PWRs in the United States operate on slightly enriched uranium fuel. These reactors convert U-238 to plutonium and produce about 50% as much plutonium as the U-235 consumed. A reactor is considered to be a converter when the amount of fissionable material produced, e.g., plutonium, is less than the amount of fissionable material consumed, e.g., U-235. A breeder reactor is one in which more fissionable material is produced than consumed.

By definition, a breeder reactor must have the value of η (neutrons produced per neutron absorbed in fissionable fuel, Table 5) greater than 2.0. One neutron is required to maintain the chain reaction, one or more for the breeding, and an additional fraction for absorption in nonfuel materials and leakage.

It is not possible to make a breeder reactor with natural uranium fuel, because η is less than 2.0. Table 5 shows that η does not greatly exceed 2.0 with any common fissionable isotopes for fissions produced by thermal neutrons. Consequently, it becomes difficult and impractical to make a breeder with a thermal reactor.

Fortunately, at high neutron energies, η has a greater value than at thermal energies, particularly with Pu-239. For this reason, and because the absorption cross-sections of most materials are less than at thermal energy, fast reactors breed plutonium more effectively than thermal reactors. In addition, fast reactors operate best with plutonium fuel.

Chapter 48

Nuclear Steam Generators

Nuclear steam generators provide the principal isolation barrier between the primary coolant system in contact with the reactor core and the secondary power cycle system, as discussed in Chapter 46. Nuclear steam generators also serve two other functional requirements as they transfer energy from the primary reactor coolant system to the secondary-side power-producing system. The first functional requirement is as the heat sink for the reactor core. The decrease of primary coolant temperature through the steam generators is virtually the same as the increase of the primary coolant temperature through the reactor core. Any difference is attributable to the fluid energy supplied by the reactor pumps, less any heat loss to ambient. The second functional requirement is to generate the flow rate of steam from the feedwater supply at the temperature, pressure and enthalpy conditions necessary to efficiently drive the steam turbine/electric generating system.

Each commercial pressurized water reactor (PWR) power system combines two to four steam generators with a nuclear reactor, pressurizer, and multiple primary coolant pumps to form the nuclear steam supply system (NSSS). The 69 operating PWR systems in the United States (U.S.) use a total of 209 steam generators. In addition, the 22 Canada Deuterium Uranium (CANDU) pressurized heavy water reactor (PHWR) systems installed in Canada employ a total of 184 with as many as 12 steam generators per reactor, although 4 is more typical.

There are two fundamental steam generator designs used in commercial power systems in North America. The Babcock & Wilcox Company (B&W) once-through steam generator (OTSG) is a vertical shell counterflow straight-tube heat exchanger design which directly generates superheated steam as the feedwater flows through the steam generator in a

single pass. The other fundamental design used by a number of suppliers and in the CANDU PHWR is a recirculating steam generator (RSG) where only part of the feedwater is converted to steam as the water passes through the unit. After the steam is separated from the water, the steam is sent to the turbine for power generation while the water is returned to the tube bundle for additional steam generation. These steam generator designs use a vertical shell and an inverted U-tube heat exchanger bundle, with steam separation equipment located inside the top shell of the RSG. With this design there are significant differences between suppliers and between different models regarding materials of construction, thermal hydraulic parameters, manufacturing techniques and tube supports, all of which can significantly influence performance.

A few other commercial PWR steam generator designs have been used, primarily in early units. The first commercial U.S. power reactor at Shippingport, Pennsylvania, used two different horizontal tube bundle steam generator designs. NPD (Nuclear Power Demonstration), the first CANDU power reactor, had one horizontal U-tube, U-shell steam generator. Current Russian PWR plants use horizontal bundle steam generators. No horizontal units are in commercial operation today in North America.

A variety of aging issues have been observed in the existing fleet of PWR steam generators. These factors have reduced the performance of some steam generators and thus effectively reduced their useful life. Intergranular attack, stress corrosion cracking, tube denting, tube wall thinning, fretting wear damage, foreign object damage and other issues have all had an impact on unit performance because of the need to plug significant numbers of steam generator tubes.¹ In some cases, the degradation has reached a stage

where repair is no longer a viable option and steam generator replacement is needed. These replacement steam generators employ new technologies to address the aging issues and to extend their useful life.

The balance of this chapter focuses on the fundamentals of steam generator design and on the design improvements that are incorporated into the replacement OTSG and RSG units. Steam generator service issues are discussed in Chapter 49, *Nuclear Services and Operations*. Steam generator manufacturing is discussed in Chapter 50.

B&W once-through nuclear steam generator (OTSG)

Design configuration and flow

The B&W once-through nuclear steam generator (see Fig. 1) is a vertical, straight tube and shell, counterflow heat exchanger, approximately 73 ft (22.25 m) tall and 13 ft (3.96 m) in diameter, each weighing approximately 570 tons (517 t_m). Each steam generator produces approximately 5.4 million lb/h (680.4 kg/s) of steam at 925 psi (6.38 MPa) and 595°F (313°C). This provides 60°F (33°C) of superheat. The more than 15,000 Inconel® 600 tubes in each steam generator are positioned by broached tube support plates (see Figs. 1 and 2) which are set within the bundle shroud, which is in turn positioned to the vessel shell by shroud pins. These plates are spaced to minimize tube vibration. The distance between tubesheets is 52.1 ft (15.9 m).

As shown in Figs. 1 and 3, primary coolant enters at the top, flows downward through the tubes, and exits at the bottom through two primary outlets. The carbon steel shell surfaces exposed to the primary side coolant are clad with stainless steel to avoid corrosion in the primary side chemistry environment. The generator functions as a counterflow heat exchanger, i.e., the primary coolant flows downward within the tubes and the secondary fluid flows upward around the

Fig. 2 OTSG broached support plate.

tubes. The steam generator is a once-through design in that the secondary fluid makes only one pass through the unit. Because the OTSG produces superheated steam, it does not require steam separators or dryers.

Referring to Figs. 1 and 3, the feedwater flows downward within the annular region formed by the lower shroud and the steam generator inside wall. Near the bottom of the downcomer the feedwater passes through the adjustable orifice plate, and then turns inward toward the bottom of the bundle. The fluid then flows upward around the tubes, passing

Fig. 3 Simplified OTSG flow circuits.

through broached holes in the 15 tube support plates. The steam is superheated prior to leaving the top of the tubed region. It turns outward and downward, flowing down the upper annular downcomer to the steam outlet nozzles.

The feedwater is introduced into the annular downcomer through thirty-two 3 in. (76 mm) connections with attached spray nozzles located 31.9 ft (9.7 m) above the lower tubesheet. The exit flow from these nozzles aspirates steam through a gap in the bundle shroud, thereby allowing the feedwater to reach saturation temperature before entering the tube bundle. This arrangement was designed to mitigate temperature mismatches between the shell and tube bundle. Later integral economizer once-through steam generator (IEOTSG) designs introduced feedwater through two nozzles lower in the shell where it directly enters an integral economizer section in the lower portion of the tube bundle region as shown in Fig. 4. With this design, external feedwater heating is used at some loads to adjust the feedwater temperature to approximate tube bundle and shell temperatures, thereby avoiding excessive temperature differentials between shell and tube bundle and within the lower tubesheet. This design is able to achieve more steam output at a higher pressure to match the output of the 1300 MW 205 fuel bundle core. Most of the discussion which follows relates to the standard OTSG design.

In the OTSG design, an adjustable orifice is located near the bottom of the downcomer, just above the ports into the tubed region. This device consists of a movable plate overlaying a fixed plate; both plates contain 24 identical flow passages. This adjustable orifice allows downcomer flow resistance to be adjusted to optimize flow stability and downcomer water level. These factors may change with operation as tube support plate deposits increase riser-side flow resistance.

Key information about the OTSG design is provided in Table 1.

Modes of secondary-side heat transfer

The secondary-side feed entering an OTSG downcomer annulus is quickly brought to saturation temperature by contact heating between the feedwater spray and aspirated steam drawn from the riser (in an IEOTSG it is heated by convective heat transfer as it begins to pass upward within the tube bundle). The remaining heat transfer is by nucleate boiling, film boiling and superheating. Nucleate boiling which begins at the bundle entrance in the OTSG (and at the top of the preheater zone in the IEOTSG) involves the formation of discrete vapor bubbles on the tubes and the release of these bubbles into the secondary flow. This combination of phase change and bubble motion creates very efficient heat transfer, in contrast to film boiling and superheating which both involve heat removal from the tube by steam convection and, consequently, are much less efficient. (See Chapter 5.) As a result, these latter modes occupy a large part of the bundle surface to transfer a relatively small portion of the heat load. The ratio of steam mass to total fluid mass (i.e., steam quality) increases as the secondary fluid flows upward. As the steam quality

reaches the high nineties, there is insufficient liquid to wet the tubes and nucleate boiling gives way to film boiling. Still farther up the generator where the moisture content of the fluid is depleted and the steam begins to superheat, heat transfer is by forced convection of vapor. The primary and secondary fluid temperatures and the modes of secondary heat transfer are indicated in Figs. 5 and 6. The secondary-side temperature remains at saturation through the nucleate and film boiling regions. The counterflowing primary fluid gradually cools as it flows through the steam generator. The drop in primary fluid temperature in the upper areas of the unit is relatively slow due to the less efficient heat transfer in the film boiling and superheater regions. In the lower regions of the unit, the primary fluid temperature change is much more rapid due to more efficient nucleate boiling heat transfer.

Instrumentation

The steam generator thermal performance measurements include fluid pressure, temperature, and level. Shell temperatures are measured at five equally spaced locations along the length of the generator. These measurements are used to determine tube to shell temperature differentials. A steam generator downcomer temperature measurement indicates the temperature of the incoming feed; this temperature is used in the temperature compensation of level. There are three ranges of steam generator level measurement: full, operate and startup. The operate range begins 8.5 ft (2.59 m) above the lower tubesheet. It is

graduated in percentage of full (operating) range, from 0% at 102 in. (2.6 m) above the lower tubesheet to 100% at a height of 394 in. (10.0 m). Whereas the common upper tap of the startup and operate range levels extends into the tubed region, their lower taps are in the steam generator lower downcomer. Feed and steam system measurements also indicate steam generator status. These include steam pressure and the pressure drop across the feedwater control valves. The flow rate of main feedwater is indicated in two ranges: startup to 15% of full flow range, and operating range. The majority of these steam generator measurements are supplied to the plant computer and the integrated control system.

Recirculating steam generator (RSG)

Design configuration and flow

Recirculating steam generators are supplied by a number of manufacturers worldwide as part of PWR and PHWR (mainly CANDU) systems. Two, three or four steam generators are supplied for each PWR system and 4 to 12 steam generators are supplied for each CANDU system. They range in height from approximately 38 to 73 ft (11.6 to 22.3 m) weighing from approximately 50 to 790 tons (45 to 717 t_m) each. See Fig. 7 for selected comparisons of sample units.

Each RSG is a vertical shell, inverted U-tube heat exchanger with steam-water separation equipment located above the tube bundle inside the upper shell (or steam drum). A cylindrical shroud or bundle wrap-

Fig. 5 Steam generator heat transfer for an OTSG.

per surrounds the tube bundle separating it from the lower shell. This creates an annular region which serves as the downcomer to return the recirculated water from the steam separators to the tube bundle inlet at the bottom of the unit. In a feed ring type RSG, feedwater is introduced by a nozzle and header to the top of the downcomer, and flows with the separator return flow down and into the tube bundle. In a preheater type RSG, feed flow enters the steam gen-

Fig. 6 Approximate primary and secondary temperature profiles at full load for an OTSG.

erator through a nozzle and feedwater distribution box to the baffled section at the cold leg outlet end of the tube bundle where it is heated to saturation before joining with the hot leg riser flow within the tube bundle. A typical RSG supplied by B&W to replace an original equipment manufacture (OEM) unit is shown in Fig. 8.

Fig. 7 Relative sizes of recirculating steam generators (RSG).

Fig. 8 B&W replacement recirculating steam generator.

A simplified schematic shown in Fig. 9 provides an overview of the flow configuration and the major design features of a typical feed ring type RSG. The hot primary coolant enters a portion of the vessel primary head which is separated into two plenums by a divider plate. The primary coolant flows through the inside of the U-tube bundle and exits the steam generator through the primary head outlet plenum. In most RSG designs, the U-tubes make a continuous 180 degree bend at the top of the tube bundle; one major OEM design uses two 90 degree bends separated by a horizontal section at the top of the tube bundle.

In the configuration shown, secondary-side feedwater enters the upper shell via a feed ring and is mixed with water returning from the steam-water separation equipment. The water flows down the downcomer annulus between the shroud and the shell to the tubesheet where it enters the tube bundle. The secondary-side water is heated as it passes up through the tube bundle generating steam through nucleate boiling heat transfer, creating a two-phase flow. Steam of 10 to 40% quality, depending on hot-side or cold-side U-tube bundle location, exits the tube bundle and is distributed to the primary and secondary steam

separators in the upper shell to send effectively moisture-free ($<0.25\%$ water) steam to the secondary-side power cycle. Water leaving the steam separators is recirculated down the annulus where it mixes with the feedwater before being returned to the bundle inlet for further steam generation.

The natural recirculation within the RSG is driven by the density difference between the higher density water column in the downcomer annulus area and the lower density steam-water mixture in the tube bundle. The RSG recirculation rate is set by the balance between the pressure drop through the flow path (downcomer, tube bundle and steam separation equipment) with the driving head created by the density differential (see Chapter 5). To minimize the potential

Fig. 9 Simplified recirculating steam generator (RSG) flow circuits.

buildup of any contaminants, a blowdown system is located in the bottom of the RSG near or as part of the tubesheet to remove a controlled quantity of water inventory. Blowdown is not very efficient at removal of many feedwater contaminants but it is the only way, other than moisture carryover, for feedwater contaminants to be removed from the steam generator during operation. Contaminants remaining in the steam generator can deposit onto the tubes and to a lesser degree build up on the tubesheet and tube supports.

Preheater (integral economizer) designs are also used for some RSGs. Here the feedwater is introduced near the tube bundle cold leg outlet to increase overall thermal efficiency. Several options have been used for this integral economizer section: counterflow, axial flow and split flow (cold leg side of the tube bundle). Simplified schematics are shown in Fig. 10.

Horizontal tube supports (support plates and/or lattice bar grids) are provided at various elevations along the vertical straight tube bundle section (see Fig. 8). A variety of supports have been used in the various original equipment designs (see Fig. 11). The tube supports provide lateral support to the tubes during steam generator manufacturing, shipment and operation and protect against seismic loads. They are spaced at intervals to minimize the likelihood of flow-induced vibration and are designed to provide adequate open area for the recirculating flow. Many of these designs were prone to accelerated corrosion, particularly if made of carbon steel (see Reference 1). B&W's advanced lattice grid tube supports (Figs. 12 and 13) have addressed many of these issues.

Additional tube supports or restraining systems are required in the upper bundle U-bend area (see Fig. 14). These maintain the position of the tubes and prevent excessive flow-induced vibration as the high velocity steam-water mixture flows out through the U-bends.

Key information on the various RSG designs is provided in Table 2.

Steam-water separation

High efficiency steam-water separation is a vital function in all recirculating steam generators, as discussed in Chapter 5. This is particularly true in nuclear RSGs. Low moisture carryover in the steam improves turbine efficiency and total power output, and minimizes the carryover of any contaminants into the turbine. The traditional limit for nuclear RSG moisture carryover at full power is less than 0.25% moisture by weight, while more recent requirements have been for 0.10% or less.

Low steam carryunder (steam entrainment) within the downcomer return water maximizes the downcomer annulus driving head, thereby maximizing the internal circulation rate. Low separator pressure drop also increases the natural circulation rate through the bundle by lowering the overall flow resistance.

The B&W steam separation system combines curved arm primary (CAP) separators (see Chapter 5, Fig. 23) with cyclone secondary separators (see Fig. 15) to accommodate the necessary steam throughput.² The actual moisture carryover as measured at steam generator startup has been well below 0.10% moisture by weight in all B&W replacement RSGs.

Fig. 10 Integral economizer designs used in RSGs.

Fig. 11 Original RSG support plate designs by various manufacturers.

Circulation and hydraulic performance

Detailed thermal-hydraulic design analyses are conducted on all RSG designs and include, among others:

1. heat transfer analysis on a local basis,
2. three-dimensional analysis of flow (velocities, pressures, qualities, etc.),
3. dynamic response of the steam generator to normal and abnormal transients,
4. potential deposit accumulation on the secondary side of the RSG,
5. recirculation rate within the tube bundle, and
6. flow-induced loadings on internal components.

The circulation ratio (total flow rising through the tube bundle divided by the exiting steam flow) is a par-

Fig. 12 B&W lattice grid tube support assembly.

Fig. 13 B&W lattice grid tube support design details.

ticularly important parameter. Higher circulation rates reduce the overall steam voidage in the tube bundle and increase the local velocities. Reduced voidage improves the steam drum water stability during transients. A higher circulation ratio also increases the margin for stability, and increases the margin for tube surface dryout and for critical heat flux in the tube support areas. It also reduces low velocity areas, especially near the tubesheet where deposits may accumulate.

Circulation rate is increased by low flow path pressure drop at the tube supports and the steam separators, and by low steam carryunder from the steam-water separators to the downcomer. High circulation

ratios (up to 6.0) have been a significant feature in B&W designs.

Replacement steam generators

Of the 69 operating PWR nuclear power plants in the U.S., 56 had 163 individual steam generators replaced or awarded by 2005. Additional RSG replacements are anticipated as the remaining installations age.

The previously unanticipated aging issues experienced by nuclear steam generators generally involve complex interactions between the materials of construction, water chemistry operation and contaminant ingress, tube support arrangements, fabrication techniques, and local thermal-hydraulic conditions. These only became apparent with long-term operation of the equipment. Examples of this damage include:

1. intergranular attack,
2. stress corrosion cracking (SCC),
3. primary- and secondary-side cracking at the tubesheet expansion transitions,
4. primary-side cracking at the U-bends,

5. wall thinning/wastage/pitting involving sludge near the tubesheets,
6. denting or permanent deformation of the tubes at the carbon steel support plates due to corrosion product buildup and volume expansion,
7. fretting wear,
8. tube circumferential cracking due to high frequency fatigue,
9. erosion-corrosion in higher velocity regions, and
10. foreign object damage.

In many cases, the affected tubes are plugged when significant leakage is detected or when degradation reaches a critical level. However, with time the overall bundle degradation can reach a stage where repair is no longer a viable option and steam generator replacement is needed. References 1 and 3 explore this in more depth.

B&W's advanced series replacement steam generators are designed with the most current technology available to overcome the steam generator issues while still meeting or exceeding all of the steam generator functional requirements. Replacement units must fit within the

Fig. 15 Primary and secondary RSG steam separator system.

established plant configuration, and must meet all performance and operational requirements. In addition, these replacement units must be redesigned to minimize or eliminate the original problematic degradation.

Replacement steam generators are also designed to support extension of power plant operating life. In many cases, the plants with replacement units have received extended licenses to operate 20 years beyond the original plant life span and may eventually operate even further. To achieve these objectives, while combating the causes of component degradation, emphasis is placed on upgrading component materials, introducing advanced design features and manufacturing methods, and incorporating the latest technical developments.

Replacement recirculating steam generators (RRSG)

The contract for the first replacement nuclear steam generator supplied by B&W was awarded in 1988, for Northeast Utilities' Millstone Unit 2 nuclear power plant. Since then and through 2004, B&W has designed and manufactured a total of 6 once-through and 34 replacement recirculating nuclear steam generator units for the U.S. market.

All of the RSG units are similar but are adapted to the requirements of the specific power plant. Significant features are shown in Fig. 8. While the basic envelope of each RSG type remained the same as the respective OEM equipment, major changes were made to the tubing and tube support materials. Design features were included to enhance reliability and facilitate in-service inspection and maintenance (see Table 3).

Tubing material The majority of critical degradation mechanisms involved the tube bundle and the tube supports; therefore, the selection and quality of the tubing are the most important factors in steam generator design. The original equipment tube material was mill-annealed (MA) Alloy 600 (Inconel: Ni-Cr-Fe alloy). However, experience has shown this material to be susceptible to stress corrosion cracking (SCC), especially in areas of cold work such as at the original tubesheet roll expansion transition regions (see Fig. 16) and in areas of harsh environments such as the top of the tubesheet. The replacement units feature

Table 3
Replacement Recirculating Steam Generator Design Features

Features	Original Design	Replacement Design	Improvement
Tube material	Alloy 600MA	Alloy 690TT	Corrosion resistance
Surface area	Nominal	Increase	Accommodates reduced conductivity and elimination of preheater Provides power uprate capacity and/or steam pressure increase
Tube support plate material	Carbon steel	Type 410S	Corrosion resistance
Tube support plate design	Drilled/broached	Lattice bars	Improves flow area Minimizes crevices
Divider plate	Floating	All welded	Minimizes bundle bypass
Drum internals	Original	Upgraded by test and field experience	Improves water inventory and performance characteristics

Fig. 16 Original equipment tube to tubesheet expansion transition.

Alloy 690TT (thermally treated) tubing which has a high resistance to corrosion. This replacement tubing is particularly resistant to SCC due to its higher chrome content and thermal treatment.

Tubing today is manufactured to very stringent specifications, resulting in a very high quality product. The new metallurgical treatment offers a material grain structure that is much more resistant to cracking. In addition, these tubes are metallurgically very clean and have a minimum of defects and inclusions. As a result, these tubes have very low eddy current noise, thus improving the resolution of in-service eddy current testing (ECT) inspections. Any small, tight cracks or other defects that may occur will be found more easily.

General design features The first requirement in the design of any replacement steam generator is the selection of a general architecture which will, as closely as possible, match that of the original unit. This is necessary to comply with Nuclear Regulatory Commission (NRC) requirements and ensure licensing. The pressure vessel envelope is designed to match the origi-

nal in size, dimensions, and pressure rating. The heat transfer surface (external surface of the tubing) is sized to match the function of the original surface and/or any upgrades required by the plant owner.

In defining the heat transfer surface, certain effects must be taken into account including:

1. the net effect of the reduced thermal conductivity of A690TT relative to A600MA,
2. any tube wall thickness and/or diameter change,
3. preheater deletion if applicable, which requires the addition of a large amount of surface, and
4. any change of rated performance such as power increase, steam pressure increase or primary inlet temperature reduction.

Having defined the vessel envelope and heat transfer surface requirements, the design is refined to address other thermal-hydraulic parameters such as primary-side flow resistance (which must closely match the original) and the range of secondary-side thermal-hydraulic issues described above. Finally, structural and reliability design features are introduced to ensure prolonged and reliable operation.

Tube supports The original equipment incorporated a variety of tube supports including flat plates with drilled flow holes, broached plates, and lattice grids (see Fig. 11). These have been replaced with a refined lattice grid arrangement made of intersecting flat bars of Type 410S stainless steel. (See Figs. 12 and 13.) This design is based on the lattice bar arrangement used in the later CANDU steam generator designs. (See also Chapter 50.) These lattice bar tube supports provide anti-vibration restraint for the straight leg portions of the tubes and provide lateral support for the entire bundle. Lateral loads include handling and shipping loads plus seismic and other accident loads. Normally the lateral in-service loads from the U-bends are taken through the uppermost lattice grid tube support; these can be well in excess of handling loads.

The U-bends are supported against flow-induced vibration (FIV) and mechanical loads by flat bar U-bend supports (see Fig. 14). FIV restraint is provided by positioning sufficient flat bar supports within the U-bends to avoid excessive tube response to turbulent or fluid-elastic instability flow excitation. Support against mechanical loads, including seismic, is basically provided by coordination and transfer of the U-bend swaying forces to the uppermost lattice, designed to sustain the lateral load of the overhung U-bends. The flat bar configurations provide an open flow arrangement and line contact tube support to ensure free flowing recirculation conditions and to avoid tube-conforming crevices or trapped spaces that may accumulate vapor and deposits, which may encourage corrosion.

The Type 410S material selected for lattice bars and U-bend supports is a low carbon version of Type 410. This material has excellent strength in its quenched and tempered condition, is resistant to tube fretting, and has good resistance to local and general corrosion. Unlike carbon steel, any oxide that does form by corrosion has a volume not greater than that of the base metal. This avoids tube and support plate degradation caused by voluminous rapid linear oxide growth,

usually referred to as denting corrosion, that plagued many earlier carbon steel support plates.

Welded divider plate All recirculating steam generators feature a flat plate in the primary head to separate the incoming primary flow from the primary outlet flow. In certain original designs, this was essentially a floating design where the divider plate was located by engaging seat bars that were welded to the head and tubesheet surfaces. Because of gaps around the plate, there was some primary flow bypass from the inlet to the outlet side of the primary head. Replacement steam generators typically have a fully welded divider plate that is joined around the full perimeter to the primary head and tubesheet, as shown in Fig. 17. This was not done in some original designs due to concerns about thermal stresses in the combined head/plate/tubesheet structure. However, three-dimensional finite element elastic-plastic analysis now allows a more accurate assessment of the operational thermal and mechanical loads and shows that the all-welded arrangement meets all design and pressure vessel code requirements.

Steam drum internals The steam drum internals for all B&W replacement RSGs incorporate the high effi-

Fig. 17 Fully welded primary head divider plate.

Fig. 18 Replacement recirculating steam generators can be supplied that use the original upper shell, which remains in containment.

ciency CAP separators and cyclone secondary separators as described earlier. The drum internals have been replaced for all replacement units whether the steam drum pressure vessel itself was replaced or retained. In many cases the drum was too large to remove, so new separators were installed into the existing drums within the reactor building. Such replacement RSGs are shipped without the upper shell, or steam drum (see Fig. 18).

Replacement once-through steam generators (ROTSG)

The Oconee nuclear plant units in the U.S. were the original lead units of the B&W PWR program. Over the years, the once-through steam generators performed very well, but like the recirculating steam generators, they eventually showed corrosion problems with their Alloy 600 tubes. Steam generators for all three Oconee units (two steam generators per unit) have been replaced.⁴ (See Fig. 19.)

A major difference between the OTSGs and the recirculating steam generators is that since there is no steam drum there is no large secondary water inventory in the once-through units. Because of such thermal-hydraulic characteristics and because the straight tubes and the straight shell are bound together at both ends, the design of these steam generators is very tightly integrated. Thermal characteristics of heat-up and cool-down and the thermal hydraulics of the down-comer flow, feedwater heating, level control, etc. are highly interdependent with each other and with the structural and hydraulic configuration of the equipment. The replacement units have been designed to retain, as closely as possible, the thermal and performance characteristics of the original units so that there is as little change as possible to this carefully integrated balance.

As with the recirculating design, the tubing material for the ROTSGs has been changed from A600MA to A690TT. The tube support configuration of the original OTSGs introduced the industry to the broached plate design. The broached plate design has been retained for the replacement units but with Type 410S material. In addition to the broaching, the flow passages use a patented hourglass configuration and the surface finish is enhanced by an electropolishing process. This minimizes deposition and reduces the potential for tube fretting and any support contact surface anomalies.

The original OTSGs were constructed with a radial open lane through the bundle to allow inspection of the bundle inner region. Long-term operation has shown this to be an undesirable feature. Secondary-side flow non-uniformity led to thermal tensile stress, localized high velocities, and localized corrosive environments, all of which contributed to fatigue in tubes adjacent to the lane.

In designing the steam generator shell, the original envelope is retained but the material is replaced with high strength steel to minimize weight, and with forgings to reduce the number of longitudinal welds. The original vessel cylindrical support skirt is replaced with a conical base to improve access for pipe work and

Fig. 19 Replacement once-through steam generator.

Table 4
Replacement Once-Through Steam Generator Design Features

Features	Original Design	Replacement Design	Improvement
Tube material	Alloy-600MA	Alloy-690TT	Corrosion resistance
Pressure vessel	Carbon steel	High strength steel	Reduces weight
Vessel support skirt	Cylindrical	Conical	Improves maintenance access
Tube support plate	Broached	Broached with added hour-glassing, enhanced surface finish, 410S material	Mitigates deposits Corrosion resistance Reduces pressure drop
Tube bundle layout	Tube-free lane	Open lane eliminated	Improves flow distribution

for manway access during manufacture, installation and service (see Fig. 19).

Other design features have been added such as feed-water header configuration improvements, addition of more inspection ports, and seal welding of infrequently used inspection ports. A summary of the major changes to the original design is given in Table 4.

Further development

Research and development (R&D) work defines the technology needs and establishes internal or external programs to achieve those objectives. The work includes development of new design configurations and features; development of manufacturing processes including specialized welding, cleaning, tube expansion and surface conditioning procedures; development of processes, tooling and robotics for field service and inspection processes including water lancing, visual inspection, cleaning and tube inspection; thermal-hydraulic, stress and flow-induced vibration design procedures; and design elements including steam separators and tube support structures. This R&D work includes the materials, chemistry and corrosion technology to support component and pressure vessel design and tube longevity. A summary of B&W's R&D activities is shown in Table 5.

Chapter 49

Nuclear Services and Operations

Nuclear service activity includes all life management planning, inspection, analysis, assessment, maintenance and repair of equipment as required to support the plant equipment throughout its operating life. This life management activity must achieve continued high reliability and high availability for the entire life of the plant. Because most routine nuclear plant maintenance is done during scheduled refueling outages and because of the extended time between such outages (12 to 24 months), successful long range outage planning is essential. Ultimately, all of this planning effort is designed to obtain approval from the appropriate regulating authority to return the plant to full operation.

In some areas, the routine maintenance for nuclear plants is similar to that for fossil-fueled plants. This includes the turbine-generator systems, pumps, valves, fans, filters, electrical distribution systems, and some of the instrumentation and control systems. Nuclear plants, however, have many inspection and maintenance activities which are different in nature, precision, extent or available maintenance time period. Also, in parts of the plant subject to radiation exposure there are significant differences due to radiological considerations. Dealing with the radiological issues imposes unique requirements on plant maintenance, especially in personnel protection, handling of radioactive materials, disposal of waste items and the need for remote robotic equipment.

The following sections focus on the maintenance of the major components and the unique aspects of working in a nuclear facility. Most of the discussion is centered on the key areas of the reactor primary heat transport system as shown in [Fig. 1](#). The reactor shown has once-through steam generators (OTSGs). Recirculating steam generators (RSGs) have similar tubing inspection and repair requirements but also have the steam drum/upper bundle area which requires periodic inspection.

Maintenance – key issues

Personnel protection

Although stringent precautions are taken, nuclear plant maintenance workers are exposed to low levels of radiation. In the United States (U.S.), allowable technician dose limits are regulated by the Nuclear Regulatory Commission (NRC). Other countries (e.g.,

Canada) set their own allowable technician dose limits. Some operating companies curtail exposure even further.

Workers entering a radioactive area must wear protective clothing. This typically consists of cotton overalls, paper and rubber shoe covers, cotton and rubber gloves, and a cotton hood or paper hat. Respiratory protection and/or plastic suits with air supply may also be required.

Limited accessibility

A major restraint to performing nuclear plant maintenance is the limited accessibility of much of the equipment. The primary reactor system is not accessible during power operation. As a result, this equipment must be maintained during outages. Repair, replacement or return-to-service of parts must be based upon maintaining fitness-for-service to the next point in time when that part will be inspected.

Most of the plant equipment is required by license to be operable during normal operation. If a safety-related system fails, the operator typically has some limited period of time for its repair and return-to-service, otherwise the entire unit must be shut down. Examples of such critical equipment include the high pressure injection system, low pressure/decay heat removal system, core flood system, building spray system, reactor protection system, and nuclear instrumentation.

Application of remote technology

Principles known as *time, distance and shielding* and ALARA (as low as reasonably achievable) are the cornerstones of performing maintenance in a radiation-exposure efficient manner. In applying remote technology, emphasis is placed on the time of personnel exposure as well as the distance between the personnel and the work piece.

When considering whether remote technology is applicable, the level of radiation, the time required for the maintenance and the work place environment are evaluated. Key areas where this technology has been applied include work in or around the reactor vessel and its internals and within the steam generators. Although the reactor vessel is highly radioactive, it is submerged in water during maintenance. While the water shields the workers from radiation, remote and/or fully robotic equipment is necessary for the underwater repairs.

While remote and robotic technology have improved the extent, quantity and refinement of inspection data being gathered, the cleaning and repair performed have increased enormously. The inspection of tens of thousands of steam generator tubes in a short outage is not unusual compared to hundreds in prior years. At the same time, efforts to optimize these activities have led to shorter outages. As a result of these shorter, more effective outages, the average U.S. reactor availability has climbed from 60% in the past 20 years to more than 90%.

Although remote technology often encompasses the use of robots, it can also be an extension of a hand tool or the development of a flexible probe and manipulator to increase distance from the work piece and to allow internal access to tight or complicated spaces. Each maintenance task requires a different degree of sophistication based on the environment and the complexity of the task. As remote technology advances, the amount of personnel radiation exposure declines even as the scope and sophistication of the work increases.

Component maintenance

Plant life management

The objective of plant life management is to ensure that the plant equipment achieves a continuing state of high availability throughout its operating life and the plant reaches at least its desired lifetime. Life management places emphasis on the assessment of component condition prior to scheduled outages and on the scheduling, planning and mobilization of workforce, equipment and methodology to achieve timely execution of the outage work. Outages may only end when all work is successfully completed and documented, and approval is granted by the appropriate regulatory authority to return to service.

Because experience has shown that much of the plant availability is dependent on the successful operation of the steam generators, the discussion and illustration of plant life management methods will concentrate on these components.

Long range life assessment Prior to development of a life management plan, a life assessment process is completed for each major component. This life assessment is necessary to establish the operating history of the component and to provide a basis for planning a multi-outage inspection and maintenance program. For steam generators, the life assessment and other work should individually address the three major areas of: 1) pressure vessel boundary, 2) the heat transfer tubing and 3) internals such as tube supports, steam separators and feedwater headers. Breakdown into these three areas is necessary because the regulatory requirements and the inspection and maintenance requirements for each are unique.

Pressure vessel boundary The design, manufacture, in-service inspection, and repair of all component pressure vessel boundaries is regulated by the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code as augmented by other regulatory requirements. During manufacture, the Code-defined volumetric inspections ensure the components

meet stringent standards and establish a baseline for in-service evaluations. In-service requirements specify examination of the pressure vessel boundary, including visual inspection and volumetric nondestructive examination (NDE) of the welds. An assessment of the steam generator must determine the condition of the equipment and any areas of non-compliance with the requirements and must identify any work needed to restore the unit to a compliant state.

Tubing The steam generator tubing is the boundary between the primary and the secondary heat transport systems and is very important to the integrity of the plant. Tube integrity is the primary concern when reviewing the steam generator. In The Babcock & Wilcox Company (B&W) plants, there are about 15,000 tubes in each of the two once-through steam generators (Fig. 1). In plants with recirculating steam generators, there are about 3000 to 11,000 tubes in each of two to four steam generators per plant. With a typical tube wall thickness of about 0.04 in. (1 mm) or less, the tubing is a vulnerable boundary and must be carefully maintained. Tube leaks are a major concern and primary to secondary leakage above certain prescribed limits requires shutdown of the plant.

Experience has shown the tubing to be a major cause of loss of plant availability, long outages, and expensive repair and replacement work. Common problems with steam generator tubing are generally related to corrosion involving a combination of materials and water chemistry issues. Some of the more common problems are stress corrosion cracking, pitting, wastage, erosion, fretting at tube supports, and denting due to corrosion of any carbon steel tube supports. Fretting due to flow-induced vibration and fretting due to foreign object ingress may also exist. In modern replacement steam generators with highly corrosion resistant tubing and good tube support, foreign object damage may be the most serious concern regarding tube integrity. Because of the magnitude and frequency of problems over the years, the tubing receives the majority of attention in the life management plan.

Internals Internals common to all types of steam generators include tube supports, shrouds (bundle wrapper) and feedwater and/or auxiliary water headers. For recirculating units, additional internals include U-bend tube supports, steam separators and various supports and baffles internal to the steam drum. In contrast to the tube bundle that contains many identical elements (tubes), the internals consist of a large number of parts that are dissimilar in terms of function, configuration and accessibility for service. The internals are subject to a variety of flow forces and flow-induced vibrations. Bundle supports in close contact with the tubing can cause tube degradation due to fretting, and tube denting due to corrosion of the supports. The life assessment process must consider the potential for a wide variety of potential problems with these internals.

Life management program plan Following the assessment of the component, a long range life management plan can be developed. Table 1 illustrates a small portion of such a plan for a set of steam generators. It shows the scope, timing, inspection, cleaning and repair activities for outages 11 through 14 of the total life

Table 1
Steam Generator Life Management Program Plan
Unit ABCD/SG 1, 2, 3, 4

Outage No.	11 October 2003	12 April 2005	13 October 2006	14 April 2008
Activity				
Pressure vessel NDE program				
Tube ECT		SG 2, 4 50% Bobbin 10% TS MRPC		SG 1, 3 50% Bobbin 10% TS MRPC
Tubesheet waterlancing		SG 1, 2, 3, 4		
Tubesheet FOSAR		SG 1, 2, 3, 4		SG 1, 3
Drum and upper bundle visual inspection		SG 2		
Tube plugging		If required		If required
Planned retrofit of bundle inspection ports				SG 1, 3 TSP 6, 8
Chemical cleaning		Assess need		

Tube ECT: Eddy current testing, with 50% of bundle using the standard Bobbin and 10% bundle using the MRPC coil.
Tubesheet FOSAR: Foreign object search and retrieval, visual examination.
Drum and upper bundle inspection: Visual/robotic inspection to meet requirements of NRC Generic letter 97-06(1977).
Tube plugging: Based on inspection results.
Planned retrofit of bundle inspection nozzles: See chapter 48.
Tubesheet water lancing: Cleaning sludge deposits on top of tubesheet surface.
Chemical cleaning: chemical dissolution of secondary-side tube deposits.

cycle. A full plan would cover many more outage cycles, more plant components, and many more activities.

Having identified the necessary inspection and maintenance tasks, significant effort is then employed to define work scope, the preparation of detailed plans, detailed procedures, and to obtain regulatory approvals to proceed. A typical outage would result in a large volume of tube eddy current testing (ECT), pressure vessel inspections, and visual and foreign object search and retrieval (FOSAR) inspections of the secondary and primary side internals. There would also be cleaning activities, repairs and possibly some component modifications that had been planned in advance. The assessment of this large database of information, which is done as soon as the inspection data is available, forms the basis for the next phase to determine fitness-for-service.

Fitness-for-service assessment The fitness-for-service assessment is a methodology for determining that a particular plant component is in an acceptable condition at the time of inspection (referred to as *condition monitoring*) and confirming that it will be in an acceptable condition at the time of its next planned inspection (*operational assessment*). The method is illustrated by Fig. 2 which shows the current as-measured size of a defect in a steam generator tube wall, the estimated growth for a period of operations and the estimated size at the time of its next inspection. Essentially, the initial as-measured size from tube inspection, with an added allowance for measurement error, is plotted at the time of the current inspection. A projection is made of the growth of this defect to the

time of the next inspection. If the projected flaw size at the time of the next inspection is greater than the allowable flaw size, the tube is considered potentially unsafe and is most likely removed from service by plugging.

The probability of detecting a particular defect in tubing is dependent on the nature of the defect (pits, frets, cracks, etc.) and its location relative to other sources of electronic signals such as tube supports, tube wall expansion transitions and corrosion deposits. With current technology, pits measuring a small percentage of the wall thickness can be detected. By contrast, tight cracks are much more difficult to detect and may sometimes be missed, even at 30% of wall thickness. Also, allowance for measurement error is necessary to ensure that a high percentage of the actual defect sizes are within the bounds of these derived defect sizes.

Steam generator primary side maintenance

Maintenance of a steam generator primary side includes the major activities of:

1. inspection of the tubing,
2. plugging tubes that fail to meet the inspection criteria,
3. repair of tubes to keep them in service and to thus reduce performance degradation, and
4. stabilizing out-of-service tubes to keep them from damaging their neighbors.

Steam generator tube inspection Based on prior experience with the steam generators under examination, some fraction of the tubing will be required to be in-

Fig. 2 Fitness-for-service assessment for a steam generator tube with defect indication.

spected on a periodic basis. For example, it may be determined that half of the steam generators in the plant will be inspected at every second outage (as in Table 1). There may also be commitments for specialized inspections or for other tube inspections as a condition for a return-to-service approval from prior outages.

Eddy current testing (ECT) ECT is the primary inspection method, although ultrasonic testing (UT) is used in special cases. The ECT is conducted by imposing an alternating current (AC) magnetic field. This field induces eddy currents in the material that creates a secondary magnetic field. If discontinuities are present, the eddy currents are altered and the apparent impedance of a detecting coil is changed. The size of the discontinuity can then be related to this change by prior calibration.

Tubes are inspected by inserting the probe and then inspecting the tube while withdrawing the probe at a controlled rate. RSG and OTSG tubes can be inspected full length except that some smaller radius RSG tubes may require access from both ends. A typical robotic positioner for the ECT probes is shown in Fig. 3.

Several different probes are used to characterize the tubing condition. A bobbin coil ECT probe basically consists of a bobbin wound with coils of wire. Eddy currents generated by the coil electromagnetically couple the probe and the test piece with the eddy currents flowing in a direction parallel to the coil winding. Eddy current signals from a bobbin coil are measured as changes in primary coil electrical impedance induced by the eddy current magnetic field. Bobbin coil ECT has been used throughout the industry for many years, although other probe types are essential to complement the basic information received. One limitation is that the signal is integrated 360 deg around the tube and is therefore unable to differentiate within that range. The bobbin coil is able to size many types of defects once the nature of such defects has been determined by laboratory analysis or by other probe types, but it is not good for exploring unknown situations such as detecting tight cracks of moderate size or circumferentially oriented cracks. It can, however, be used to see further in the radial direction than

other ECT techniques. It is sensitive at low operating frequencies to conditions (supports, deposits) beyond the tube outer surface; at high frequencies it has a shorter range of vision.

Because of these limitations, a number of rotating and array probes have been developed. MRPC (motorized rotating pancake coil), +Point® (plus point) rotating probes and X-Probe® array probes are examples. Rotating probes like MRPC and +Point provide excellent and finely detailed data but have the disadvantage of very slow probe travel speed. The X-Probe offers the speed of the bobbin with the detail of rotating probes, although with the generation of a very large amount of data. Fig. 4 shows a typical arrangement of the bobbin coil and X-Probe; the data acquisition and analysis system is shown in Fig. 5.

Ultrasonic testing (UT) UT of tubing is a valuable tool, particularly in the early investigative phase where a newly discovered condition must be characterized. The process requires a rotating surface-riding UT probe where the signal path must be flooded by a couplant such as water. Because of the rotation and the couplant, the process is slow and somewhat awkward, but it does have excellent resolution. It has the advantage of seeing indications differently than ECT, thereby providing results to supplement the ECT information.

Destructive examination (DE) DE is a vital part of investigating any newly discovered degradation condition in tubing (or in other component areas). Except perhaps for phenomena like fretting, it is not possible to characterize a degradation condition and to determine its root cause without sample removal and laboratory examination. Until newly discovered defects are characterized in the lab, it is not possible to know with any certainty the relationship between the defect and the ECT signal it produced in the field. Because some

Fig. 3 Robotic eddy current inspection shown in a recirculating steam generator mockup.

Fig. 4 Multi-coil array probe with bobbin coil.

of the more critical defects such as tight cracks are difficult to see at any time, even where they are relatively large, such characterization is vital.

Remote technology In the early years of nuclear power all of the maintenance work was performed manually by technicians who entered the steam generator head. As maintenance activities and radiation levels increased with plant aging, it became increasingly difficult to perform repairs manually. As inspecting ever larger numbers of tubes during refueling outages became mandatory, this work was a logical candidate for early remote technology. B&W's first manipulator used on OTSGs was positioned manually on the tubesheet, locked in place, then computer controlled from a remote location. For RSGs, an articulated arm manipulator was used. Although also manually installed, it was not computer controlled. Both manipulators performed well for inspection, but they

Fig. 5 Eddy current data acquisition and analysis system for multi-coil array probe.

could not support the heavy tools required for plugging and other repair operations. In addition, because of reduced radiation dose limits, the practice of manually installing the manipulators had to be eliminated.

Advanced manipulators Advanced manipulators have been developed to minimize human exposure, to perform multiple inspection and repair duties, and to be computer controlled.

An earlier design of a remote manipulator is shown in Fig. 6. The unit is installed in the steam generator head by a series of cables and pulleys as shown in Fig. 7. Although lightweight in construction, it has a load capacity of 200 lb (91 kg). Once calibrated, it can be directed to any tube in the steam generator. With the exception of tool head installations, all operations are remotely controlled and video equipment is used to monitor the work. The control center is located outside the containment building.

Fig. 8 shows an advanced manipulator that loads itself into the channel head while its arm exits the manway for attachment of tool heads. Being mounted on the manway opening, it provides unobstructed access to all parts of the tubesheet. It also reduces personnel radiation exposure.

Tube plugging Any tube not meeting the established criteria for acceptability must be taken out of service or repaired. While explosive plugs were used in the

Fig. 6 Tubesheet-mounted manipulator inside a recirculating steam generator primary head.

Fig. 7 Installation sequence for the tubesheet-mounted manipulator in Fig. 6.

Fig. 8 Manway-mounted manipulator in an RSG head mockup.

1970s and 1980s, mechanical plugs are now more common. Fig. 9 shows typical mechanical plugs. Seal welded plugs are also used. The rolled plug is installed in one tube end with an air-powered roll expander, which forces the plug wall outward into the tube wall. Expansion continues until the plug and tube wall contact the tubesheet bore and the proper torque is reached by the tool. This process is repeated at the opposite end of the tube.

Tube repair A limited number of tubes may be plugged before unit efficiency is impaired. For nuclear steam generators, this limit is set by thermal performance parameters. One method of repairing damaged tubes and returning plugged tubes to service is *tube sleeving*. In this technique, a short tube (sleeve) is inserted into the base tube to bridge the degraded area. Should the defect continue to grow, the sleeve effectively seals the leak from the secondary side. However, this technique is generally limited to the portion of the tubes near the tubesheet. Fig. 10 shows a typical tube sleeved with roll expanded sleeves.

Fig. 9 Steam generator tube mechanical plugs – rolled (left) and expanding mandrel (right). Note: clearances and expansion transition profiles are greatly exaggerated radially for illustration.

Because of extensive steam generator replacement taking place, the need and practice of sleeving have been reduced.

Steam generator secondary side maintenance

While control of secondary side water chemistry helps to minimize repairs in this area, some maintenance is necessary. Two conditions, fouling and sludge buildup, must be eliminated. Fouling consists of deposition of solids, primarily iron, on the outside of tubes and at the tube support plates. Support plate deposits can increase pressure drop resulting in reduced steam generator performance. Tube bundle deposits can reduce heat transfer capability and also degrade performance. More important, buildup of these deposits can concentrate contaminants such as chlorides and fluorides that promote stress corrosion cracking—a problem which has destroyed tens of thousands of tubes and has led to the need for extensive steam generator replacement.

Sludge deposit buildup occurs at the lower tubesheet of the steam generator where solids from the feedwater are deposited. Again, other contaminants can concentrate in this sludge, degrading the tubes.

Different techniques are used to remove these sludge buildups. Chemical cleaning is used for the tube support plate and tube bundle. A chemical solution is introduced into the secondary side during a shutdown. Then, following a soaking period, the unit

is flushed. Sludge piles are removed by water lancing. This process, also known as *sludge lancing*, uses high pressure water introduced robotically through a secondary side opening to loosen deposits. The loose deposits and water are then suctioned out of the steam generator and processed through a filter system.

Fig. 11a shows the flexible inter-tube water lancing system used by B&W for steam generator cleaning. The system uses six or eight small-diameter pressure tubes to deliver high pressure water to the very small nozzles in its end manifold. These end manifolds direct intense water jets at the tubesheet face and upward toward the lowermost support. The flexible lance is fed into the steam generator through a secondary side inspection port just above the tubesheet. A semi-rigid guide directs the flexible lance along the steam generator's central tube-free lane, guides it through a tight right-angle turn, and projects it into the individual intertube lanes and ultimately to the bundle periphery. The jet action dislodges the sludge deposits from the tubesheet (and/or from tube supports) and permits the deposits to be flushed out of the bundle and removed by suctioning. This inter-tube system is particularly effective for hard deposits. Fig. 11b shows the water jet spraying from a flexible lance positioned within a small demonstration tube bundle.

The need for chemical cleaning or sludge lancing is determined by performance degradation, visual inspections using small fiberscopes and cameras, and by the removal of tube samples to detect degradation (or in some cases to directly measure the deposit loading).

Reactor vessel and internals

While the reactor vessel and its internals are static equipment, they are not free from either degradation or the need for maintenance. Maintenance ranges from care for the studs, gaskets and gasket surfaces during each refueling outage to repairs for various severe and costly degradation mechanisms.

Reactor vessel The vessel closure is the large diameter, high pressure bolted flange with its delicate gasket face which is the joint between vessel and head. During refueling, the reactor head must be removed from the vessel to gain access to the core. Each of the very large studs that retain the head is also removed from the vessel for cleaning. Special precautions are taken to contain the contaminated particulate that is released by stud cleaning equipment. Following cleaning, each stud is lubricated for reinsertion into the vessel flange. Likewise, each stud hole is cleaned prior to retensioning the studs.

The primary seal between the reactor vessel flange and head is a double O-ring configuration. Both mating surfaces must be thoroughly cleaned before installing the O-rings, which are replaced each time the head is removed. The seals are installed on the head and, just prior to setting the head, the vessel flange is cleaned and inspected for scratches that could cause leakage.

Reactor vessel heads worldwide have, of late, been subject to extensive degradation and some leakage due to stress corrosion cracking of the weld joints between the control rod drive mechanism (CRDM) guide tubes and the head. These guide tubes penetrate the

Fig. 10 Steam generator roller expanded tube sleeves – free span upper expansion (left) and tubesheet region upper expansion (right).

Fig. 11b Waterlance jet spray pattern in a small demonstration tube bundle.

head and are welded to the cladding at the inner surface of the head. In at least one case, extensive corrosion of the head itself had occurred before this problem was discovered.

Because these welds are difficult and costly to inspect and repair, many utilities have chosen to replace the heads with components made with new, more corrosion resistant materials (Alloy 690, 52, 152 versus the prior Alloy 600, 82, 182 materials).

The small instrument guide tubes in the lower head of the reactor have also required attention at times but to a much lesser degree than the head penetrations.

In addition to the above more conventional forms of degradation, the effect of neutron radiation on reactor vessels must be considered. Neutrons can reduce the toughness of steels, increasing their susceptibility to brittle fracture. As a result, the welds in the reactor core region are subjected to extensive UT examination. Of particular interest is the surface just under the cladding. Special techniques are used to achieve maximum coverage and sensitivity.

To gain access to the inside surface of the reactor vessel, all the fuel and internals must be removed. Due to its highly irradiated condition, the vessel must remain filled with water to provide shielding. Each weld, including those between the nozzles and primary piping, must be examined. This can be accomplished using an automated reactor inspection system, shown in Fig. 12. A typical vessel inspection can take from 10 to 20 days, depending on the quantity of welds and the need for rescanning.

Internals While the reactor vessel internals require little routine maintenance, there have been various core barrel integrity problems, mostly related to vibration due to inlet flow buffeting. Because the internals

are highly radioactive, any repairs must be done under water. The bolted joints of the reactor internals have required the most repair activity. Stress corrosion cracking of high strength steel or Inconel® bolts has been the most common cause for repair. Although the performance of A-286 stainless and X-750 Inconel bolts was expected to be good, pure water stress corrosion has been a problem.

In replacing these bolts, standard wrenches, drills and sockets have been adapted to be operated from an extension or underwater platform. Underwater cameras facilitate these remote repairs.

Control rod drive mechanisms (CRDM)

The CRDMs are mounted to the top of the reactor vessel head and control the movement of the reactivity control rods in the core. A central shaft known as either a lead screw or drive shaft attaches to the control rod and is moved by the mechanism. The CRDM is powered electrically, and position indication (PI) switches are used to let the reactor operator know the position of the control rod. During refueling outages, inspection, tests and routine maintenance are performed on the mechanisms to assure the motors and PI systems are functioning properly. Motors with unacceptable characteristics are replaced. PIs are also replaced if not functioning properly. Some CRDM designs attach to the reactor vessel head with bolts and use gaskets to provide the sealing. Occasionally these joints leak and require replacement of the gaskets and rework of the flange faces. This work is performed during the refueling outage while the reactor vessel head is on its storage stand. Remote tooling and appropriate shielding are used to minimize the radiation dose to the workers.

Reactor head service support structures are designed for several major functions. They provide cooling and lateral support for the CRDMs, support power and instrumentation cables, facilitate reactor head lifts, and act as an internal missile shield. On some reactors the original service structures were not fully optimized to simplify refueling activities. These original inefficiencies together with increased economic performance goals have resulted in the replacement of original service structures independent of or in conjunction with reactor vessel closure head (RVCH) replacement. The primary objective of an enhanced service structure (ESS) is to reduce the disassembly and reassembly times of the reactor head during refueling outages thereby shortening critical path activities as well as reducing personnel dose and improving safety. These objectives can be met by striving for a redesigned configuration which integrates all functions into a single assembly which can be removed with a single point pickup after disconnecting instrumentation, CRDM power cables and the head closure studs. Service structure enhancement can entail integrating the entire cooling system into the ESS, missile shield integration and building in a single point pickup tripod arrangement. Improvements to allow quick disconnects for cables and more efficient RVCH stud removal will also improve critical path time. Despite building more functionality into the ESS, overall access for reactor head inspections can be improved by providing handholes and by spacing the RVCH insulation away from the head surface, thereby allowing remote visual inspection of the head with the insulation still in place.

In-core instrumentation

Most pressurized water reactors (PWRs) utilize in-core instrumentation inserted through the bottom of the reactor vessel. During refueling, these very long, slender rods are withdrawn from the fuel assemblies. At that time, instruments that are not performing properly are replaced. Because the instrument (detector) is radioactively hot, the end that was in the core is pushed back into the reactor vessel and cut off using underwater remote tooling and is then disposed. The remainder of the instrument is pulled out the other end and also disposed. Additional inspections and maintenance to the sealing system can be performed. New detectors are inserted for use during the next operating cycle.

Reactor coolant pumps

Depending on the size of the plant, there are from one to four reactor coolant pumps in the primary system. Because the pumps and motors are constantly engaged, they require more maintenance than passive components. Pump seals are the items most frequently replaced. Nuclear plant motor maintenance is similar to that performed in other industries, except that the motors are very large and must operate with very little vibration for the sake of the seals and, of course, they must be maintained within the reactor building.

Pump repair While infrequent, pump repairs, other than seals, and general overhauls are important in a comprehensive maintenance program. Overhauls are conducted to minimize pump failures due to wear.

Fig. 12 Automated reactor inspection system.

Because of the contaminated environment in which a pump operates, special tooling is used when making repairs to minimize radiation exposure to technicians.

Mechanical shaft seal maintenance The mechanical shaft seal is a primary boundary for the reactor coolant. The seals are typically a three stage design, with each successive stage being subjected to a lower pressure drop. Sealing is provided by rotating and stationary surfaces that contact each other or are separated by a thin film. The seal faces are typically carbon or aluminum oxide. Because they must operate continuously in vibrating conditions with exceedingly low leakage, pump seals need regular attention and sometimes replacement during outage maintenance.

Pressurizer

The pressurizer serves to establish and control the operating pressure within the primary heat transport system. This is achieved by electrical heaters that raise the saturation pressure of the pressurizer's water and steam inventory to the appropriate value.

Heaters within the pressurizer are generally the only components that require maintenance. These heaters consist of side mounted bundles, used in B&W designs (Fig. 13), or bottom mounted individual heaters, used in other pressurized water reactors. Heater maintenance primarily consists of element/bundle replacement, power cable replacement, cable-to-element connector repair, and element recovery.

Moisture is often the cause of a defective heater element. Element recovery can be done by drawing a vacuum at the electrical connector and sucking out the

Fig. 13 Pressurizer heater bundles – bottom mounted (left) and side mounted (right).

moisture. If moisture is present in the connector area, the connector pins may be damaged by arcing and may break when removing the power cable from the heater. This damage may be repaired. However, if these intermediate repairs are not successful, the heater element/bundle must be replaced.

Instrumentation and controls (IC)

The critical nature of and general inaccessibility to nuclear plant IC dictate that they be extremely reliable. This reliability is achieved by stringent qualification and by incorporating multiple channels to measure the same parameters. Such *coincident logic* reduces the possibility that a single failure will trigger a safety action.

If a component fails suddenly or gradually degrades, this must be detectable. Detection is achieved by monitoring parameters with the plant computer and annunciator systems and by alarming abnormal conditions.

Checks are often made by comparing the output from redundant sensors. On critical components, these tests are run and documented at specified intervals.

Channel calibrations are performed routinely to ensure that instrumentation and electrical devices meet specifications for accuracy and response time. Integrated system tests may also be performed. If a device fails a test, it is replaced or declared inoperable. The number of such failures permitted before output reduction or shutdown is very strictly regulated.

Valves and actuators

Valves in a nuclear plant serve two basic functions: control and isolation. Nevertheless, all valves have their individual requirements of opening and closing time, shutoff tightness, monitorability, etc. In addition, the number of valves of all types in a nuclear plant is very large – and each valve can change the configuration of the plant.

Therefore, in a nuclear plant, a systematic maintenance plan is mandatory. For example, a plan for motorized isolation valves should address packing and seat leakage, opening and closing stroke times, actuator output and lubrication, function of control switches, wear of internal actuator parts, and the reliability of its controller, etc.

Piping

Piping is subject to operating pressure and to imposed forces and motions due to its own thermal and pressure effects and to that of the equipment it serves. Piping is subject to stress, fatigue, cracking, corrosion and to flow accelerated corrosion (FAC) which is an ongoing industry challenge of pipe wall thinning and, in some cases, failure.

Piping and pipe welds are examined using ultrasonic testing (UT), liquid penetrant (PT) or magnetic particle testing (MT). Where UT is required, it may be performed manually or with automated scanners. Complex shapes, such as nozzle intersections, can be scanned using robotic manipulators as depicted in Fig. 14. Robots and scanners provide precise positioning and automatic data analysis with minimal personnel radiation exposure.

Equipment diagnostics

Loose parts monitoring Loose parts, or foreign objects, such as bolts and small metal pieces caught in the high velocity flow of the reactor coolant system can bounce around in the primary system and cause significant damage to areas such as steam generator tubesheets and seal welds. While loose parts are seldom encountered, the NRC requires a system to detect them. A typical system features acoustic sensors in the primary system to detect loose parts. These sensors, or accelerometers, detect the noise generated by impacting loose parts. The system records impact data and provides an audible alarm for impacts beyond a prescribed energy level.

Foreign object damage to steam generator tubing on the secondary side persists; sources include the windings of upstream valve gaskets which unravel in service or bits of metal, weld slag and tooling. In new replacement steam generators with high corrosion resistance, foreign object damage is often the most significant remaining failure risk. Such foreign object

change is normally detected by eddy current and/or visual tube inspection during an outage.

Neutron noise monitoring The internals of the reactor vessel provide support for and alignment of the core. Maintenance of both is important to assure that the control rods can be inserted for reactivity control. The internals are subjected to high velocity reactor coolant flow, which causes them to vibrate. Although some vibration is normal, excessive amounts must be detected. During power operations, neutron flux is monitored by special instrumentation located outside the reactor vessel. Certain characteristics of this neutron signal are affected by vibration of the reactor internals. Analysis of this signal can detect abnormal vibration patterns. Measurements are typically made at the end of a fuel cycle and at the beginning of the next cycle to verify that the internals are aligned and secure.

Reactor coolant pump monitoring Two principal pump characteristics are monitored, shaft vibration and seal performance. Accelerometers and noncontacting displacement probes located on the pump provide continuous vibration monitoring. The displacement probes are mounted radially; the accelerometers are located on and near the pump bearing. Monitoring equipment in or near the control room records the sensor data and sounds an alarm if certain limits are exceeded.

Seal performance is also monitored. Parameters such as seal cavity pressures, seal injection flow and temperature indicate when seal replacement is needed.

Valve monitoring and diagnostics The valve population of a typical nuclear plant is very large and all valves are critical to plant operation. Nuclear plant valves control and direct flow, isolate systems and relieve pressure. Motor operated valves (MOVs) and check valves are especially important because they provide isolation for critical systems and are often required to operate under severe temperature and pressure conditions. To determine the condition of these valves, diagnostic systems have been developed.

MOVs provide isolation. They may remain open or closed during plant operation. The ability of the MOV to function is directly related to the thrust applied to the valve stem to overcome differential pressure and subsequent high friction. However, control switches limit the thrust of the motor actuator to avoid damaging the valves and internals. Special diagnostic systems determine the available thrust of the actuator and assure that the switches are properly set. Preventive maintenance programs use the data generated by these diagnostic systems.

Check valves are passive devices that only permit flow in one direction. Because the active parts of the valves are wholly contained in the fluid stream, it has been difficult to determine functionality without disassembly. However, diagnostic systems that evaluate in-service check valves have been developed. These systems use ultrasonics and acoustics to evaluate the disc position and the impact of the disc on the seat and back stop. They can detect wear at the hinge pin and flutter of the disc, which can lead to premature failure. As with MOV diagnostics, data from these systems are used in scheduling maintenance.

Fig. 14 Automated UT inspection of complex pipe shapes.

Refueling

Major activities

During refueling, approximately one-third of the fuel assemblies are removed and replaced and the remaining assemblies are usually moved inward within the core. Scheduled maintenance is performed during refueling outages. Depending on the extent of maintenance required, either that maintenance or the refueling operation determines the length of the outage.

Fuel movement activities are centered around the reactor vessel and the spent fuel building. To access the fuel, the reactor vessel must be opened. The following major steps are involved in this process:

1. remove the missile shields,
2. vent the primary system,
3. uncouple the control rods from their drives,
4. raise and park the drive lead screws,
5. disconnect the power to the control rod drives,
6. install the canal seal plate,
7. detension (loosen) and remove the reactor vessel studs,
8. install the guide studs,

9. install the lifting rig, lift the vessel head and place on a stand,
10. install the internals guide fixture,
11. raise the water level in the refueling canal,
12. install the lift fixture, remove the upper internals and place on a stand under water, and
13. retract and park in-core instruments (detectors).

The fuel can now be moved.

These operations are shown in Fig. 15. Fuel movement is performed under water with permanently installed equipment. When each fuel assembly is removed, it is transferred to the on-site spent fuel storage area. Here, control rod assembly changes and the appropriate inspections are made. Fuel that is to be reused is moved back to the reactor building and placed in its new core location; new fuel is also installed at this time. Final verification of fuel assemblies is recorded with underwater video equipment.

Fuel handling equipment

Fuel handling equipment can be grouped into three areas: 1) main fuel handling, 2) fuel transfer, and 3) spent fuel/new fuel handling. The main fuel handling system, used to remove and install fuel in the reactor

vessel, consists of a motorized bridge spanning the canal or cavity and riding on rails. A handling mast, mounted to and extending below the carriage, is positioned over the fuel assembly to be moved. The grapple, or gripping device, is then lowered and engages the assembly. Once engaged, the grapple is raised and the fuel is drawn into the hollow mast. Sensors indicating load and fuel assembly position assist the operator. The bridge is then moved to the fuel transfer area, where the fuel is lowered into a vertical transfer basket and released from the grapple. At this point, the basket is lowered to the horizontal position and is moved through a transfer tube into the spent fuel area. Finally, the fuel is upended and moved to storage.

The main fuel handling and transfer systems are only accessible during a plant shutdown, because they are located inside the reactor building. As a result, maintenance on this equipment is scheduled at the beginning of an outage.

Reactor vessel disassembly and reassembly

To allow access to the fuel, the reactor vessel head and upper internals must be removed from the reac-

Fig. 15 On-site fuel movement system.

tor vessel. In the B&W nuclear steam supply system (NSSS), each control rod drive must be disconnected from its control rod before this operation can begin. The control rod remains with the fuel. Special tooling is used to reach down through the top of the drive, and to attach to and rotate the lead screw and disconnect it from the control rod. The lead screw is then raised and parked inside the drive assembly. Other NSSS designs require similar procedures; however, the sequence and exact techniques may differ.

The tensioned studs and nuts that secure the reactor vessel head to the reactor vessel must be detensioned and removed before fuel handling can continue. A typical hydraulic detensioning operation is shown in Fig. 16. Generally, three detensioners are used simultaneously and follow a prescribed pattern. Once the studs are detensioned, they are screwed out of the threaded holes in the reactor vessel flange and either removed or parked on the head. A lifting fixture is then attached to the head. The head is then raised using the reactor building crane and moved aside to its storage stand inside the reactor building.

The upper internals are lifted in a similar manner; however, due to their highly contaminated and activated nature, the lifting fixture is attached remotely. The upper internals are stored on a stand under water in the refueling cavity.

Once the refueling operations are completed, the upper internals are reinstalled, the head is placed back on the reactor vessel and the studs are tensioned. In preparation for these activities the flanges on both the reactor head and vessel are cleaned and new O-rings are installed on the head flange. The control rod drives are recoupled to the control rods, power cables and cooling water lines are reattached and, at the appropriate time, the system is filled and vented.

Fig. 16 Service technicians operating reactor closure head stud detensioning equipment during a plant service outage.

Radiation detection and monitoring

Because no human sense can detect nuclear radiations, special instruments and techniques are used for detecting and measuring radiation. In general, three types of checks are required as follows:

1. Measurement of beta and gamma radiations by instruments such as the Geiger counter and *ionization chamber* provide instantaneous indications of the total level of β and γ . Most instruments are read as dose rate, usually in Sieverts. All persons in areas where radiation may be encountered normally wear a film badge or a thermoluminescent dosimeter (TLD). These devices are used for official records for exposure control. However, one's exposure can not be determined without evaluating the device with special processes or instrumentation. These devices measure the amount of β and γ radiation a person absorbs in terms of the total dose of radiation for a day, week or month.
2. Protection against neutrons is provided, primarily, by the concrete and water shielding around nuclear reactors. When a reactor first goes into service, neutron counters as well as gamma counters are used to make a careful survey of the

- surrounding area. Should leakage exist, the shielding is modified. Thereafter, periodic checks are made for γ and neutron leakage. In experimental installations, or where neutron surveys indicate the need for continuous surveillance, special film badges and neutron dosimeters may also be used.
3. Keeping the concentration of alpha emitters in working spaces and in outgoing air below prescribed tolerances is sufficient to protect against α particles. Alpha counters monitor air quality in working spaces on a regular schedule. Samples of dust accumulating in various areas of a room are monitored periodically for alpha radiation. The air concentrations are then converted into internal exposures for the worker. Whole body counters and urinalysis can also help ensure that the workers' internal exposures are well within the regulatory limits. Portable alpha *friskers* are also used to monitor hands, shoes and clothing of personnel leaving risk areas.

When high radioactive air concentrations occur, other precautions such as respirators, self-contained breathing air and glove boxes are used to protect the workers from internal exposures.

Nuclear operations

Nuclear power plant operations and services described here are generally applicable to light water moderated and cooled pressurized water reactor (PWR) systems, as depicted in Fig. 17, and are modeled on plants with reactors designed by B&W. As design details vary among PWR types, operational differences are noted.

Major licensing requirements

In the U.S., civilian use of nuclear energy was authorized by the Atomic Energy Act of 1954. The act also established an Atomic Energy Commission (AEC) for developing and regulating nuclear energy. A major objective of the AEC was to protect the public health and safety. The Energy Reorganization Act of 1974 replaced the AEC with the Nuclear Regulatory Commission (NRC), established to regulate the construction and operation of nuclear power plants as well as research facilities. Public health and safety continue to be a major goal of the NRC.

The safety of nuclear power plants is based on:

1. *Defense in depth* This is a feature of PWR reactors based on three barriers between the nuclear fuel and the environment: 1) the fuel cladding, 2) the reactor coolant system (RCS) pressure boundary (i.e., the envelope created by reactor vessel, pumps, piping, pressurizer and the steam generators and their tubing), and 3) the reactor containment building (typically a pre-stressed concrete structure with an inner steel liner).
2. *Design approval* This includes NRC review and approval of the site and the design of safety systems and safety-related equipment.
3. *Quality assurance program* Construction of the station and erection of the equipment as well as maintenance and operation are guided by NRC approved quality assurance programs.
4. *Operating license review* Following construction, the NRC grants the utility (owner) an operating license. The license and the technical specifications define the operating bases of the plant.

The nuclear licensing steps, described as follows, are primarily designed to ensure public safety.

Plant licensing

In addition to licensing by the NRC, approvals for the plant site, construction and operating licenses must be obtained from the respective authorities. Additional regulating agencies in the U.S. include the Federal Energy Regulatory Commission (FERC), the Environmental Protection Agency (EPA) and the Corps of Engineers. Public Utilities Commission (PUC), state environmental control board and local governmental approvals are also often required for nuclear power plant siting, construction and operation.

NRC power plant licensing takes place in two major steps: the construction permit and the operating license. Completion of each step entails hearings conducted by an advisory safety licensing board.

In the construction permit stage, certain documen-

tation must be prepared for the NRC. The proposed plant site is characterized, the preliminary design features are outlined, and conformance to the Code of Federal Regulations standards is presented.

A preliminary safety analysis report, which contains design and safety information, is prepared by the utility and its contractors, and is submitted to the NRC. The review includes questions by the NRC and subsequent responses from the plant owner. Along with the review, these become part of the public record and licensing process. The NRC staff prepares a safety evaluation report as a result of their review. This report leads to an Atomic Safety and Licensing Board hearing, which is open to the public. Upon approval by the board, a construction permit is issued by the NRC and plant construction can begin.

As the plant design becomes final and construction proceeds, the information contained in the review is revised and expanded. A complete description of the site characteristics, safety systems, quality assurance programs and technical specifications is included. This revised information becomes the final safety analysis report. This report is also submitted to the NRC for review and approval. As with the preliminary report, the review includes NRC questions and owner responses. Following review, the NRC again prepares a safety evaluation report of the site and plant. This provides the basis for a second public hearing to approve an operating license for the utility. During construction, on-site NRC inspectors are assigned to assure conformance to the final report.

Upon receipt of the operating license, the utility performs system pre-operational and hot functional testing and prepares to load fuel. Approval by the NRC is required for fuel loading and low power operation at about 5% of full power. Following successful fuel loading and low power operation, the NRC grants permission for power escalation.

In 1989, the nuclear power plant approval procedure in the U.S. was revised to allow one-step licensing. The objectives of this simplified procedure are to streamline the licensing process, to promote standardized vendor designs and to minimize NRC required design changes during and after construction. It also provides for combined licensing (construction and operation) which allows the owner and other stakeholders a much higher level of confidence in the viability of a project.

The simplified rule differs from the original licensing process in that: 1) a whole plant design certification by the NRC is required; 2) following design certification, a combined construction and operating permit may be obtained; and 3) site permits may be obtained prior to design certification.

Technical specifications

The technical specifications for a system or plant design are, in the broadest sense, the licensed limits for operation. These specifications are based on the analyses and evaluations of the final safety analysis report and include the following.

Safety limits Limits are imposed on important process variables to prevent an uncontrolled release of ra-

radioactivity. If any limit is exceeded the reactor must be shut down, the licensee must notify the commission, review the matter, and record the results of the review. The review includes the cause of the condition and the corrective action taken to prevent recurrence. Operation shall not be resumed until authorized by the commission.

Limiting conditions for operation These conditions are the lowest permissible equipment performance levels for safe operation of the facility. When a limiting condition for a nuclear reactor is exceeded, the licensee shall shut down the reactor or follow any remedial action permitted by the technical specifications until the condition can be met. In most cases, the licensee must notify the commission, review the incident, record the results of the review, and submit corrective actions.

Surveillance requirements Safety-related nuclear power plant equipment must be tested periodically; frequency depends on the specific equipment. If safety equipment fails a surveillance test, corrective action must be implemented within a specified time. If corrections can not be made within this time period, the plant must be shut down.

Design features Certain plant design features are included in the technical specifications. These features, such as construction materials and layout, would affect plant safety if altered.

Administrative controls Administrative controls are the provisions relating to organization, management, procedures, record keeping, review and audit, and reporting that are necessary to assure safe operation of the facility.

Pre-operational testing

System checkout During nuclear power plant construction, it is desirable to test each system (electrical, hydraulic, pneumatic, etc.) as soon as possible. Pre-operational testing is integrated into the plant erection schedule so that system testing can begin as soon as support systems are available. Test procedures are prepared for each component and system. The tests are performed and witnessed by designated engineers and reviewers.

Pre-critical testing is performed on all systems and components. These tests are conducted on the reactor coolant system, the feedwater system, the steam system, the reactor makeup and purification system, the emergency feedwater system, and the control and protective systems. In general, pre-critical testing consists of the following sequence of events:

1. **Cleaning and inspection** Fluid systems are flushed to remove construction debris and are inspected for cleanliness and proper installation of piping and components.
2. **Electrical tests** Alternating current (AC) and direct current (DC) power wiring and distributions are inspected and tested for proper hookup and circuit continuity. Rotating and moving equipment, such as pumps and valves, are given no-load tests to determine proper direction of motion.
3. **Instrumentation tests** Instrumentation and control wiring is inspected and tested for proper hookup and electrical continuity. The instrumentation (transmitters, temperature sensors, flow meters

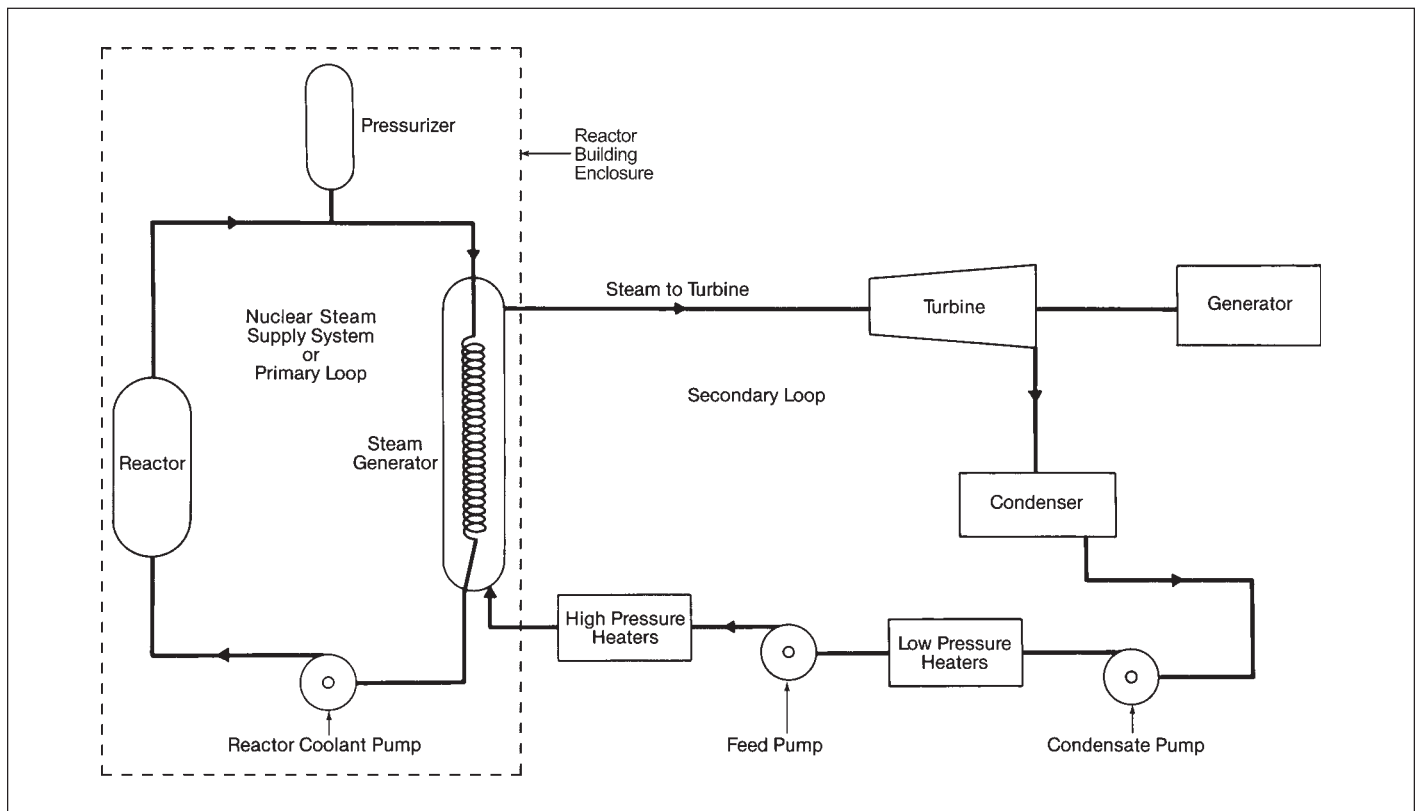

Fig. 17 Pressurized water reactor (PWR) primary and secondary heat transport and electricity generation systems.

and level indicators) is calibrated and the control systems are tested. A control simulator is used by some utilities for cold system testing.

4. **Hydrostatic tests** All fluid systems and components except the reactor coolant system (RCS) are cold tested hydrostatically to greater than design pressure. Because of the relatively high nil ductility temperatures of the reactor vessel welds, the RCS is hydrotested at a temperature slightly above ambient.
5. **Functional tests** Functional tests which demonstrate component performance are conducted. Typically, system flow rates, pump head capacity relationships, valve stroke times and controls are tested.
6. **Operational tests** Additional tests at near normal operating conditions are performed for low temperature and pressure systems. Instrument air systems, the spent fuel pool cooling system, component cooling water systems and the decay heat cooling systems are typical systems tested.

Performance of the high temperature and pressure systems, such as the RCS, the makeup and letdown system, the feedwater system, the steam system and the emergency feedwater system are verified during hot functional testing.

Water quality Many of the elements of water treatment, water chemistry and corrosion discussed in Chapter 42 for fossil fuel systems also apply to nuclear steam systems. Key differences exist between these treatments, however. In a pressurized water reactor (PWR) system, two independent flow circuits are used as discussed earlier: the primary or reactor coolant system and the secondary or steam generator condensate feedwater system. Additional differences include more extensive use of high alloy steel, nickel-based alloys and other non-steel materials. The ultimate goals of the water treatment system remain to minimize corrosion and deposition. The basic premise of the nuclear steam supply system chemistry program is that it is better to prevent contaminants (both ionic and particulate) from entering the cycle than to attempt to remove them later. This is the basis of the ALARA (As Low As Reasonably Achievable) chemistry philosophy employed at nuclear plants.

For their primary circuits, PWR plants use chemical shim reactivity control which utilizes a soluble neutron poison (boric acid) to regulate core reactivity. In addition, a pH chemical additive, lithium hydroxide, is used to adjust the pH toward the alkaline side. The industry has developed a set of guidelines for the proper concentrations of these chemicals, including the reduction of boric acid concentration as fuel burnup progresses.^{1,2}

These guidelines attempt to minimize the impact of water chemistry on the integrity of the primary system internals, including the pressure boundary and fuel cladding, and to minimize the transport of radioactive corrosion particles throughout the system. In addition to lithium and boric acid concentration, primary system chemistry control parameters include chloride, fluoride, dissolved hydrogen and dissolved oxygen. Hydrogen is added to maintain reducing conditions in the primary coolant to minimize primary system corrosion.

For the secondary circuit, the major goals of the

chemistry program are to minimize both corrosion product transport and the corrosion of steam generator tubes. Corrosion product transport and corrosion of the tube material is mainly affected by the water chemistry related factors of: 1) pH, 2) electrochemical potential (ECP) and 3) the particular species beyond those which affect pH (e.g., lead, copper, and sulfur). Corrosion is also affected by material susceptibility, tensile stress and operating temperature.

The pH of the secondary circuit is controlled by the use of volatile amines (e.g., ammonia, morpholine, and ethanolamine). Reducing conditions are maintained in the secondary circuit by the use of a volatile oxygen scavenger (e.g., hydrazine). Strict water purity requirements are imposed to minimize the transport of contaminants in the system. To achieve maximum system reliability, the industry has developed a set of secondary-side water chemistry guidelines for the proper control of operating chemistry conditions.³

Hot functional testing (HFT) During commissioning and prior to installation of the fuel and plant operation, a process called hot functional testing is implemented. This serves to check out the operation and performance of all of the functioning systems. It also serves to establish a protective oxide layer on all carbon steel and alloy materials in the primary and secondary heat transport systems which, in turn, minimizes corrosion during normal operation.

HFT occurs after all nuclear plant systems have been erected and have completed pre-operational testing. This testing provides warmup and operation at zero power operating conditions. The fuel is not loaded in the core for HFT. In B&W plants, a plate is placed in the core region to simulate the core pressure drop for the RCS pump and flow testing.

The HFT begins by establishing water levels in the RCS as indicated by the pressurizer level in the steam generators and in the condenser hot well.

The pressurizer heaters (Fig. 13) are energized to raise the RCS to a pressure that provides a net positive suction head of about 250 psig (1.72 MPa). This permits operation of the reactor coolant pumps. Upon reaching this pressure, the reactor coolant (RC) pumps are energized to heat the reactor coolant and steam systems at a rate of about 30F/h (17C/h) from about 70 to 530F (21 to 277C).

There are several temperature hold points during the HFT warmup at which specific tests are performed. Typical testing includes the pressurizer spray bypass flow calibration. This bypass has a trickle flow of about 1 GPM (0.06 l/s), which keeps the pressurizer spray line and the spray nozzle at a relatively uniform temperature.

At about 600 psig (4.24 MPa), the RCS high pressure safety injection pumps are tested to demonstrate flow capability and to adjust the safety injection flow distribution.

Following testing at the hold points, system heating continues to the hot zero power (HZP) level. Typically, in pressurized water reactors, the HZP temperature and pressure ranges are:

- RC temperature – 500 to 550F (260 to 288C)
- RC pressure – 2100 to 2200 psig (14.6 to 15.3 MPa)
- Steam temperature – 525 to 570F (274 to 299C)
- Steam pressure – 800 to 1200 psig (5.62 to 8.37 MPa)

Before fuel loading, the reactor protection system (RPS) and the control systems are calibrated and checked.

In addition, all protective system instrumentation, including the out-of-core neutron detectors (Fig. 18b), RCS pressure transmitters and temperature sensors, nuclear instrumentation and transmitters, RC pump monitors and the feedwater pump turbine hydraulic oil pressure switches, are calibrated and tested.

The reactor, coolant system pressure and inventory, feedwater, steam pressure and electrical generation are controlled by the integrated control system (ICS) (Figs. 18a and 18b) and the non-nuclear instrumentation (NNI). The NNI provides most of the instrumentation for the reactor, feed and steam systems, including signal inputs to the ICS, the control console indicators and recorders, and the plant computer as well as many of the test inputs to the reactimeter. The ICS is made up of unit load demand controls, integrated master controls, turbine and turbine bypass system controls, feedwater controls and reactor control subsystems. The ICS also controls the reactor, feedwater flow and the turbine-generator output to meet the electrical power demand.

The NNI also controls the RC system makeup flow, the pressurizer heaters, the pressurizer power operated relief valve (PORV) and the reactor coolant pump seal flow.

The feedwater and steam control subsections of the ICS provide automatic control over the full power range; manual reactor control is used up to 15% power and automatic control is available from 15% to full

power. Manual control can be used in each subsection of the ICS or its actuated components such as control rods, feedwater valves, feed pump turbine and turbine bypass valves. Alternately, the turbine can be manually operated from the control room.

Below 15% power, the ICS maintains the steam generator water level at a constant set point and the turbine bypass system similarly controls the steam pressure. The RCS temperature rises with power. The temperature is typically 532F (278C) at zero load and increases to about 580F (304C) at 15% power. As the load increases to full power, the temperature remains at about 580F (304C). Above 15% power, the RCS temperature and steam pressure are controlled by the ICS.

PWRs designed and built by other suppliers use recirculating steam generators (RSG), which have different operating characteristics than the once-through steam generators (OTSG). In the RSG plants, the RCS average temperature rises with the power level, the steam generator operating pressure drops with increasing power (Fig. 19), and the steam generator water level is controlled to a constant RSG secondary inventory or to a relatively narrow variable RSG band.

An RSG plant's average RCS temperature is controlled to a variable set point; the feedwater flow is controlled by a multi-element unit that monitors steam flow, feedwater flow, steam generator water level and, for some plants, RC temperature and steam pressure.

The RSG units typically control electrical output by controlling the turbine to a variable first stage pres-

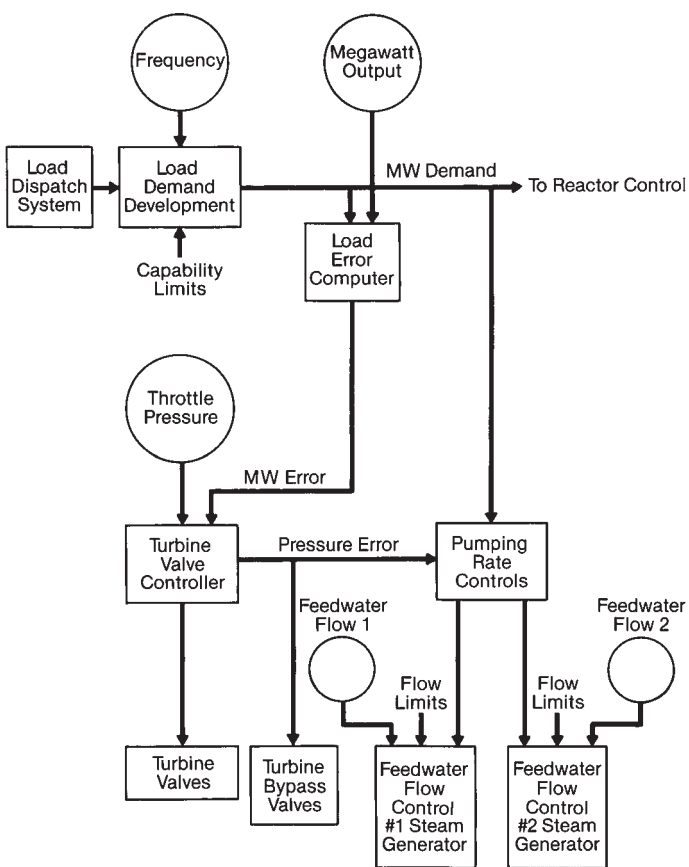

Fig. 18a Integrated control system.

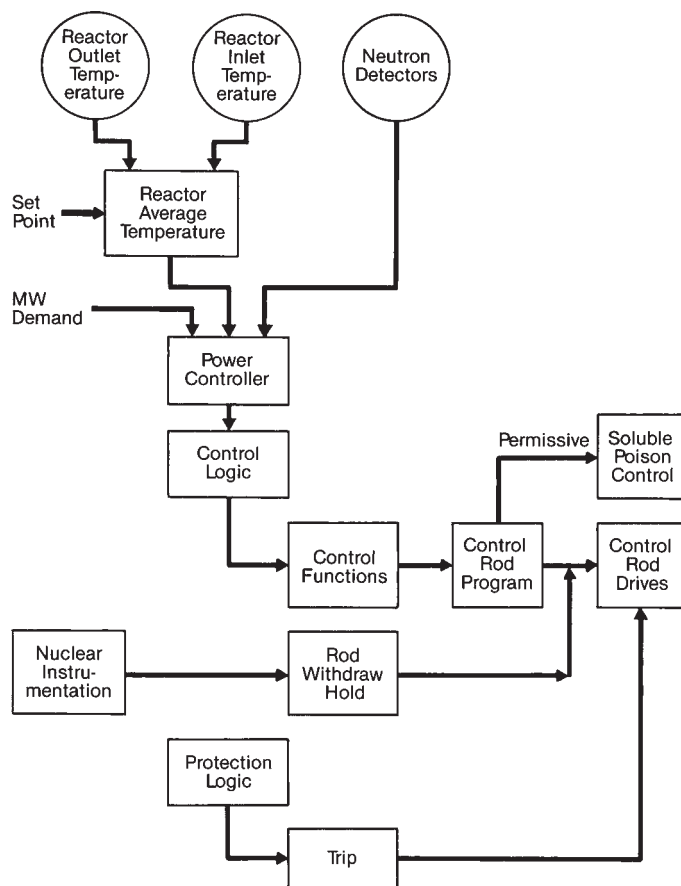

Fig. 18b Integrated control system – reactor controls.

Fig. 19 Typical recirculating steam generator plant reactor coolant system (RCS) average temperature and steam pressure.

sure signal. This control allows the steam pressure to change with power level.

The duration of an HFT is usually 500 hours for a first-of-a-kind unit and about 250 hours for all other units.

A significant portion of the HFT period is allocated to operator training because the plant conditions are near those of normal operation. In performing the hot tests, the operators gain valuable experience in managing the systems under normal and abnormal conditions. This operating experience constitutes one of the final stages of operator training prior to the NRC operator's license examination.

After completion of the test, the RCS is cooled and depressurized and the reactor vessel head is removed. The steam, feedwater and fluid safety systems are inspected and modified as necessary. Following successful HFT, permission for fuel loading is granted by the NRC.

Operator training U.S. regulations require that the reactor operators and supervisory personnel be licensed. An individual who has the basic operational qualifications is called a reactor operator; a senior reactor operator has completed more intensive training. The utilities develop, manage and conduct NRC approved operator training and requalification programs to satisfy regulatory requirements and to maintain the required operating staff. The training programs cover all facets of nuclear operations, including equipment malfunctions, design faults and severe transients. An operator's license is issued for a period of two years and is renewable by requalification.

Fuel loading and zero power testing

The nuclear fuel is first loaded into the reactor vessel only after pre-loading tests and practice fuel handling operations are completed. Neutron detectors and sources placed in the reactor vessel are used to monitor neutron multiplication during the core loading process.

Fuel loading takes place with the reactor vessel and the fuel handling pool filled with ambient temperature demineralized water. The borated water is a neutron poison and assures a multiplication factor of 0.95 or less with a fully loaded core.

With the system prepared, fuel loading begins. Neu-

tron multiplication measurements, slow fuel assembly insertion and frequent pauses to relocate sources and neutron monitors take place until all fuel assemblies are installed. After loading, the system is closed and prepared for low power. Testing following fuel loading includes calibrating neutron source range detectors, assuring sufficient source range signal for warmup to hot zero power, and verification that the reactor is sufficiently subcritical for the warmup.

Following completion of this testing, safety control rod groups are withdrawn to provide a subcritical shutdown margin should a reactor trip be required during the warmup.

After reaching about 250 psig (1.83 MPa) in the RCS and with one or more RCS pumps running, the system high points and control rod drives are vented to release noncondensable gases. Venting of the drives is particularly important because gas in the control drive path can interfere with the hydraulic snubbers which prevent impact of the rods upon trip.

Upon reaching HZP conditions, excess heat from the RCS pumps is removed by the turbine bypass system. This maintains constant RCS temperature and steam pressure conditions.

Initial reactor criticality is achieved in one of two ways. One method is to dilute the boric acid concentration in the RCS until a subcritical margin is achieved. Criticality is then achieved by slowly withdrawing the control rods. A second method is preferred by most B&W plant owners. All control rods are withdrawn while maintaining subcriticality by boric acid concentration. The concentration is then diluted until criticality is achieved. After initial criticality is attained, a series of zero power physics tests are performed:

1. **Control rod reactivity worth** This verifies that the individual rod worth, control rod group (banks) rod worth, and total rod worth are within acceptance criteria. The tests must show that the control rod worth is capable of power operation. Performance of the safety function, which brings the reactor to a subcritical condition following a trip, is also verified. Typical control rod reactivity worth for each of seven banks is shown in Table 2.
2. **Core reactivity coefficients** The reactivity coefficients are the moderator deficit (or coefficient), the fuel temperature (Doppler) coefficient, the RCS pressure coefficient and the power (overall) coefficient. This testing verifies that the reactivity coefficients are within acceptance criteria and that the power coefficient is negative at levels above about 20% power.
3. **Soluble poison (boric acid) reactivity worth** Tests are conducted by exchanging control rod position with soluble poison concentration to determine that the reactivity worth of the poison is within core acceptance criteria. Boric acid dissolved in the reactor coolant is used to limit the core's reactivity throughout the fuel cycle. The boron concentration at HZP is about 1500 ppm. As xenon and other reactivity poisons build into the fuel and the fuel is depleted, the boron concentration is reduced to maintain full power (see Fig. 20).

Table 2
Control Rod Group Reactivity Worths
at Hot Zero Power, Beginning of Fuel Cycle

Group	Purpose	Reactivity Worth % Δ K/K
1	Safety	0.95
2	Safety	3.05
3	Safety	0.79
4	Safety	1.75
5	Control	1.15
6	Control	1.26
7	Control	1.17
Total		10.12

4. *Nuclear instrumentation range and overlap tests* At criticality, the three neutron detector ranges (startup, intermediate and power) must be on scale and must have the proper overlap. Testing is conducted at initial criticality to assure proper neutron detection signal strength.
5. *Pseudo-control rod ejection tests* In addition to the standard control rod testing, pseudo-control rod tests are performed. This testing assures that the control rod with the most reactivity worth does not exceed the licensed limits.

The zero power physics tests as well as testing of the protection systems are performed to:

1. measure operational parameters,
2. measure performance against design criteria,
3. provide compliance with NRC requirements, and
4. obtain data for design improvements and potential power upgrades.

Most initial operation parameters are recorded by special equipment and by the plant computer.

Power ascension tests

After completion of the zero power physics tests and low power operation (5% or less), the power is raised in stages. Typically, the power plateaus are 15, 45, and 75% and full power.

The objectives of power escalation include:

1. determining the plant operating characteristics,
2. familiarizing the operators with the plant,
3. verifying that the plant is capable of operating safely and within the design and technical specifications,
4. verifying that the operating procedures provide reliable operation, and
5. bringing the unit to rated capacity.

Testing at each stage includes operating the reactor systems and the entire power plant. The test time at each plateau is sufficient to provide adequate operator familiarization and training.

Operation to the first test plateau is by manual control of the reactor and with the turbine-generator offline. Plant heat removal is by the turbine bypass system, which controls steam flow from the steam generators to the condenser. In this low power range, the

operating performance of the turbine bypass system, feedwater system, and the feedwater and steam pressure controls is tested for the first time. Initial heat balances are performed by calculating the primary heat balances (RCS flow and temperature change across the reactor) and the secondary heat balances (feedwater flow and enthalpy rise across the steam generators).

The heat balances, in addition to RCS flow measurements, permit calibrating the nuclear instrumentation using the plant thermal power as a baseline. The secondary heat balances also provide an initial cross check of the RCS flow measurements.

Near the completion of 15% power level testing, a reactor shutdown from outside the control room is performed. Reactor control is from a remote panel and the reactor is brought to and maintained at HZP conditions. This test demonstrates safe control and shutdown of the unit should a fire or toxic gas require the operators to evacuate the main control room.

The performance at the next power plateau is extrapolated from the previous plateau. For example, operation at the 45% power plateau is estimated from the operating experience at the 15% plateau. Following satisfactory operation at 15% power, the system may be placed in automatic control and the power level raised to the 45% level. Power escalation, however, is typically performed with the reactor in manual control and the feedwater and steam systems in automatic control. As the power is raised above 15%, the turbine-generator is brought up to speed, loaded and synchronized to the electrical grid. At the 45% power level, heat balances are again calculated and the neutron power and RCS flow are calibrated. Control system

Fig. 20 Boron concentration in the RCS during a fuel cycle.

tests, consisting of decreasing and increasing power ramps, are also conducted. At the 45% power level, the in-core instrumentation (rhodium detectors) is on-line, and the core performance indicators can be investigated by mapping the core power distribution.

Following successful testing at the 45% power level, the power is raised to about 75%. During this increase, the second main feed pump is typically placed in operation at about 45 to 50% power. Heat balances at 75% power are again calculated for the reactor and the secondary systems, and the neutron detectors and RCS flow are calibrated.

Testing with three of the four reactor coolant pumps is conducted at 75% power. This provides the core and RCS temperature distribution characteristics. It also verifies proper feedwater flow to the steam generators.

Ramp power changes at rates up to 10% per minute are also conducted at the 75% power level. This tests the control system operation and permits control setting changes.

As testing is completed at the 75% power level, the unit's performance is reviewed and its full power performance is extrapolated. The reactor is then gradually raised to full power and further testing preparations are made.

At full power, the RCS and the secondary system heat balances are again performed, the neutron instrumentation is calibrated, and final reactor coolant flow calibrations are performed.

During steady-state, full power operation, power maps are obtained from the in-core neutron monitors and the core neutron flux distribution is evaluated against the acceptance criteria. Final tests of the reactivity coefficients, control rod worth and boron reactivity worth are also performed and compared with design values.

Several important safety tests are conducted at the 100% power level, including:

1. *RC flow coast down testing* For first-of-a-kind plants, the RCS pumps are tripped in various combinations to characterize the flow coast down performance and to test the trip functions related to loss of RCS flow or pumps.
2. *Reactor trip testing* A reactor trip test is performed from full power to verify that the control rod insertion rates, the pressurizer performance, and the control of steam pressure and feedwater flow are within acceptance criteria.
3. *Loss of off-site power* Testing of the unit's response to separation from the electrical grid is conducted to verify that performance during the subsequent reactor trip, startup of the emergency diesel generators, operation of the turbine driven emergency feedwater pumps, and the natural circulation of the RCS are within acceptance criteria.
4. *Control system tests* Steady-state and transient control systems are tested at full power to verify their performance.
5. *Turbine trip testing* The turbine-generator is tripped at full power to verify that the turbine, the main steam system, the RCS, and the feedwater system perform as designed to bring the unit to reduced power.

Acceptance testing

After testing at full power is complete, final acceptance testing is performed before turning the unit over to the utility. Acceptance testing demonstrates that the steam pressure, flow and temperatures meet specifications and that the electrical output of the turbine-generator is as designed. Additional tests, such as transient capability, operation with three of four RC pumps, and load rejection capability are often included in the acceptance testing.

Typically, steady-state acceptance testing to demonstrate that steam conditions and electric generation meet the warranties is carried out for about 100 hours. Parameters such as reactor power, RCS temperatures, feedwater flow and temperatures, steam temperature and pressure, and electrical generation are monitored to maintain a running account of the performance.

Transient tests are scheduled and are typically of short duration. A typical transient acceptance test is as follows. Power is reduced from 100 to 60% at the design rate. Power is held at 60% until peak xenon poison builds into the core, which is normally six to eight hours after power reduction. The unit is then returned to full power at the design rate. This test demonstrates the transient capability of the control systems, as well as the boron-handling system's capability to dilute and then increase the RCS boric acid concentration.

Certain plant parameters, and those necessary to demonstrate performance, are recorded. The data are used for performance evaluation and to demonstrate that the warranties are met.

Upon satisfactory completion of the acceptance tests, the plant is turned over to the utility and begins commercial operation.

Commercial operation

Most U.S. nuclear power plants are base loaded, primarily because of associated lower fuel costs. During base load operation, the plant operates at or near full power, regardless of demand.

Electrical power production

The main control room and its adjacent control equipment, offices and work areas form the center of nuclear plant operations. The operations personnel, including the reactor operators, auxiliary operators and supervisory personnel, perform their functions in and around the control room. All control stations, switches, controllers and indicators necessary to start up, operate and shut down the nuclear units are located here. Operations that maintain safe conditions after upsets are also coordinated from this central control room. Controls for certain auxiliary systems are located at remote stations.

The station operator has many duties including monitoring plant performance and making adjustments as necessary. The operator must periodically reduce the RCS boron concentration, as indicated in Fig. 20. This compensates for reactivity loss due to fuel burnup and maintains full power with the control rods

within a specified operating band. The operator must also maintain a log of operations, review and approve maintenance activities, and supervise and perform surveillance tests.

One of the most time consuming functions of the plant operating staff is scheduling and performing mandatory surveillance testing of the safety equipment. There are about 400 surveillance tests required for each nuclear power plant. The emergency diesel generators, for example, are tested monthly. Most fluid systems, such as high pressure injection, emergency feedwater and decay heat removal, are also tested

monthly. Finally, the reactor protection system and related safety systems are tested on a similar schedule.

During power production, the staff conducts maintenance on accessible systems and plans the inspection, maintenance and repair work scope for the next planned outage. Preventive maintenance and, more recently, reliability centered maintenance programs have been instituted and have contributed to improved station reliability.

Nuclear power plant operations are audited periodically by teams from the Institute for Nuclear Power Operations and the NRC.

Chapter 50

Nuclear Equipment Manufacture

Many manufacturing operations for nuclear steam supply system components are similar to those used for fabricating fossil fueled equipment. However, the unique requirements and geometry of nuclear components call for special manufacturing methods, equipment and facilities. Nuclear equipment must operate reliably with minimal maintenance because of its operating environment. For this reason there are rigorous equipment specifications by customers and regulatory authorities. Quality assurance requirements are stringent and special attention must be given to cleanliness and material control.

Selecting the manufacturing sequence and methods requires balancing design requirements with manufacturing capabilities while meeting commercial obligations. As a result, special equipment and fabrication sequences are usually required.

Typical component description

Commercial nuclear components are typically cylindrical pressure vessels. Some of the components are large and heavy and require customized shipping and handling arrangements. Reactor vessels and components for pressurized water reactor (PWR) systems up to 32 ft (9.75 m) in diameter, 125 ft (38.1 m) long and weighing 1000 t (907 t_m) have been built by The Babcock & Wilcox Company (B&W). Some nuclear components also have close assembly tolerances. This requires specialized equipment and extraordinary care during machining and welding operations.

Manufacture of reactor vessel components

Different reactor systems have differing reactor vessel designs. B&W has experience in several systems, including the PWR, which is the focus of this chapter.

Each reactor vessel is made up of a cylindrical main section and two hemispherically shaped heads. The reactor closure head is attached by a bolted flange and has several penetrations for the reactor control rods, venting and/or instrumentation (Fig. 1). Control rod

drive mechanism (CRDM) tubes penetrate the hemispherical section and are welded at the inside surface. Similar tubes for venting and instrumentation may also be present, and follow the same general arrangement. In recent years, plant owners have replaced reactor closure heads because of stress corrosion cracking of the weld between the head and the reactor CRDM tubes, and boric acid wastage of the carbon steel base material. (See Chapter 46.) The inside of the reactor vessel includes many attachments for the fuel support system. (See Chapter 49.) Since there have been no reactor vessels manufactured recently by B&W, this section will only focus on reactor vessel components, such as the reactor closure head.

Fabrication of replacement reactor vessel closure heads

The closure head has a hemispherical dome with a bolting ring flange. The closure heads for typical B&W reactors measure 16.67 ft (5.08 m) outside diameter (OD), with a dome radius of approximately 7.25 ft (2.21 m) and a nominal dome thickness of 7 in. (178 mm). The bolting ring flange is 30 in. (762 mm) thick.

Fig. 1 Reactor vessel closure head.

Typical replacement closure heads are fabricated from a one-piece forging. This eliminates the periodic in-service inspection required for pressure boundary welds. Large diameter heads may have their hemispherical portion made from a single forged partial hemisphere with additional forged rings or segments that are welded together. The bolting ring is forged separately and welded to the hemisphere. All reactor components made of ferritic material have their internal surfaces clad with austenitic stainless steel or Inconel® to provide resistance to corrosion from the reactor coolant. The cladding can be applied using various welding methods such as submerged arc welding (SAW) or gas metal arc welding (GMAW) using wire or strip.

Critical features There are several critical features on the closure head that must be fabricated to close tolerances. The gasket surface on the bolting ring must be flat and have the required surface texture and lay to ensure a leak-tight joint. The CRDM center lines must be true to the axis of the head and the CRDM tube diameters must be held within tightly controlled tolerances to ensure that the operation of the control rods is not hampered in any way. The weld between the CRDM tube and the head is designed and fabricated to avoid residual stress and to maintain the position of the CRDM tube. It is critical to control residual stresses during the manufacturing process to avoid stress corrosion cracking of the closure head during operation. Residual stress is controlled during manufacture by limiting the cold work and by electropolishing the CRDM tubes and welds.

Machining The CRDM tube weld preparations (preps) are machined on a computer numerical control (CNC) horizontal boring mill. Machining the geometry of the weld prep requires careful three-dimensional modeling and programming of the tool path because the geometry varies depending upon the radial location of the hole on the head. The stud holes and CRDM penetrations are drilled using a trepanning cutter (Fig. 2).

Testing and inspection The closure head is tested and inspected to the requirements of the American Society of Mechanical Engineers (ASME) Boiler & Pressure Vessel Code Section III and V. Material testing includes chemistry and mechanical properties and may include other tests such as ultrasonic, hydrostatic and surface finish depending on the material form and application. Fabrication testing includes magnetic particle (MT), dye penetrant (PT), radiographic (RT) and ultrasonic (UT). Pressure testing includes hydrostatic testing of the tube material and the closure head assembly. This is done by using a thick circular disc that is bolted to the head using tooling studs (Fig. 3).

Electropolishing Electropolishing is an electrochemical technique that removes a very thin layer of material from a work piece. Electropolishing can be used to smooth a surface or to remove a cold worked layer of material to reduce residual stress. The work piece is connected electrically as an anode and, along with an adjacent cathode, simultaneously brought in contact with an electrolyte. The amount of material removed is a function of the electrolyte chemistry and flow, the electrical current and exposure time. Electropolishing is applied to CRDM nozzle welds to

Fig. 2 Horizontal boring mill used to drill holes in reactor pressure vessel head.

reduce residual stress and is applied to once-through steam generator (OTSG) tube support plates to smooth their surface.

Manufacture of steam generators

B&W manufactures once-through steam generators (OTSG) and recirculating steam generators (RSG) for PWR and Canada Deuterium Uranium (CANDU) reactor systems. (See Chapter 48.) Both steam generators have many components and manufacturing methods in common. The following sections describe the fabrication of the common components and the manufacture of items that are unique to each design. Fig. 4 shows a simplified cross section of an RSG, and Fig. 5 shows a simplified cross section of an OTSG. An RSG consists of cylindrical and conical shells, hemispherical heads, nozzles, a tubesheet, U-tubes, lattice grid or broached-hole tube supports, baffle and divider plates, a shroud, and steam drum internals. A typical RSG is about 75 ft (22.9 m) long, 12 to 15 ft (3.7 to 4.6 m) in diameter and weighs up to 400 t (363 tm). An OTSG consists of cylindrical shells, hemispherical heads, nozzles, two tubesheets, broached-hole tube support plates, straight

Fig. 3 Hydrostatic testing of closure head assembly.

Fig. 4 Advanced series recirculating nuclear steam generator.

tubes, a shroud, and feedwater inlet header. A typical OTSG is about 73 ft (22.3 m) long, 12 ft (3.7 m) in diameter and weighs up to 470 t (426 tm).

Cylindrical shells

The shell *courses* used in fabricating the cylindrical portion of the steam generators may be made from forged ring sections or from plate formed by rolls as shown in Fig. 6. The rolling method depends upon the size, thickness and material. Cylindrical shells for steam generators are typically less than 4 in. (101.6 mm) thick and are cold rolled. Some designs require thicker sections near the tubesheet area or where reinforcement for nozzle openings is required. These shells are usually hot rolled.

For shells made from rolled plate, the longitudinal seam of each course is submerged arc welded using an automatic guidance system. In preparation for circumferentially welding several courses, each course edge is machined to improve weld quality. The sections are then aligned, tack welded and set up on drum rotators. A stationary submerged arc welder, automatically guided, is positioned over the seam and the circumferential welds are made while accurately rotating the drum.

Fig. 5 Once-through nuclear steam generator.

Fig. 6 Cold rolling plate for steam generator cylindrical shell.

The advantage of using forgings for cylindrical shells is the elimination of the longitudinal seam. This eliminates the cost of making and examining the weld during manufacture, and eliminates the need to conduct in-service inspection of the weld. Forged cylinders can usually be made to tighter diameter tolerances.

Tubesheet manufacture

The tubesheet is made from a forging that can weigh up to 80 t (73 t_m). The first major manufacturing operation is cladding the primary side of the tubesheet with stainless steel or Inconel using GMAW welding methods, discussed in Chapter 38. The tubesheet is heated before, during and after welding using large electric heaters. Usually the welding head is moved over the stationary tubesheet, however, in some cases the tubesheet geometry requires it to be rotated under a stationary welding head. In these cases, speed control of the rotator is critical to maintaining weld integrity. The clad tubesheet is post weld heat treated to 1125F (607C). The cladding is then machined and examined using UT. Cladding thickness after machining is typically 0.3125 in. (7.9 mm).

Drilling the holes through which the tubes are inserted is the most critical operation for tubesheet manufacture. A typical tubesheet is 24 in. (610 mm) thick and has up to 15,000 holes or more ranging in diameter from 0.5 to 0.875 in. (12.7 to 22 mm), depending upon the tubing size. These holes must be located accurately, be precise in diameter, and be straight and perpendicular to the tubesheet surface. Variations from perpendicularity, often called drill drift, are typically limited to 0.015 in. (0.38 mm) through the thickness of the tubesheet. Extreme care is therefore given to gundrilling.

Gundrilling is done on a multi-spindle, computer-controlled horizontal drilling machine (Fig. 7). Gundrills are designed to drill holes with large depth-to-diameter ratios. Coolant travels through the center of the drill and removes cutting chips through a channel along its shank.

Regular dimensional and visual inspections of the drill tools and the hole diameters and locations are conducted. After gundrilling, the tubesheet has its circumferential weld preparations machined on a vertical or horizontal boring mill.

Steam generator heads

Recirculating steam generators The primary head of an RSG is typically 10 ft (3.1 m) in diameter, 6 in. (152.4 mm) thick and weighs up to 35 t (31 t_m). Primary heads used in PWR plant steam generators are clad on the inside surface. Similar ferritic material primary surfaces on CANDU RSGs do not require cladding. Two or three nozzles as large as 41 in. (1041 mm) in diameter are attached to the head. The head is mounted on a large capacity welding positioner so that it can be properly oriented for submerged arc welding of nozzles and attachments. Several attachments for internal components, such as the divider plate seat and manway hinge, are also welded to the inside surface of the head.

The steam drum head on an RSG is either semi-elliptical or hemispherical, is forged or formed from plate, and is up to 15 ft (4.6 m) in diameter. It also contains one large diameter 30 in. (762 mm) steam outlet nozzle. The nozzle to head weld is performed using the submerged arc welding process.

Once-through steam generators The primary head of an OTSG (Fig. 8) is similar in size to an RSG and is also clad on the inside surface. However, there is no divider plate in the primary head of an OTSG. The lower head is set up on a boring mill and the base support weld prep is machined. The manway gasket seat and stud holes are drilled and the threads milled.

Fig. 7 Gundrilling a tubesheet.

The base support is fitted and set up on a weld positioner for submerged arc welding. The primary nozzles are fit and welded using an orbital gas tungsten arc welder (GTAW) that travels around the weld seam utilizing specialized guidance systems, and video cameras to provide visibility for the operators. This equipment is necessary due to the restricted access around the weld seam created by the base support. All nozzle welds are backclad to ensure that there is a continuous corrosion resistant cladding on surfaces in contact with primary side water. The welds then receive a post weld heat treatment (PWHT) and volumetric examination by ultrasonic testing (UT) or radiographic testing (RT), and surface examination using magnetic particle (MT) or dye penetrant testing (PT). The head is then set up on a vertical boring mill and the base support and circumferential seam weld prep are machined.

Pressure boundary assembly

Pressure boundary components include the cylindrical shells, heads, the tubesheet, and external and internal supports.

Alignment, welding, nondestructive examination (NDE), PWHT and machining are critical operations when assembling these components. The sequence of adding nozzles and attachments depends on the accuracy requirements and anticipated weld distortion during assembly. If there are tight tolerance requirements on the location of nozzles and attachments, these features are machined after final assembly and PWHT of the pressure boundary components. However, this adds to the critical path schedule and, where it can be accommodated, these features are attached to the individual components and machined prior to component assembly.

Circumferential weld seams are typically made with submerged arc welding (SAW) (Fig. 9). The components are aligned and then rotated under a stationary submerged arc weld head. The welds are generally two-sided (first welded on the inside and then on the outside of the wall thickness) so that the root of the weld can be ground clear prior to welding the opposite side. If access to the inside is restricted, the welds are one-sided and are made from the outside. This requires precise alignment of the mating weld preps to avoid any defects at the root of the weld. This area may have restricted access for grinding and examining the surface. The welds receive surface NDE (MT, PT) and volumetric NDE (UT, RT). The ASME Code specifies when these examinations shall be made with respect to the PWHT.

The OTSG pressure boundary assembly has some unique differences from an RSG, mainly because the second tubesheet must be installed after the shroud and tube bundle supports are installed. The lower primary head is installed after the tubes are inserted. This sequence is explained in more detail later in this chapter.

Pressure boundary post weld heat treatment PWHT is an important consideration in planning the assembly of a steam generator. All carbon steel pressure boundary welds require PWHT. In the assembly sequence, these welds must be accessible for NDE after PWHT, as specified by the ASME Code (Fig. 10). PWHT is conducted on as large an assembly as possible to save on the cost of the PWHT furnace operation. Offsetting this are the risk and cost of having to re-PWHT this large assembly in the event of a major weld repair. Consequently, an assurance NDE is conducted prior to PWHT. If there are many complex welds in an assembly, a subassembly of these components may receive its own PWHT and NDE.

Fig. 8 Once-through steam generator primary head.

Fig. 9 Submerged arc welding.

Fig. 10 Radiographic examination of a steam generator weld.

The pressure boundary assembly is prepared for PWHT by sealing all openings. The tubesheet holes are cleaned to ensure that all contaminants that might adhere to the surface during PWHT are removed. Thermocouples are attached in strategic locations to monitor and control the heating and cooling operation and to ensure that the welds achieve their required temperature. The vessel is filled with argon, which is slowly circulated through the inside of the vessel during PWHT to eliminate oxidation. The pressure boundary is then heated in a computer-controlled gas-fired furnace.

PWHT of RSG pressure boundary PWHT can cause significant temperature differences and thermal stress in the pressure boundary assembly, especially if its geometry is complex. Therefore, the pressure boundary is assembled and post weld heat treated prior to installation of the tube bundle to avoid harmful differential thermal expansion effects. The primary head is welded to the tubesheet prior to the tube bundle assembly to avoid PWHT effects, although this means that the tube seal welding must be done in a confined area. After installing the tube bundle, the final closing seam is welded and locally heat treated. This is described later in this chapter. The welds are then examined according to ASME Code.

PWHT of OTSG pressure boundary The upper tubesheet and upper primary head of an OTSG are installed after the shroud and bundle supports are installed. These two circumferential seams receive a local PWHT. The straight tubes are inserted through the lower tubesheet and seal welded at both ends. Then the lower primary head is installed. The circumferential seam between the lower primary head and lower tubesheet requires local PWHT after welding. These operations are described later in this chapter.

Tube bundle components

Tube support assemblies The tube supports of modern RSGs are lattice grids. These grids consist of a ring assembly and a grid of flat bars that are assembled in the ring to form the lattice pattern. The flat bars intersecting each other on their edges form a diamond shape around each tube. This provides good vibration dampening yet allows the steam-water mixture to flow through the bundle with minimal pressure drop (Fig. 11).

Lattice grids (see also Chapter 48) must be accurately manufactured so each diamond is precisely aligned with the tubesheet drilling pattern. During tube bundle assembly, each tube is inserted through each grid then through the holes in the tubesheet. The accuracy of the lattice grids determines the ease with which the tube bundle is assembled.

The most critical operation in manufacturing lattice grids is cutting slots in the rings and bars where the bars intersect and fit together. Slotting is done using a special milling cutter setup driven by a boring mill. It is extremely important for the cutter setup to be accurate and the work piece to be set up true to the machine to control slot depth and angle. The mill must be calibrated to ensure that it is capable of precisely positioning the tool. CNC machines are essential to ensure consistent quality. After final assembly, the completed grid is inspected to verify that the diamonds are properly located.

OTSGs use broached tube support plates (TSP) to support the bundle. These TSPs are typically flat plates made of stainless steel that are drilled to the tube bundle pattern using a multi-spindle drill. Each hole is then machined by broaching so that the final hole shape resembles a trefoil pattern consisting of three contact areas that support the tube and three enlarged areas that allow flow through the plate (Fig. 12). Broaching is done on a multi-spindle CNC ma-

Fig. 11 Lattice-grid tube supports.

chine that pulls the broaches through the plate vertically downward (Fig. 13). Before broaching, the holes are tapered on one or both ends depending upon their location in the bundle to accommodate tube bundle assembly and to provide improved pressure drop for secondary side flow. After broaching, each plate is electropolished by immersing the plate into a tank containing electrolyte and passing appropriate current between the plate and a nearby cathode. Electropolishing removes burrs and smooths the surface to avoid damage to the tubes during insertion.

Baffle plates Baffle plates are installed in the preheater section of RSGs to direct water flow. Baffles are fabricated from machined plates. The plates are normally drilled by assembling them into a tightly clamped stack using bolts and welds and then gundrilling. Drilling a stack of plates requires the plates to be ground flat and to uniform thickness to ensure that the holes in individual plates have accurate perpendicularity to their individual plate surface. Generally, larger diameter baffle plates are best drilled individually using a gantry drill because of the difficulty of clamping, handling and accurately drilling a stack of large diameter plates.

U-bend supports The tube U-bends (Fig. 14) of RSGs are protected from flow-induced vibration by U-bend supports. These consist of an assembly of stainless steel flat bars that are GTAW welded to a collector bar to form a fan bar assembly. Some types of stainless steel require that these GTAW welds receive a PWHT in a controlled atmosphere. The angular separation of the fan bars depends upon the U-bend size and flow conditions, and the bars are located to minimize unsupported tube lengths. The fan bar assemblies are installed between the tube rows, and the outer ends of the fan bars are joined after assembly in the bundle with an arch bar. The U-bend support assembly is not connected to the shroud, thus allowing the assembly to float with the tube bundle during operation.

Tube bending Tubes for steam generators are typically 0.5 to 0.875 in. (12.7 to 22 mm) diameter with a typical nominal wall thickness of 0.045 in. (1.14 mm).

Fig. 13 Multi-spindle CNC broaching machine.

In the OTSG design, the bundle consists of straight tubes. In the RSG, bundles are composed of U-tubes.

The U-tubes must have accurate bend radii, straight leg lengths, and must be within a strict ovality and wall thinning tolerance. These tolerances are required to ensure that tolerance stack-up does not cause interference in the U-bend region. To achieve these tolerances, the tubes are purchased to a length tolerance of 0.125 in. (3.18 mm). The tubes are formed on a draw bender over dies to a radius tolerance of ± 0.03 in. (0.8 mm). The dies for the tight radius bends are

Fig. 12 Broached tube support plate.

Fig. 14 U-bend tube supports.

designed to contain the tube and to minimize ovality during bending. After the tubes are bent, they are dimensionally checked to verify that all tolerances have been met.

Shrouds The shrouds are fabricated from steel plates rolled into cylinders and their longitudinal seams are joined by SAW. The sections of the shroud near the preheater section of the RSG may have their inside diameters machined round. This ensures that baffle plates can slide axially and can expand during various operating conditions. These shroud sections for RSGs may also contain manifolds to distribute the incoming feedwater and recirculating water.

It is critical to ensure that the inside radius of the shroud is accurate so that the required clearance exists to allow lattice grids and baffles to be aligned with the tubesheet pattern. The inside radius of the RSG shroud is measured by projecting a laser down its centerline and using a radial micrometer. Alternatively, an optical instrument can be used in a similar setup.

Tube bundle assembly

The tube bundle is assembled in a *clean room* (Fig. 15) to ensure that the components are not contaminated. Cleanliness and material control procedures are carefully monitored. All internal components are cleaned just prior to enclosing them.

Installation of shroud and bundle supports The shroud must be installed and aligned to ensure that the tube bundle supports can be aligned with the tubesheet drilling pattern. The shroud is installed horizontally by using wheels or bearing rollers bolted onto one end. This allows the tubesheet end of the shroud to roll into the shell as a crane supports the other end and provides a horizontal push. The shroud is then aligned using pins located around its circumference.

If the RSG design includes an integral preheater, a secondary divider plate is installed with a powered cart, which also adjusts the position of the divider plate. This plate fits into grooves in the shroud. The preheater baffle plates are then installed by mounting them on the end of a boom that is driven by a floor mounted power unit. The holes in the baffle plates must be aligned with those in the tubesheet.

Baffle plates are supported by tie rods machined to

length that ensure parallel placement of the plates to the tubesheet. The baffle plates must have radial clearance to allow for thermal expansion. This clearance, however, creates an installation problem because the baffles must support the tube bundle and remain in alignment with the tubesheet while the tubes are being installed. This problem is overcome by installing a special shim that fits into the clearance between the baffle plates and the shroud. This shim dissolves during vessel operation, thereby maintaining the proper clearance.

The lattice grids for RSGs are installed by mounting them on a boom (Fig. 16). The grids are aligned with the tubesheet using optical scopes mounted on the primary side of the tubesheet. A small target is positioned in selected tube locations on the lattice grids, and the grid is adjusted using wedges around its circumference until the target aligns with the scope's line of sight. Alignment rods that are the same diameter as the tube are also used to check the alignment of the lattice grids. The grids are held in place by support blocks welded to the inside of the shroud.

To ensure that the tubes can be installed in an OTSG without misalignment or damage to their surface, it is critical that the TSPs are aligned with the hole pattern in the tubesheet and are parallel to the tubesheet face. The TSPs for OTSGs are connected together with tie rods. The first set of tie rods is installed into the tubesheet, and the ends are checked with a coordinate measuring machine to ensure they provide a flat plane for the first TSP to rest against. Support blocks are aligned and welded to the shroud, providing support to the circumferential edge of the TSP. The first support plate is installed and aligned using similar optical techniques to that used for aligning lattice grids. Then, wedges and keys are installed to firmly support the TSP and to keep it in alignment during rotation of the vessel for subsequent manufacturing operations. This sequence is repeated for each TSP. After all the TSPs are installed, the top tubesheet is set up on an alignment fixture in preparation for installation. Optical alignment scopes are set up, and the tubesheet is fit to the cylindrical shell. Ceramic backing bar is installed to the inside diameter of the circumferential seam along with alignment wedges.

Fig. 15 Nuclear clean room.

Fig. 16 Installation of lattice grid tube bundle support.

After fitup and alignment have been confirmed, the root passes of the weld are made while monitoring the alignment. The ceramic backing bar is removed, the optical instruments are removed, and the remainder of the weld is completed with SAW. The completed seam then receives MT, UT (Fig. 17) and RT.

Installation of tubes Tubes are installed with the vessel in a horizontal position. Each tube hole and tube are dry-swabbed clean just prior to assembly. Cleaning operations at this stage are done without liquids. Any moisture or contaminants trapped between the tube and tube hole can cause tube-to-tubesheet welding defects.

In an RSG, the U-tubes are fitted with a plastic tube end pointer and installed in layers from the smallest bend radius tubes to the largest bend radius tubes (Fig. 18) starting with the lowest layer. This tubing sequence simplifies the temporary supports that must be installed to keep the U-bend supported during tube installation. As each layer is installed, the appropriate U-bend support fan is installed. The partially completed bundle is temporarily supported to prevent sagging due to the weight of the tubes. Each U-tube is inserted until it protrudes the specified amount from the primary face of the tubesheet. This amount of protrusion depends upon whether the tube-to-tubesheet weld is a fillet weld or a flush weld. The installer also checks for proper clearance between each U-bend. The tubes are tack expanded by inserting an expander inside the tubes about 0.75 in. (19 mm). The expander consists of a split collet actuated by a hydraulically driven tapered mandrel. This yields the tube sufficiently to hold it in place and to close the gap for welding. This expansion method produces less residual stress in the tube than other methods, such as roller expansion.

In an OTSG, the straight tubes are fitted with plastic tube end pointers, cleaned, and installed in layers starting from the top layer and working down. This tubing sequence avoids any particulate matter that may be picked up by the tube during insertion from falling down onto tube ends that have already been installed. This sequence also simplifies retrieval of a tube end pointer in the unlikely event that one comes loose during tube insertion. Tubes are inserted through the bottom tubesheet, through the TSP assembly, and through the upper tubesheet. The tubes are inserted so that the correct tube projection is achieved at the upper tubesheet. The tubes are then tack expanded using the same tack expansion techniques that are used for RSGs. The tubes in the upper tubesheet are final tack expanded and seal welded. The tube ends in the lower tubesheet receive an initial expansion to provide some support to the tube while the tube ends are machined to the proper protrusion at the lower tubesheet. This is followed by a final tack expansion.

Tube-to-tubesheet welding The tubes and tubesheets are joined with automatic gas tungsten arc welding (GTAW). The tube-to-tubesheet welding heads are specially designed units to provide welds of consistent quality (Fig. 19). At the beginning of each shift, each operator makes a tube-to-tubesheet weld test

Fig. 17 Ultrasonic inspection of seam weld.

Fig. 18 Installation of tubing.

block. The block receives a visual and PT inspection, and is then sectioned for further metallurgical examination.

Each weld is visually compared to a workmanship sample. All welds not meeting the sample quality are repaired and then rewelded. This is followed by PT examination of all tube-to-tubesheet welds. Finally, a leak test is done by pressurizing the secondary side with a mixture of air and helium. The primary tubesheet face is then monitored for helium leaks at the welds.

Tube expansion Each tube is hydraulically expanded into its hole after tube-to-tubesheet welding. This expansion closes the crevice between the tube and the hole to avoid a potential corrosion site. The tube may be expanded near the secondary face of the tubesheet or it may be expanded full depth or at the primary face depending on customer specifications. Hydraulic expansion is the recommended method for nuclear steam generators because it produces less residual stress in the tube and reduces the potential for stress corrosion cracking compared to other expansion methods. Each tube is expanded by inserting a probe that has a seal positioned at each end of the expansion zone. Distilled water at approximately 35,000 psi (241.3 MPa) is pumped through the probe, expanding the tube and sealing it against the tube hole.

The expansion probe must be carefully positioned with respect to the secondary face of the tubesheet. If the probe is positioned beyond the face, then unacceptable tube deformation could occur. If the probe is too far inside the tube hole, an unacceptably long crevice could possibly result. Therefore, the tubesheet thickness variation is measured and the probe length is adjusted to ensure proper positioning.

Tubes located near the tubesheet periphery may require expansion using special probes because the curvature of the head encroaches on the probe insertion area. A flexible extension is attached to the probe, which allows it to be inserted in confined areas. In cases where the tube must be expanded full depth, the

expansion is done in two or more steps. Following expansion, each tube is examined with eddy current testing (ECT) techniques.

Steam drum internals

RSGs require a steam drum and steam separators to remove moisture from the steam (Fig. 20). OTSGs provide steam at slightly superheated conditions and do not require steam separators. The steam separators are similar in design to those used on fossil-fuel boilers. Generally, the separators in nuclear steam generators are an axial flow type, although tangential flow separators have been used. There are typically more than 100 separators in a large RSG. Most designs also have smaller secondary separators located above the primary units.

The fabrication and assembly tolerances of steam separators are critical. The shape and assembly clearances of internal components have a significant effect on separator performance. Custom made assembly jigs and fixtures are used to ensure that the required tolerances are met. In addition, all internal welds are carefully ground to avoid discontinuities that affect separator performance.

The steam separators are installed in a deck structure made of steel plate. This deck support structure is welded to the inside of the drum, and the supports are designed to accommodate differential thermal expansion during steam generator operation as well as loads due to specified accidental pipe break and seismic events. The separator and deck structure is usually of modular construction to simplify installation into the steam drum.

Final assembly

Closing seam fitting and welding of RSGs The final assembly operation for RSG fabrication consists of fitting and welding the closing seam, which is usually one of the circumferential seams on the cone. The steam drum and the cylindrical shell are positioned on rotators and the circumferential seam is aligned. Previous machining of the component mating surfaces assures good alignment. The weld could be either a two-sided weld if there is sufficient access to the inside of the vessel, or a one-sided weld. If a one-sided weld is used, it is generally of a narrow groove design to limit the volume of weld deposit. The sequence of making a one-sided weld is described later.

Prior to starting work on the inside of the vessel, the tube bundle and the steam separator assembly are sealed off to prevent weld flux and other material from entering. The drum and cylindrical shell are aligned and the seam is tack welded to hold the components in position. The next several weld passes are completed using shielded metal arc welding (SMAW). This additional welding provides enough structural strength to allow the assembly to be moved to a submerged arc welding station where the outside of the weld is finished using SAW. As the vessel is rotated, the weld is completed.

Due to access limitations at some sites installing replacement RSGs, fitting and welding of the closing seam may not occur until after the RSG is inside the

Fig. 19 Tube-to-tubesheet welding.

Fig. 20 Fabrication of steam separator subassembly.

containment building. In these cases, the lower half of the steam generator is generally assembled to the refitted upper half of the original steam generator. Typically, the steam drum and head will be refit with new separators and steam flow control equipment before the closing seam is made with the steam generator vertical and in place.

Local PWHT of RSG closing seam The closing circumferential seam requires post weld heat treatment. Because temperature differences during this procedure can exceed those experienced during normal operation of the vessel, care must be taken to avoid excessive and harmful differential expansion of internal components. Temperatures can be controlled using an electric furnace designed to fit around the closing seam. Insulation is applied to the outside of the vessel shell and to the attachments in the vicinity of the seam. The tube bundle U-bend region is also insulated to reduce radiant heat transfer. Internal heat transfer is further reduced by drawing a vacuum on the secondary side of the vessel. During PWHT, air may be blown through the tube bundle primary side to limit tube temperature. Thermocouples are mounted in each critical area to monitor and control the process.

The electric furnace has several zones that can be independently controlled to keep the temperatures within prescribed limits. A computer is used to control the furnace and to collect data and provide a record of temperatures.

Final assembly and local PWHT of OTSG pressure boundary After the straight tubes are inserted through the lower tubesheet, seal welded and helium leak tested, the lower primary head is installed. The circumferential seam between the lower primary head and lower tubesheet requires local PWHT after welding. This operation is complex because the tube bundle will be partially heated during the operation. Temperature gradient limits are imposed to limit the stresses in each component and to limit the loads on the tubes due to the difference in coefficient of thermal expansion between the tubes and carbon steel pressure boundary. An electrically heated clamshell furnace is installed around each circumferential weld seam. Supplementary electric heaters may be placed on other components such as the tubesheet primary

face to further control the temperature gradients. Heat transfer by convection to the secondary side may be controlled either by drawing a vacuum, or by providing air circulation, depending on the requirements during heat-up or cool-down.

Final inspection and testing

A hydrostatic test is done on the completed vessel; the primary and secondary sides are tested separately. The test consists of filling the vessel with treated water that is pressurized to 125% of the design pressure. The pressure is reduced and held at the design pressure while an inspector examines the vessel for leaks. The metal temperature must be held above 70F (21C) to keep it well above its brittle transition temperature.

After hydrostatic testing, the vessel is drained and dried. A vacuum is drawn on the secondary side to assist drying. Felt plugs are also blown through the tubes to dry them. All accessible pressure boundary welds are then examined by the MT method.

Nozzles and integral support surfaces, called terminal points, connect to mating components in the field and must be within specified tolerances to simplify field installation and minimize stresses caused by fitup. Special coordinate measuring machines (Fig. 21) are used to set up the tools used to machine the final terminal point geometry (Fig. 22). It is common practice to finish machine nozzle weld preps at this stage to bring them within tolerance.

Just prior to closing the vessel, the insides of the tubes are cleaned by blowing felt plugs through them. The secondary side of the steam generator is examined and cleaned, and final drum internal components are installed. All manway covers are bolted on. The primary and secondary sides of the vessel are evacuated and backfilled with nitrogen to reduce the formation of oxides. Steam generators are wrapped in shrink-wrap plastic to protect them during shipment.

Surface conditioning

Some steam generator owners specify that the inside surfaces of the primary side (excluding the tubing) are to be surface conditioned or electropolished. This process produces a very smooth surface finish,

Fig. 21 Set up of nozzle machining tools using coordinated measuring machine.

Fig. 22 Final nozzle end machining.

typically 10 microinches or better. This results in a significant reduction in true surface area of the work piece which in turn reduces radioactive isotope uptake and occupational exposure. Reduced occupational exposure makes these components more easily maintained in the field.

The first step in surface conditioning is to grind the surface with abrasive flap wheels. Several passes are required, each one made with progressively finer abrasives until a surface finish of 40 microinches is achieved. This operation can be done by machine on an individual component prior to assembly. However, this is usually impractical because the component must then be protected from surface damage for the remainder of the manufacturing operation. Usually, the grinding is done near the end of the assembly sequence with hand tools. This is a time consuming operation, especially if as-welded surfaces are involved.

The second step in surface conditioning is to impart further improvements in surface roughness on a microscopic scale by electropolishing. In electropolishing, an applied electric current flows from the metal surface (anode or work piece) through a conductive electrolytic solution to another conducting surface (cathode). This process smooths the micropeaks formed by mechanical grinding.

Shipping

Steam generators may be shipped by rail or by special road transport directly to the plant site, or may travel part of the way by barge or heavy lift ship. For rail transportation, the load must be centered on the car for even weight distribution. If the vessel is long, it can span two railway cars. If it is short, a single heavy-duty flat car is usually sufficient (Fig. 23). The vessel is oriented to minimize its width and height and is loaded onto bunks fastened to the car. Loads up to 16 ft (4.9 m) in diameter can be shipped along most routes in the United States and Canada. Shipping larger units requires measurement of bridge clearances and other potential obstructions. If the vessel spans two

cars, the bunks must be designed to allow movement of the load while negotiating curves. Additional ballast may be attached to the rail car to lower the center of gravity.

Manufacture of pressurizers

Pressurizers are cylindrical vessels that help stabilize the pressure in the primary heat transport system. (See Chapter 46.) Each unit is fitted with special penetrations in which electrical heaters are installed.

Pressure boundary assembly

The pressure boundary consists of cylindrical shells and hemispherical heads. The pressure boundary contains a surge nozzle, spray inlet nozzle, several connections for electric heaters, and various small water level nozzles. The manufacturing methods and quality assurance requirements for these components are the same as those described previously for steam generators.

Heater connections and installation The heaters are the direct immersion type, sheathed in stainless steel or Inconel and assembled in bundles. In some designs, the heaters consist of a single straight element. Each of the elements is field assembled through penetrations in the vessel wall and is sealed by means of a bolted closure. The closure is sealed by gaskets or patented mechanical seals. An electrical connection is then made to the end of each heater using a special insulated fitting.

Post weld heat treatment

PWHT of pressurizers is simpler than that of steam generators because there are no complex geometries or internals that limit heating and cooling rates. PWHT is done by putting the completed pressurizer in a gas furnace and heating to 1125F (607C).

Some patented mechanical seals used for the heater connections must be installed prior to PWHT because of their required machined surface finish. This machining can not be done after the component is welded onto the vessel because of inadequate access for specialized equipment. As a result, the sealing surface is protected from the furnace environment by coating it with an antiscaling compound. Some minor surface dressing of the sealing surface may be required after PWHT.

Fig. 23 Steam generator awaiting offloading to heavy lift ship.

Manufacture of dry shielded canisters¹

Dry shielded canisters are part of a system of containers used to store and ship spent nuclear fuel. The canisters are designed to safely store bundles of spent fuel at plant sites, and some designs allow transport to long-term storage sites. The design of the canisters and internal structures serves as the containment boundary to confine radioactive spent fuel and provide a leak-tight, inert atmosphere to ensure that the integrity of the fuel cladding is maintained. A typical canister consists of an outer cylindrical shell made of stainless steel, typically 5.5 ft (1.7 m) in diameter by 15.5 ft (4.7 m) in length. The internal assembly consists of an array of guide sleeves that are square in cross-section. Each one is designed to accept a bundle of spent fuel. The guide sleeves are made of stainless steel. The ends of the canisters are capped with shield plugs that include lead shielding. Although many individualized components are similar to other nuclear pressure vessels, there are several unique features that require specialized manufacturing operations. For example, for some designs, it is necessary to limit the canister weight due to specific lifting capabilities at the plant site. Therefore, material thickness must be checked frequently to allow the manufacturing tolerances to be worked toward their minimum material condition.

The cylindrical shells are made from stainless steel plate using manufacturing operations common to other components described earlier. However, their outside surface must meet tight tolerances on circularity, diameter and straightness because the cylinder must fit inside a shielded storage container. The minimum diameter is limited by the requirement to insert the basket assembly into the cylinder without restriction. The diameter must also provide sufficient allowance for differential expansion of shell and basket assembly components when the assembly is subject to elevated temperature during service.

The shield plugs consist of a stainless or carbon steel circular disk with ribs or stiffeners welded to it. The entire shield plug assembly is poured full of lead typi-

cally 5 in. (127 mm) thick. A gamma ray scan confirms the effective thickness of the lead shielding.

The top cover plates are welded to the canister in the field. Consequently, it is critical to maintain a specific radial gap between the cover plate and the inside diameter (ID) of the cylinder. One way of accomplishing this is by machining and hand working the OD of the cover plates to suit the as-built ID of the cylinder. The cover plate must also meet a specific thickness tolerance to ensure that the maximum amount of fuel can physically fit into the canister. This requires flattening operations of the plates during machining and frequent UT thickness checks. There are similar requirements to custom machine, flatten and hand work the top shield plug to achieve specified radial gap.

The guide sleeves are made to form a square cross-section and are sized to suit the dimensions of PWR and BWR fuel assemblies. The tight tolerances on the guide sleeves ensure that a spent fuel bundle can be inserted without binding. The guide sleeves are formed from stainless steel sheet, and the longitudinal seams are welded using a welding jig that maintains the sleeve geometry. The welding equipment utilizes cooling methods and heat input techniques that minimize distortion due to welding.

During manufacture and assembly of the basket assembly, it is critical to align the spacer discs that support the guide sleeve so the sleeves can be installed without distortion or binding. The spacer discs are set up in an alignment jig and welded to the support rods. The entire assembly must meet exacting geometric requirements of overall perpendicularity, cylindricity and height to accommodate thermal expansion during service and to resist potential impact loading during transport.

After the basket assembly is assembled into the cylinder, the final alignment of each guide sleeve is checked using a plug gauge. The plug gauge, representing the maximum size of fuel to be stored in the canister, must pass through the guide sleeve within a specified load limit.

Appendix 1

Conversion Factors, SI Steam Properties and Useful Tables

This appendix provides tables, charts and figures that can be useful in evaluating the generation and use of steam. They supplement the material presented throughout *Steam* and are divided into four subsections: selected conversion factors; SI versions of the Steam Tables and graphical data; useful charts and figures; and typical operating parameters for a 500 MW pulverized coal-fired power plant.

Table 1.9
Power or Rate of Doing Work

Starting With Multiply By To Obtain	Btu per Minute	Foot-pounds per Minute	Foot-pounds per Second	Horsepower	Kilowatts	Watts
Btu per Minute	1	1.285 X 10 ⁻³	7.716 X 10 ⁻²	42.44	56.91	5.691 X 10 ⁻²
Foot-pounds per minute	778	1	60	3.3 X 10 ⁴	4.426 X 10 ⁴	44.26
Foot-pounds per second	12.97	1.667 X 10 ⁻²	1	550	737.6	0.7376
Horsepower	2.357 X 10 ⁻²	3.030 X 10 ⁻⁵	1.818 X 10 ⁻³	1	1.341	1.341 X 10 ⁻³
Kilowatts	1.757 X 10 ⁻²	2.260 X 10 ⁻⁵	1.356 X 10 ⁻³	0.7457	1	10 ⁻³
Watts	17.5725	2.260 X 10 ⁻²	1.356	745.7	1000	1

Table 1.10
Density (Mass/Volume)

Starting With Multiply By To Obtain	Pounds per Cubic Foot	Pounds per Gallon (U.S. Liquid)	Grams per Cubic Centimeter	Kilograms per Liter	Kilograms per Cubic Meter
Pounds per Cubic Foot	1	7.481	62.43	62.43	6.243 X 10 ⁻²
Pounds per Gallon (U.S. Liquid)	0.1337	1	8.345	8.345	8.345 X 10 ⁻³
Grams per Cubic Centimeter	1.602 X 10 ⁻²	0.1198	1	1.000	1.000 X 10 ⁻³
Kilograms per Liter	1.602 X 10 ⁻²	0.1198	1.000	1	1.000 X 10 ⁻³
Kilograms per Cubic Meter	16.02	119.8	1000	1000	1

Table 1.11
Thermal, Heat Transfer and Flow Parameters

Thermal Conductivity
1 Btu/h ft F

= 1 Btu/h ft R
= 12 Btu in./h ft² F
= 1.7307 W/m K

Heat Content

1 Btu/lb = 2.326 kJ/kg
1 Btu/Standard cubic foot = 0.039338 MJ/Nm³

Heat Flux, or Heat Transfer Rate

1 Btu/h ft² = 3.1546 W/m²

Volumetric Heat Release Rate

1 Btu/h ft³ = 10.3497 W/m³

Heat Transfer Coefficient or Conductance

1 Btu/h ft² F = 5.6784 W/m²K

Mass Flow Rate

1 lb/h = 0.000126 kg/s

Mass Flux

1 lb/h ft² = 0.001356 kg/m²s

Volumetric Flow Rate

1 ft³/min (ACFM) = 0.000472 m³/s
1 GPM = 0.06308 l/s

Table 1.12
Multiplying Prefixes

Multiplication Factors	Prefix	SI Symbol
1 000 000 000 000 = 10 ¹²	tera	T
1 000 000 000 = 10 ⁹	giga	G
1 000 000 = 10 ⁶	mega	M
1 000 = 10 ³	kilo	k
100 = 10 ²	hecto*	h
10 = 10 ¹	deka*	da
0.1 = 10 ⁻¹	deci*	d
0.01 = 10 ⁻²	centi*	c
0.001 = 10 ⁻³	milli	m
0.000 001 = 10 ⁻⁶	micro	μ
0.000 000 001 = 10 ⁻⁹	nano	n
0.000 000 000 001 = 10 ⁻¹²	pico	p
0.000 000 000 000 001 = 10 ⁻¹⁵	femto	f
0.000 000 000 000 000 001 = 10 ⁻¹⁸	atto	a

* To be avoided where possible.

Table 1.13
Selected Additional Conversion Factors

Length and Area

100 feet (ft)/minute (min)	= 0.508 meter (m)/second(s)
1 square mile (mi ²)	= 640 acres
	= 259 hectares (ha)
1 m/s	= 196.9 ft/min
1 square kilometer (km ²)	= 100 ha
	= 0.3861 mi ²
1 ha	= 10,000 m ²
	= 2.471 acres
1 nautical mile	= 6080 ft
	= 1.151 statute mi
	= 1.853 km
1 nautical mile/hour (h)	= 1 knot

Weight

1 pound (lb)	= 16 ounces (oz)
	= 7000 grains (gr)
	= 0.454 kilogram (kg)
1 oz	= 0.0625 lb
	= 28.35 grams (g)
1 grain (gr)	= 64.8 milligrams (mg)
	= 0.0023 oz
1 lb/ft	= 1.488 kg/m
1 g	= 1000 mg
	= 0.03527 oz
	= 15.43 grains
1 kg/m	= 0.672 lb/ft

Volume

1 cubic foot (ft ³)	= 1728 cubic inches (in. ³)
1 cubic inch (in. ³)	= 16,390 cubic millimeters (mm ³)
1 imperial gallon	= 277.4 in. ³
	= 4.55 liters (l)
1 U.S. gallon (gal)	= 0.833 imperial gallon
	= 3.785 l
	= 231 in. ³
1 U.S. barrel (bbl)	= 42 U.S. gallons
(petroleum)	= 35 imperial gallons
1 liter (l)	= 10 ⁶ mm ³
	= 0.220 imperial gallon
	= 0.2642 U.S. gallon
	= 61.0 in. ³
1 board ft	= 12 in. x 12 in. x 1 in. thick
	= 144 in. ³
1 ft ³ /min	= 1.699 m ³ /h
1 m ³ /h	= 0.589 ft ³ /min

Temperature, Measured

F	= (C x 9/5) + 32
	= R - 459.67
C	= (F - 32) x 5/9
	= K - 273.15

Density

1 ft ³ /lb	= 0.0624 m ³ /kg
1 grain/ft ³	= 2.288 g/m ³
1 grain/U.S. gallon	= 17.11 g/m ³
	= 17.11 mg/l
1 m ³ /kg	= 16.02 ft ³ /lb
1 g/m ³	= 0.437 grain/ft ³
	= 0.0584 grain/U.S. gallon
1 g/l	= 58.4 grain/U.S. gallon

Water at 62F (16.7C)

1 ft ³	= 62.3 lb
1 lb	= 0.01604 ft ³
1 U.S. gallon	= 8.33 lb

Water at 39.2F (4C), maximum density

1 ft ³	= 62.4 lb
1 m ³	= 1000 kg
1 lb	= 0.01602 ft ³
1 l	= 1.0 kg
1 kg/m ³	= 1 g/l
	= 1 part per thousand
1 g/m ³	= 1 mg/l
	= 1 part per million (ppm)

Pressure

1 atmosphere (metric)	= 98,066.5 pascals (Pa)
	= 1 kg force (kgf)/square centimeter (cm ²)
	= 10 m head of water
	= 14.22 lb/in. ²
1 lb/ft ²	= 47.88 Pa
	= 0.1924 in. of water
	= 4.88 kg/m ²
1 ton (t)/in. ²	= 13,789 kilopascals (kPa)
	= 1.406 kg/mm ²
1 in. head of water	= 5.20 lb/ft ²
1 m head of water	= 9806 Pa
	= 0.1 kg/cm ²
1 m head of mercury (Hg)	= 133.3 kPa
	= 1.360 kg/cm ²
	= 1333 millibars
1 kg/m ²	= 9.806 Pa
	= 1 mm head of water
	= 0.2048 lb/ft ²
1 kg/cm ²	= 98.066 kPa
	= 735.5 mm Hg
	= 0.981 bar
	= 14.22 lb/in. ²
1 kg/mm ²	= 9.8066 megapascals (MPa)
	= 0.711 t/in ²

In these conversions, inches and feet of water are measured at 62F (16.7C), millimeters and meters of water at 39.2F (4C), and inches, millimeters, and meters of mercury at 32F (0C).

Note: The following steam tables and Fig. 2.2 have been abstracted from *ASME International Steam Tables for Industrial Use* (copyright 2000 by The American Society of Mechanical Engineers), based on the IAPWS industrial formulation 1997 for the Thermodynamic Properties of Water and Steam (IAPWS-IF97)

Table 2.1
SI Properties of Saturated Steam and Saturated Water (Temperature)¹

Temp K	Press. MPa	Volume, m ³ /kg			Enthalpy, kJ/kg			Entropy, kJ/(kg K)			Temp K
		Water v_f	Evap v_{fg}	Steam v_g	Water H_f	Evap H_{fg}	Steam H_g	Water s_f	Evap s_{fg}	Steam s_g

Table 3.1
SO₂, SO₃ Estimated Emissions from
Boilers Firing Coal or Fuel Oil

SO₂:

$$\text{lb SO}_2 \text{ produced/lb fuel} = K \left(\frac{\text{lb sulfur}}{\text{lb fuel}} \right) \left(\frac{64 \text{ lb SO}_2/\text{mole}}{32 \text{ lb sulfur/mole}} \right)$$

$$\text{lb SO}_2 \text{ produced/h} = K \left(\frac{\text{lb fuel}}{\text{h}} \right) \left(\frac{\% \text{ sulfur in fuel} \times 2}{100} \right)$$

$$\% \text{ SO}_2 \text{ by weight} = \frac{\text{lb SO}_2/\text{h} \times 10^2}{\text{lb flue gas/h}}$$

$$\text{ppm SO}_2 \text{ by weight} = (\% \text{ SO}_2 \text{ by weight}) \times 10^4$$

$$\% \text{ SO}_2 \text{ by volume} = \frac{100 (\% \text{ SO}_2 \text{ by weight}/64)}{(\% \text{ SO}_2 \text{ by weight}) + \frac{100 - (\% \text{ SO}_2 \text{ by weight})}{M}}$$

$$\text{ppm SO}_2 \text{ by volume} = \% \text{ SO}_2 \text{ by volume} \times 10^4$$

where K = 0.95 Cyclone furnace firing
0.97 dry bottom PC firing
0.99 oil firing

M = molecular weight of flue gas
30.2 coal firing
29.0 oil firing

SO₃:

SO₃ quantity = 1% of SO₂ quantity (coal firing)
= 2% of SO₂ quantity (oil firing)

Table 3.2
Conversion Formulae for Emission Rates

EPA F-Factor Method

A common method of reporting emissions is in pounds of pollutant per million Btu of fuel input. An EPA-approved conversion formula called the dry, oxygen based F-factor method can be used to convert ppm by dry volume of a pollutant to lb/10⁶ Btu as follows:

$$\frac{\text{lb}}{10^6 \text{ Btu}} = \text{ppmdv} \times \frac{20.9}{(20.9 - \%O_2 \text{ dv})} \times F_d \times (2.59 \times 10^{-9}) \times M$$

where: F_d = a fuel factor representing the dry standard cubic feet (DSCF) of flue gas produced by burning a million Btu of fuel at theoretical air (0% excess air). Standard conditions are 68F and 14.7 psia. F_d can be calculated from an ultimate fuel analysis, or a fuel specific default value may be used as follows:

$$F_d = \frac{1,000,000 [3.64(\% H) + 1.53(\% C) + 0.57(\% S) + 0.14(\% N) - 0.46(\% O)]}{\text{Higher heating value, Btu/lb}}$$

Note: The percentage by weight of each constituent in the above equation is acquired from an ultimate fuel analysis and must be on the same basis as the higher heating value (both wet or both dry).

Fuel Type	F_d Default Values
Refuse (Municipal solid waste)	9,570
Bituminous and subbituminous coal	9,780
Anthracite	10,100
Lignite	9,860
Natural gas	8,710
Fuel oils	9,190
Black liquor	8,800
Wood	9,400

2.59×10^{-9} = A constant based on the ideal gas law that equals 10⁶ moles per DSCF. The ideal gas law, $PV=nRT$, says that 1 mole of ideal gas will occupy 385.5 ft³ at 68F and 14.7 psia. 10⁶ moles would, therefore, occupy 385.5×10^6 ft³ and 10⁶ moles per DSCF = $1/385.5 \times 10^6 = 2.59 \times 10^{-9}$.

M = the molecular weight of the pollutant being measured (lb/lb-mole), where

Pollutant	Expressed as Equivalent	M
NO _x	NO ₂	46.01
CO	CO	28.01
SO ₂	SO ₂	64.06
VOC	CH ₄	16.04
SO ₃	SO ₃	80.06

ppmdv = the parts per million of pollutant in the flue gas measured on a dry volume basis.

$\frac{20.9}{(20.9 - \%O_2 \text{ dv})}$ = a correction factor for the amount of excess air as measured by percent O₂ on a dry volume basis in the flue gas.

Additional Conversion Methods

Instructions: Multiply the given pollutant value by the factor listed to convert to the units listed in the left-hand column.

Given Value →	ppm (dry vol.)	grains/DSCF	mg/DSCM	mg/Nm ³	lb/10 ⁶ Btu	ng/Joule*
ppm (dry vol.)	1	$\frac{5.504 \times 10^4}{(M)}$	$\frac{24.056}{(M)}$	$\frac{22.417}{(M)}$	$\frac{1 \times 10^6 (HI)}{(M)(N')}$	$\frac{2.321 \times 10^3 (HI)}{(M)(N')}$
grains/DSCF	$1.817 \times 10^{-5} (M)$	1	4.371×10^{-4}	4.074×10^{-4}	$\frac{18.162 (HI)}{(N')}$	$\frac{4.217 \times 10^{-2} (HI)}{(N')}$
mg/DSCM	$4.157 \times 10^{-2} (M)$	2.288×10^3	1	0.932	$\frac{4.156 \times 10^4 (HI)}{(N')}$	$\frac{96.432 (HI)}{(N')}$
mg/Nm ³	$4.461 \times 10^{-2} (M)$	2.455×10^3	1.073	1	$\frac{4.458 \times 10^4 (HI)}{(N')}$	$\frac{1.035 \times 10^2 (HI)}{(N')}$
lb/10 ⁶ Btu	$\frac{(M)(N')}{1 \times 10^6 (HI)}$	$\frac{5.506 \times 10^{-2} (N')}{(HI)}$	$\frac{2.406 \times 10^{-5} (N')}{(HI)}$	$\frac{2.243 \times 10^{-5} (N')}{(HI)}$	1	2.321×10^{-3}
ng/Joule*	$\frac{4.308 \times 10^{-4} (M)(N')}{(HI)}$	$\frac{23.716 (N')}{(HI)}$	$\frac{1.037 \times 10^{-2} (N')}{(HI)}$	$\frac{9.664 \times 10^{-3} (N')}{(HI)}$	430.8	1

grains/DSCF = grains per dry standard cubic foot (68F and 29.92 in. Hg)

mg/DSCM = milligrams per dry standard cubic meter (68F and 29.92 in. Hg)

mg/Nm³ = milligrams per normal cubic meter (0C and 760 mm Hg)

lb/10⁶ Btu = pounds per million Btu, fuel heat input (HHV basis)

ng/Joule = nanograms per Joule, fuel heat input (HHV basis)

* **Caution:** Should not be used for conversion calculations when ng/Joule is stated as an electrical output based standard.

M = molecular weight of pollutant (lb/lb-mole)

N' = moles of dry flue gas per hour

HI = heat input in fuel, 10⁶ Btu/h (HHV basis)

$\frac{N'}{HI}$ and its reciprocal occur in many of the above conversion formulae.

$\frac{N'}{HI}$ can be calculated using the EPA F-factor (F_d) discussed above as follows:

$$\frac{N'}{HI} = \frac{F_d}{385.5} \times \frac{20.9}{(20.9 - \%O_2 \text{ dv})} \times \frac{\text{moles dry flue gas}}{10^6 \text{ Btu}}$$

Dry gas weight 9.244	
Water in wet gas (as%) 5.711%	12.001

*Local requirements vary.

Appendix 2

Codes and Standards

There are many codes and specifications which control the design and construction of boilers, steam generators, pressure vessels and piping. Two of the most important are the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (BPVC) and the ASME B31 Pressure Piping Code. Pressure-containing components may be required by law to meet the requirements of these codes. In the United States (U.S.) and Canada (and recently in some other countries), state, city and provincial laws, enforced by local jurisdictions (see Note below), require new pressure parts to comply with the requirements of the ASME BPVC. The design and construction of pressure parts for repair or replacement are established by the local jurisdiction (see note below) and/or insurance carrier generally following the National Board Inspection Code (NBIC) in the U.S.

In addition to the BPVC and B31 Pressure Piping Codes, the ASME Performance Test Code provides uniform procedures for the testing and performance evaluation of power plant equipment. This code is frequently used to establish contract compliance of a particular component.

The ASME Boiler and Pressure Vessel Code

The ASME BPVC establishes rules of safety governing the design, fabrication and inspection during construction of boilers, pressure vessels and nuclear power plant components. The objectives of the rules are to assure reasonably certain protection of life and property and to provide a margin for deterioration in service. These rules do not provide criteria for thermal performance, but rather set minimum necessary guidelines for structural integrity to ensure safe operation during the expected component life. The BPVC provides a systematic approach to evaluating

the stresses and applying material properties in a way which provides a safe pressure vessel design. The rules are established through a structured voluntary consensus code writing system and are implemented through specific contract terms and/or adoption by various jurisdictions (see Note below).

ASME BPVC history

To understand why the ASME Boiler and Pressure Vessel Committee was formed and how it operates, some historical background is necessary.

During the mid 1880s, explosions in fire tube boilers were common. Design knowledge and construction expertise generally were held by large companies, such as The Babcock & Wilcox Company (B&W), and were based essentially on experience.

In 1887, the American Boiler Manufacturers Association (ABMA) was organized to develop general rules for design and construction of boilers and pressure vessels. However, participants were reluctant to give up trade secrets and the effort to develop rules or standards failed. There was, however, some exchange of technical information such as materials data, riveting methods, safety factors, head and flange design rules and hydrostatic testing which helped manufacturers improve the safety of their products.

From 1898 to 1903, more than 1200 people were killed in the U.S. in 1900 separate boiler explosions. The catastrophic explosion of a fire tube boiler in a factory in Brockton, Massachusetts, in 1905 killed 58 people. This tragedy led the governor of Massachusetts to request and obtain the first legal set of rules for the design and construction of boilers. The next year a similar set of boiler design and construction rules was issued by the State of Ohio. Other jurisdictions followed with their own rules. This wide array of rules and regulations caused problems for manufacturers and users because equipment which was acceptable and met the rules in one state was frequently not acceptable in another.

Colonel E.D. Meier, a founder of the ABMA, campaigned to get acceptance of uniform boiler laws. In 1911, he was elected president of the ASME. Finally, on February 13, 1915, the first ASME Boiler and Pressure Vessel Code of 147 pages was issued. It was entitled *Boiler Construction Code, 1914 Edition*.

Note: *Local jurisdiction* refers to the municipal, state, provincial or federal authorities enforcing boiler and pressure vessel laws or regulations.

ASME BPVC additions

After the 1914 Edition, the following major sections were issued:

- 1921 Section III – Boilers for Locomotives. (With the 1962 Edition, this Section was integrated into Section I and the Section III designation was later reassigned.)
- 1922 Section V – Miniature Boilers. (With the 1962 Edition, this Section was integrated into Section I and the Section V designation was later reassigned.)
- 1923 Section IV – Low Pressure Heating Boilers.
- 1924 Section II – Material specifications. (Until 1924, materials were included as part of Section I.)
- 1925 Section VIII – Unfired Pressure Vessels. (With the 1968 Edition, this title was changed to Rules for Construction of Pressure Vessels, Division 1 and Division 2 was first issued.)
- 1926 Section VI – Rules for Inspection (of Power Boilers). (With the 1970 Addenda, this section was reassigned with a new title.)
- 1926 Section VII – Suggested Rules for Care of Power Boilers.
- 1937 Section IX – Welding Qualifications. (This section was originally a supplement to Section VIII, but with the 1941 Edition the section was published separately.)
- 1963 Section III – Nuclear Vessels. (Now Rules for Construction of Nuclear Facility Components.)
- 1968 Section VIII, Division 2 – Alternative Rules for Pressure Vessels.
- 1968 Section X – Fiber-Reinforced Plastic Pressure Vessels.
- 1970 Section XI – Rules for Inservice Inspection of Nuclear Power Plant Components.
- 1970 Section VI – Recommended Rules for Care and Operation of Heating Boilers.
- 1971 Section V – Nondestructive Examination.
- 1975 Section III, Division 2 – Code for Concrete Reactor Vessels and Containments. (Now Concrete Containments.)
- 1997 Section III, Division 3 – Containment Systems for Storage and Transport Packagings of Spent Nuclear Fuel and High Level Radioactive Material and Waste. (Now Containments for Transportation and Storage.)
- 1997 Section VIII, Division 3 – Alternative Rules for Construction of High Pressure Vessels.
- 2004 Section XII – Rules for Construction and Continued Service of Transport Tanks.
- 2004 Section II – Metric values of material properties were added as Part D.

As of 2004, the current sections of the BPVC are summarized in Table 1.

Organization of the ASME Boiler and Pressure Vessel Committee

The first ASME Boiler and Pressure Vessel Committee in 1911 had seven members. By the early 1990s, the ASME Boiler and Pressure Vessel Committee had grown to about 800 people involved at all levels from working groups to the Boiler and Pressure Vessel Main

Table 1
ASME Boiler and Pressure Vessel Code Sections, 2004

I	Power Boilers
II	Materials
III-1	Division 1, Rules for Construction of Nuclear Facility Components
III-2	Division 2, Code for Concrete Containments
III-3	Containments for Transportation and Storage (of nuclear spent fuel or high level radioactive waste)
IV	Heating Boilers
V	Nondestructive Examination
VI	Recommended Rules for the Care and Operation of Heating Boilers
VII	Recommended Guidelines for the Care of Power Boilers
VIII-1	Pressure Vessels, Division 1
VIII-2	Pressure Vessels, Division 2 – Alternative Rules
VIII-3	Alternative Rules for Construction of High Pressure Vessels
IX	Welding and Brazing Qualifications
X	Fiber-Reinforced Plastic Pressure Vessels
XI	Rules for Inservice Inspection of Nuclear Power Plant Components
XII	Rules for Construction and Continued Service of Transport Tanks

Committee. The BPVC tries to maintain balance on the committees with representatives from manufacturers, users, insurance carriers, jurisdictions and other areas. However, the representatives from these groups may maintain their position within the Boiler and Pressure Vessel Committee even if they change their affiliation.

The administrative structure of the ASME Boiler and Pressure Vessel Committee consists of the Main Committee, the Executive Committee, the Conference Committee and the Headquarters Staff. Subcommittees report to the Main Committee.

In general, there are three different types of subcommittees reporting to the main committee. First, there are the component or *book* committees which are responsible for all the rules of design and construction for a particular type of component and for that Section of the BPVC in which the rules are given. Presently, the book subcommittees are:

- Section I – Subcommittee on Power Boilers (SC I)
- Section III – Subcommittee on Nuclear Power (SC III)
- Section IV – Subcommittee on Heating Boilers (SC IV)
- Section VIII – Subcommittee on Pressure Vessels (SC VIII)
- Section X – Subcommittee on Reinforced Plastic Pressure Vessels (SC X)
- Section XII – Subcommittee on Transport Tanks (SC XII)

Second, there are the service book subcommittees. These subcommittees are responsible for developing a specific set of rules which may be used by the component committees. Currently, these are:

- Section II – Subcommittee on Materials (SC II)
- Section V – Subcommittee on Nondestructive Examination (SC V)
- Section IX – Subcommittee on Welding (SC IX)

Section XI – Subcommittee on Nuclear Inservice Inspection (SC XI)

Finally, there are the service subcommittees which are responsible for a specific area of technology or administration of the BPVC that may be applied to the book sections. These currently are:

- Subcommittee on Design (SC D)
- Subcommittee on Safety Valve Requirements (SC SVR)
- Subcommittee on Boiler and Pressure Vessel Accreditation (SC BPVA)
- Subcommittee on Nuclear Accreditation (SC NA)

Code Editions, Code Addenda and Code Cases

A new edition of the BPVC is issued every three years (...1998, 2001, 2004...). The code requirements become mandatory on the date of issue. No items are included in the new edition of the BPVC which have not been covered by the previous edition or its three Addenda.

Additions, revisions and deletions to the BPVC are contained in the Code Addenda, issued every year on December 31. The Code Addenda becomes mandatory six months after the date of issue although its contents are optional and may be used up to that date. This permits a thorough review by the public without having to comply with mandatory rules. It also gives a transition period for changing any affected company standards.

Except for Section III, the date of the appropriate edition and addenda of the BPVC for a particular contract is the date the contract is negotiated or signed. Most sections indicate that it is the date of the contract, although the actual signing of the contract may come very much later. Section III permits, for some applications, the use of an edition and addenda which are not the latest versions. In general, this is used for construction of a component which is used for repair or replacement. The other sections of the BPVC do not control the repair or replacement of components after the product has been installed; consequently, the decision of the date of the edition and addenda is the responsibility of the owner, the local jurisdiction and/or the insurance carrier.

Code Cases are contained in two special volumes independent from the BPVC Sections. Code Cases are issued four times a year after each Main Committee meeting and are subject to the same approval procedures as other changes and additions. Code Cases permit the use of a material or construction for which there are no current BPVC rules. The scope of Code Cases is purposely kept very specific to limit their usage. Each is reviewed for incorporation into the text of the appropriate BPVC Section. Code Cases are numbered sequentially, and nuclear Code Cases carry an N prefix. Code Case use is optional, not mandatory. When one is chosen, all parts are mandatory and the Code Case number shall be listed on the Manufacturer's Data Report form.

Technical Inquiries

When any user of the BPVC is unable to interpret a specific rule, a Technical Inquiry may be sent to the

Boiler and Pressure Vessel Committee for an interpretation. Each Section of the BPVC includes an appendix that describes the preparation of Technical Inquiries. It is important that the inquiry meet all of the requirements so that action can be taken without delay. Inquiries are approved by two methods. The first is consideration by a special group of five people who must vote unanimously on the answer. If that method fails, the inquiry must be considered and approved by the entire subcommittee. Once the inquiry and reply are approved, a reply is sent to the inquirer. The question and reply are also published in the *Interpretations*, issued twice each year to BPVC subscribers.

There are several reasons that an inquiry will not be handled by the committee:

1. indefinite question – no reference to BPVC paragraph or rule,
2. semi-commercial question – doubt as to whether question is related to BPVC requirements or is asking for design approval,
3. approval of specific design – inquirer wants approval of specific design or construction as meeting BPVC requirements, and
4. basis or background of BPVC rules – inquirer wants rationale or basis of BPVC requirements. These are not given. Suggested revisions and additions are accepted for consideration.

General design philosophy and safety factors

The basic design philosophy of the BPVC from its beginning was one in which the primary membrane stress, or maximum direct stress, does not exceed the allowable design stress. (See Chapter 8 for an in-depth discussion of stress analysis and stress categorization, e.g., primary membrane stress.) The calculated stress is based on the maximum stress theory. This design philosophy is still used in Section I; Section VIII, Division 1; and Section IV. In most instances, these sections do not call for a detailed analysis to determine the local and secondary stresses. Instead, they rely on a design-by-formula approach.

The BPVC makes a significant distinction between allowable stress limits and the physical properties of the material such as ultimate tensile strength. The published allowable stresses incorporate a safety factor which reduces measured properties to account for: 1) the degree of complexity of the stress evaluation method, 2) certain levels and types of stress concentration, 3) certain nonuniformity in the materials, and 4) geometric factors. The safety factors are based upon experience, experimental evidence and theoretical evaluations. In general, where the BPVC allows a more detailed exact stress evaluation, a smaller safety factor is permitted in determining the allowable stress. The BPVC therefore specifies the evaluation procedures and the applicable allowable stresses (including safety factors) to provide a uniform, safe design procedure.

In the original BPVC in 1914, the allowable stress limits were based on a safety factor of five applied to the minimum specified ultimate tensile strength of the material. However, in December 1931, a joint American Petroleum Institute (API)-ASME Committee on Unfired Pressure Vessels was formed to develop a spe-

cial code for Petroleum Liquids and Gases. The first edition was issued in September 1934. The API-ASME Code permitted a safety factor of four with only minor changes in the design equations used for establishing the minimum wall thickness of cylinders and heads, for reinforced openings, and for other parts. At that time, the ASME BPVC maintained a safety factor of five with some special provisions which permitted a safety factor of four. One of the reasons for the special provisions was to conserve metal during World War II.

The safety factor of five, except for the special provisions in Section VIII, was used by all sections of the BPVC through the 1949 Edition. Based upon the satisfactory experience in using a safety factor of four with the API-ASME Code and the special paragraphs of Section VIII, the 1950 editions of Section I and Section VIII were issued with a safety factor of four. The safety factor of Section IV remains at five.

During the 1950s, Admiral Hyman Rickover led the development of the first nuclear submarine, the *Nautilus*. Westinghouse's Bettis Atomic Power Laboratory was the prime contractor, and B&W designed and built the reactor vessel, pressurizer and steam generators. Bettis, General Electric's Knolls Atomic Power Laboratory and the U.S. Atomic Energy Commission developed and published rules for the stress analysis and design basis. This was entitled *Tentative Structural Design Basis for Reactor Vessels*. These rules permitted increased allowable stresses because a thorough and accurate stress analysis was required.

During the late 1950s, the ASME Code Committee and the U.S. government began to see the need for an ASME code which would contain design rules similar to the tentative basis. The first consideration was to do a major upgrading of Section VIII either by a supplemental document or major revision of Section VIII. After much discussion in various committees, it was decided to develop a new code section.

In 1958, the ASME established a Special Committee to Review Code Stress Basis. This special group met many times to develop and review all facets of nuclear vessel requirements – not only design rules, but also fabrication, inspection, materials and other kinds of rules. Fatigue analysis methods were introduced for explicit use for the first time.

In 1963, a public hearing was held in Baltimore, Maryland. As a result of the meeting, Section III, *Nuclear Vessels*, was issued which permitted a safety factor of three (on minimum specified ultimate tensile strength). However, in order to use this factor, many requirements had to be met. A very thorough stress analysis procedure, called design by analysis based on the maximum shear stress theory, had to be applied. Also, more rigid fabrication, examination and testing procedures were required to allow a reduction in the safety factor.

While the development of the Nuclear Code was being concluded in late 1961, a task group was formed to develop an extension of Section VIII. The original title was *Task Group on Code for Industrial Pressure Vessels of Superior Quality*. Later, this name was changed to *Alternative Rules for Pressure Vessels* and ultimately it became Section VIII, Division 2.

In 1968, the new division was issued as an alternative method for constructing pressure vessels, Section VIII, Division 2. It required a much more extensive structural investigation in order to reduce the safety factor to three.

In 1998, the safety factor for Section I, Section III Class 2 and 3, and Section VIII, Division 1 was reduced from 4.0 to 3.5 on minimum specified ultimate tensile strength, based mainly on acceptable experience, and improvements in materials achieved over the years.

Allowable stress values

The BPVC provides the basis for establishing allowable stress values for Section I, Section VIII, Division 1, and Section III, Division 1, Classes 2 and 3. (See Chapter 8.) For wrought or cast ferrous and nonferrous materials, the allowable stress values are based on the following criteria:

1. at temperatures below the creep range, the lowest of the following:
 - 1/3.5 of the specified minimum tensile strength at room temperature,
 - (1.1)/3.5 of the tensile strength at temperature,
 - 2/3 of the specified minimum yield strength at room temperature, and
 - 2/3 of the yield strength at temperature.

In addition, for austenitic stainless steels and certain nonferrous nickel alloys, excluding bolting, flanges and other strain sensitive usage where slightly greater deformation is objectionable, the factor on yield strength at temperature may be increased from 2/3 to 0.90.
2. at temperatures in the creep range, the lowest of the following applies:
 - 100% of the average stress to produce a creep rate of 0.01% in 1000 hours,
 - 80% of the minimum stress to cause rupture at the end of 100,000 hours, and
 - 67% of the average stress to cause rupture at the end of 100,000 hours.

Method for development of allowable stress values

Allowable stress values are developed by the Subcommittee on Materials (SC II) by applying the various safety factors to data which the committee has obtained from tests conducted for the committee or various other industrial sources. The published allowable stress values at any given temperature are then the lowest stresses evaluated using the criteria discussed above. (See also Chapter 8.)

The BPVC also provides the basis for establishing allowable stress values, called *design stress intensity values*, for Section VIII, Division 2, and Section III, Division 1, Class 1. No design stress intensity values have been established in the creep range for Section VIII, Division 2. For Section III, Division 1, Class 1 applications in the elevated temperature range, rules

for some materials are given in Section III, Division 1, NH. For the various materials permitted, except for bolting materials, the design stress intensity values, i.e., allowable stress values, are based on the lowest value of the following criteria:

1/3 of the specified minimum tensile strength at room temperature,

(1.1)/3 of the tensile strength at temperature,

2/3 of the specified minimum yield strength at room temperature, and

2/3 of the yield strength at temperature except for most austenitic stainless steels and certain nonferrous materials where the factor may reach as high as 90% of the yield strength at temperature. This may result in a permanent strain of as much as 0.1%. When this amount of deformation is not acceptable, the designer must reduce the allowable stress to obtain an acceptable amount of deformation.

There are tables in Section VIII, Division 2 which list factors for limiting permanent strain in high alloy steels and in nickel and high-nickel alloys. In effect, the criteria permit the designer to choose a factor between 67 and 90% of the yield strength depending on the tolerable deformation. For example, suppose that by some limiting clearances the tolerable strain is limited to 0.05% in a shell. The designer can then refer to the table of limiting permanent strain for 18-8 stainless steel and see that the factor on yield strength should be limited to 0.80. The designer then goes to the yield strength values to establish his own allowable stress values.

Bolting materials have their design stress intensity values, i.e., allowable stresses, established by similar, but more restrictive, criteria. (See Section II, Part D, Table 3 and also Appendix 2 of the Standard.)

Strength theories

The three commonly used theories to predict failure are the maximum principal stress theory, the maximum shear stress theory, and the distortion energy theory as discussed in Chapter 8.

Test results show that for ductile materials, such as those ferrous and nonferrous materials permitted by the BPVC, either the maximum shear stress theory or the distortion energy theory predicts yield and fatigue failure better than the maximum stress theory. However, the maximum stress theory is easy to apply in boiler components and pressure vessels where the circumferential and the longitudinal stresses are calculated using simple formulas with an adequate safety factor to set the allowable stress values. Where a more exact analysis is desired and the safety factor may be less, the BPVC uses the maximum shear stress theory. Section I, Section IV, Section VIII, Division 1, and Section III, Division 1, Subsections NC, ND and NE use the maximum stress theory while Section III, Division 1, Subsection NB and Section VIII, Division 2, use the maximum shear stress theory. The former use a safety factor of 3.5 or 5 on tensile strength; the latter use a safety factor of three.

Design criteria

The design criteria for different sections of the BPVC are related to the theory of failure and safety factors which are applied to the allowable stress values. For both Section I, *Power Boilers*, and Section IV, *Heating Boilers*, the requirements call for the calculation of the required minimum wall thickness which will keep the basic circumferential stress at or below the allowable stress limit for that section. Additional rules, equations and charts are given to determine the minimum required thicknesses of components other than those with circular cross-sections. A more detailed stress analysis may be required for special designs and configurations for which there are no rules. Both Section I and Section IV recognize that high local stresses (discussed below) and secondary stresses may exist within a component, but those sections have established design rules that keep stresses at a safe level with a minimum of additional analysis.

Section VIII, Division 1, *Pressure Vessels*, and Section III, Division 1, Class 2 and 3, *Nuclear Facility Components*, have similar design criteria to Sections I and IV except Sections VIII, Division 1, and III, Division 1, Class 2 and 3 require the minimum thickness of cylindrical shells to be calculated in both the circumferential and the longitudinal directions. The actual minimum required thickness of the cylinder may be set by stress in either direction. In addition, Sections VIII, Division 1, and III, Division 1, Class 2 and 3 have rules which permit the combination of primary membrane stress and primary bending stress to be as high as 1.5 S where S is the basic allowable stress value. At elevated temperatures, consideration must be given to inelastic strain due to creep.

The design criteria for Section VIII, Division 2 provide rules for the more common shell and head geometries for design temperatures that are below the creep range. A detailed stress analysis is required for most complex geometries and loadings including internal pressure loading. For Section III, Division 1, Classes 2 and 3, the requirements are similar to those of Section VIII, Division 2. However, rules are provided requiring detailed analysis and there are fewer formulas.

Both Sections VIII, Division 2, and III, Division 1, Class 1 have adopted the maximum shear stress criteria. This method requires calculated stresses to be assigned to various categories and subcategories that permit different allowable stresses for various combinations of calculated stresses. The various categories and subcategories of stresses are:

1. primary stresses
 - a. general primary membrane stress
 - b. local primary membrane stress
 - c. primary bending stress
2. secondary stresses
3. peak stresses

Primary stresses are caused by loadings which are necessary to satisfy the laws of equilibrium with applied pressure and other loads, and they are not self-limiting by deformation and redistribution. Secondary stresses are developed by self-constraint in the

structure. A basic characteristic of secondary stresses is that they are self-limiting. That is, rotation, deflection or deformation takes place until the forces and moments are in balance even though some geometric change may have occurred. Peak stresses are highly localized stresses in a structure usually caused by an abrupt change in the geometry such as a notch or a nozzle fillet weld. Peak stresses are considered only during fatigue analysis of cyclic loadings.

Failure modes, stress limits and stress categories are related. One of the most important aspects of a stress analysis is to make sure that various stresses are assigned to the proper stress categories. Limits on primary stress are set to prevent plastic deformation and burst. Secondary stress limits are set to prevent excessive plastic deformation which may lead to incremental collapse and to ensure the validity of the use of an elastic analysis for making a fatigue analysis. Peak stress limits are set to prevent fatigue failure due to excessive cyclic loadings. For analysis according to Section VIII, Division 2, and Section III, Division 1, Class 1, thermal stresses are considered only in the secondary and peak categories.

The ASME Code for Pressure Piping, B31

The ASME Code for Pressure Piping is divided into many sections relative to different applications. Currently, these sections are:

- B31.1 Power Piping
- B31.3 Process Piping
- B31.4 Pipeline Transportation Systems for Liquid Hydrocarbons and Other Liquids
- B31.5 Refrigeration Piping and Heat Transfer Components
- B31.8 Gas Transmission and Distribution Piping Systems
- B31.9 Building Services Piping
- B31.11 Slurry Transportation Piping Systems

The scope of jurisdiction of the ASME BPVC Section I applies to the boiler proper and to the boiler external piping. The boiler external piping is that piping connecting the boiler proper with the nonboiler ex-

ternal piping as defined in PG-58 of Section I. For boiler external piping, the materials, design, fabrication, installation and testing shall be done according to ASME B31.1, *Power Piping*. In addition, most of the connecting piping outside of the Section I jurisdiction is done according to ASME B31.1.

Editions, Addenda, Cases and Interpretations

With the responsibility of the B31 Pressure Piping Code Committee resting with ASME, procedures of releasing editions, addenda, cases and interpretations are the same for the Piping Code as for the BPVC.

Design philosophy, safety factors and strength theory

The design philosophy of the Piping Code is one where the primary membrane stress is not permitted to exceed the allowable stress. In the Piping Code, the longitudinal pressure stress is a major consideration because it combines with longitudinal bending stress developed from the supporting of dead loads and from flexibility stress due to the thermal expansion of the piping system. Although circumferential pressure stress is calculated and sets the minimum required thickness for internal pressure, the longitudinal stress often influences piping arrangement.

Two sections of the ASME B31 Code for Pressure Piping are primarily used in combination with the ASME BPVC sections. The two are: ASME B31.1 Power Piping, and ASME B31.3 Process Piping. B31.1 is closely associated with Section I while B31.3 is associated with Section VIII. However, there are no ASME requirements assigning one or the other. This is essentially done by the jurisdictions and the laws they enforce.

Both sections of the Piping Code use the maximum stress theory for combining and evaluating stresses. The allowable stress values for Section I and B31.1 are the same as are the safety factors. However, B31.3 is unique because it uses the maximum stress theory but permits higher allowable stresses which are based on a safety factor of three on ultimate tensile strength similar to Section VIII, Division 2 and Section III, Division 1, Class 1.

Greene, A.M., *History of the ASME Boiler Code*, American Society of Mechanical Engineers, New York, New York, 1955.

Symbols, Acronyms and Abbreviations

Symbols

Symbols used in *Steam* are defined within the chapters. The following is a summary of those that are commonly used. Specialized symbols are not repeated here. Symbols for chemical elements appear in Appendix 1, Table 3.3. The frequently used units are listed for each parameter, for illustration purposes. Other units used are defined in the chapter text.

a	crack size, ft or in. (m or mm)
a	inside radius, ft or in. (m or mm)
a	major axis of an ellipsoid, ft or in. (m or mm)
a, b, c	general coefficients
A	area, cross-sectional area or surface area, ft ² (m ²)
A	mass number (total number of protons plus neutrons)
A_n	cross-sectional area of nozzles, ft ² (m ²)
b	minor axis of an ellipsoid, ft or in. (m or mm)
b	outside radius, ft or in. (m or mm)
B	barometric pressure, in. Hg
B	ratio of throat diameter to pipe diameter, dimensionless
B_w	moisture fraction, lb/lb (kg/kg)
c	distance, ft (m)
c	speed of light
c_p	specific heat at constant pressure, Btu/lb F (J/kg K)
c_{pa}	specific heat of air, Btu/lb F (J/kg K)
c_{pg}	specific heat of gas, Btu/lb F (J/kg K)
c_v	specific heat at constant volume, Btu/lb F (J/kg K)
C	crack geometry factor, dimensionless
C or c	coefficient
C_a	concentration of specie at duct conditions, lb/lb (kg/kg)

C_{eff}	collection/removal efficiency, dimensionless or percent
C_f	cleanliness factor, dimensionless
C_i	concentration of specie in the impinger, lb/lb (kg/kg)
C_{in}	concentration at inlet, lb/lb (kg/kg)
C_m	mass flow of specie, lb/h (kg/s)
C_{out}	concentration at outlet, lb/lb (kg/kg)
C_p	pitot tube correction factor, dimensionless
$C_{ppm,d}$	concentration of specie on a dry basis, ppm
$C_{ppm,w}$	concentration of specie on a wet basis, ppm
C_q	coefficient of discharge, dimensionless
C_s	concentration of specie at standard conditions, lb/lb (kg/kg)
C_t	energy release rate (power) parameter, in. lb/in. ² h (J/m ² s)
C_t	thermal capacitance, Btu/ft ³ F (J/m ³ K)
C_V	valve flow coefficient
d	diameter, ft or in. (m or mm)
d_a	percent reduction in area
D	diameter, ft or in. (m or mm)
D or d	displacement, ft (m)
D_e or D_H	equivalent or hydraulic diameter = $4A/Per$, ft or in. (m or mm)
D_i	internal stack diameter, ft
D_{sm}	diameter, Sauter mean
DL	dead load, psi (Pa)
e	available energy, Btu/lb (J/kg)
E	emission rate, dry, at 0% O ₂ , lb/h (kg/s)
E	energy, Btu (J)
E	weld joint efficiency or ligament efficiency, dimensionless
E	Young's modulus of elasticity, psi (Pa)
ΔE	change in energy
E_b	blackbody emissive power, Btu/h ft ² (W/m ²)

EQ	seismic loading, psi (Pa)	J_I	J-integral, in. lb/in. ² (J/m ²)
Eu	Euler number = $\Delta P / \rho V^2$, dimensionless	J_{IC}	J-integral, critical, in. lb/in. ² (J/m ²)
f	friction factor, dimensionless	J_R	material crack growth resistance, in. lb/in. ² (J/m ²)
f_x	body force		
F	geometry correction factor, dimensionless	k	coefficient or parameter
F	heat exchanger arrangement factor, dimensionless	k	specific heat ratio compressibility factor, dimensionless
F	peak stresses	k	thermal conductivity, Btu/h ft F (W/m K)
F	radiation configuration factor, dimensionless	k_c	insulation thermal conductivity, Btu/h ft F (W/m K)
\mathcal{F}	total radiation exchange factor, dimensionless	k_T	isothermal compressibility
F_a	crossflow arrangement factor, dimensionless	K	discharge coefficient, dimensionless
F_A	allowable axial compressive stress, psi (Pa)	K	factor or coefficient
F_d	F-factor, dry, at 0% O ₂ , dimensionless	K	thermal conductance, Btu/h F (W/K)
F_d	tube bundle depth factor, dimensionless	K_{eg}	equilibrium constant, dimensionless
F_e	effectiveness factor, dimensionless	K_I	stress intensity factor, ksi in. ^{1/2} (MPa m ^{1/2})
F_{pp}	fluid property factor	K_{IC}	critical stress intensity factor or fracture toughness, ksi in. ^{1/2} (MPa m ^{1/2})
F_T	fluid temperature factor, dimensionless	K_r	stress intensity factor/toughness ratio, dimensionless
FS	factor of safety, dimensionless	K_y	mass transfer coefficient, lb/ft ² s (kg/m ² s)
FV	future value	ΔK	stress intensity range
g	acceleration of gravity, 32.17 ft/s ² (9.8 m/s ²)	l_{\parallel}	tube centerline spacing parallel to flow, ft (m)
g	Gibbs free energy, Btu/lb (J/kg)	l_{\perp}	tube centerline spacing transverse to flow, ft (m)
g_c	proportionality factor, 32.17 lbf ft/lbf s ² (1 kg m/N s ²)	l_e	equivalent plate thickness, ft or in. (m or mm)
G	incident thermal radiation, Btu/h ft ² (W/m ²)	L or l	length or dimension, ft or in. (m or mm)
G	mass flux or mass velocity, lb/h ft ² (kg/m ² s)	L_h	fin height, ft or in. (m or mm)
G_{max}	critical flow mass flux, lb/h ft ² (kg/m ² s)	$LMTD$	log mean temperature difference, F (C)
Gr	Grashof number = $\frac{g\beta(T_s - T_{\infty})\rho^2 L^3}{\mu^2}$, dimensionless	LS	limestone consumption, lb/h (kg/s)
		L_t	fin spacing, ft or in. (m or mm)
h	heat transfer coefficient, Btu/h ft ² F (W/m ² K)	m	mass, lb (kg)
h	thickness, ft or in. (m or mm)	\dot{m}	mass flow rate, lb/h (kg/s)
h_{ct}	contact coefficient, Btu/h ft ² F (W/m ² K)	m_s	mass of steam, lb (kg)
h_c	crossflow heat transfer coefficient, Btu/h ft ² F (W/m ² K)	m_w	mass of water, lb (kg)
h'_c	crossflow velocity and geometry factor	M	moisture in steam sample, percent
h_l	longitudinal heat transfer coefficient, Btu/h ft ² F (W/m ² K)	M	molecular weight, lb/lb-mole (kg/kg-mole)
h'_l	longitudinal flow velocity and geometry factor	M_d	molecular weight of gas, dry basis
H	enthalpy, Btu/lb (J/kg)	M_o	redundant bending moment, lb ft (N m)
H_f	enthalpy of saturated water, Btu/lb (J/kg)	M_w	molecular weight of gas, wet basis
H_{fg}	enthalpy of vaporization, Btu/lb (J/kg)		
H_{fw}	enthalpy of feedwater, Btu/lb (J/kg)	n	parameter, coefficient or number of cycles
H_g	enthalpy of saturated steam, Btu/lb (J/kg)	N	coefficient, number of cycles or number of concentric thermocouple shields
		Nu	Nusselt number = $h L / k$, dimensionless
		N_v or N	number of velocity heads, dimensionless
		p	particle size, in. (mm)
I	electrical current, amperes	p_r	partial pressure, atm
I	intensity	P	parameter
I	moment of inertia, in. ⁴ (m ⁴)	P	pressure or partial pressure, psi (Pa)
		P	primary stress
J	mechanical equivalent of heat, 778.17 ft lbf/Btu (1 N m/J)	P	temperature ratio for surface arrangement factor, dimensionless
J	radiosity, Btu/h ft ² (W/m ²)	P_b	primary bending stress

Pe	Peclet number = $RePr$, dimensionless	s_f	entropy of water, Btu/lb F (J/kg K)
Per	perimeter, ft or in. (m or mm)	s_{fg}	entropy of evaporation, Btu/lb F (J/kg K)
P_L	local primary membrane stress	s_g	entropy of steam, Btu/lb F (J/kg K)
PL	furnace gas pressure loading, psi (Pa)	S	allowable stress
P_m	pressure at meter, psi (Pa)	S	entropy, Btu/F (J/K)
P_m	general primary membrane stress	S	surface area, or total exposed surface area for a finned surface, ft ² (m ²)
Pr	Prandtl number = $\frac{c_p \mu}{k}$, dimensionless	S	general source term
P_s	absolute pressure at duct, psi (Pa)	S	quantity of entropy, Btu/F (J/K)
P_{total}	total pressure, lb/ft ² (N/m ²)	S	steam-water slip ratio, dimensionless
P_v	total vertical design load	SE	stack effect, in. wg/ft
PV	present value	S_f	fin surface area; sides plus peripheral area, ft ² (m ²)
PVFF	present value factor	S_L	longitudinal (parallel) spacing, ft or in. (m or mm)
ΔP	pressure differential, psi (Pa)	S_m	allowable stress intensity, psi (Pa)
ΔP_l	stack flow loss, in. of water	S_r	applied stress/net section plastic collapse stress ratio, dimensionless
ΔP_{SE}	stack effect driving pressure, lb/ft ² (N/m ²)	S_T	transverse (side) spacing, ft (m)
q	heat flow rate, Btu/h (W)	St	Stanton number = $Nu/(RePr)$, dimensionless
q''	heat flux, Btu/h ft ² (W/m ²)	S_u	material tensile strength, psi (Pa)
q'' _{CHF}	heat flux at CHF conditions, Btu/h ft ² (W/m ²)	Sy	material yield strength, psi (Pa)
q'''	volumetric heat generation rate, Btu/h ft ³ (W/m ³)	SPVF	series present value factor
q _{rel}	heat release rate, Btu/h ft ³ (W/m ³)	t	thickness, ft or in. (m or mm)
q _{rev}	reversible heat input per unit mass, Btu/ lb (J/kg)	t	time, h or s
Q or q	heat input, Btu (J), or heat input per unit mass, Btu/lb (J/kg)	t_c	current wall thickness, in. (mm)
Q	gas flow rate, lb/h (kg/s)	t_e	time at end of life
Q	heat absorption or heat added to system, Btu (J)	t_p	present time
Q	secondary stresses	T	temperature, F or R (C or K)
Q _{ac}	actual volumetric flow rate, ft ³ /h (m ³ /s)	T_{cv}	temperature at critical viscosity, F (C)
Q _{sd}	dry volumetric flow rate at standard conditions, ft ³ /h (m ³ /s)	T_{sat}	saturation temperature, F (C)
r	radius or inside radius, ft or in. (m or mm)	T_w	wall temperature, F (C)
R	constant or coefficient	T_{250}	temperature at 250 poise viscosity, F
R	forcing function	T^o	temperature at initial time, F (C)
R	radius or outside radius, ft or in. (m or mm)	T_o	sink temperature, F or R (C or K)
R	specific gas constant – R/M, lbf ft/lbm R (J/kg K)	TD	terminal temperature difference, F (C)
R	temperature ratio for surface arrangement factor, dimensionless	TS	tensile strength at temperature, psi (Pa)
R	thermal resistance, h ft ² F/Btu (m ² K/W)	Δt	time interval, h or s
R	universal gas constant, 1545 ft lb/lb-mole R (8.3143 kJ/kg-mole K)	ΔT	temperature difference, F (C)
Ra	Rayleigh number = $GrPr$, dimensionless	ΔT_{LMTD}	log mean temperature difference, F (C)
Re	Reynolds number = $\frac{\rho V L}{\mu} = \frac{G L}{\mu}$, dimensionless	ΔT_{sat}	$T_{sat} - T_w$, F (C)
R_f	fouling index – bituminous ash	u	internal stored energy, Btu/lb (J/kg)
R_s	slagging index – bituminous ash	u, v, w	velocity in x, y, z coordinates respectively, ft/s (m/s)
R_s^*	slagging index – lignitic ash	U	overall heat transfer coefficient, Btu/h ft ² F (W/m ² K)
R_{vs}	slagging index – viscosity	v	specific volume, ft ³ /lb (m ³ /kg)
s	specific entropy, Btu/lb F (J/kg K)	v_a	specific volume, air
		v_f	specific volume, water
		v_{fg}	specific volume, evaporation
		v_g	specific volume, steam
		V	electrical voltage, volts
		V	velocity, ft/s (m/s)
		V	volume, ft ³ (m ³)

V_d	dry gas volume, ft ³ (m ³)	π	3.1415926
V_m	dry gas volume at meter conditions, ft ³ (m ³)	ρ	density, lb/ft ³ (kg/m ³)
V_n	sample gas velocity through the nozzle, ft/s (m/s)	ρ	reflectivity, dimensionless
V_o	redundant shear force, psi (Pa)	$\bar{\rho}_d$	average downcomer density, lb/ft ³ (kg/m ³)
V_s	velocity of the flue gas, ft/s (m/s)	ρ_{hom}	homogenous density, lb/ft ³ (kg/m ³)
		$\rho(z)$	local density, lb/ft ³ (kg/m ³)
		σ	atomic cross-section, barns
w	work per unit mass, ft-lb/lbm (J/kg)	σ	standard deviation
w_{rev}	reversible work per unit mass, ft-lb/lbm (J/kg)	σ	Stefan-Boltzmann constant, 0.1713×10^{-8} Btu/h ft ² R ⁴ (5.669×10^{-8} W/m ² K ⁴)
W	width, ft or in. (m or mm)	σ	stress, psi (Pa)
W	work, ft-lb (J)	σ_a	allowable alternating stress, psi (Pa)
W_1	leakage flow rate, lb/h (kg/s)	$\sigma_r, \sigma_t, \sigma_z$	radial, tangential and axial stress, psi (Pa)
WL	wind loading, psi (Pa)	σ_t	thermal stress, psi (Pa)
		$\sigma_{y.p.}$	yield point stress, psi (Pa)
x	dimension, ft or in. (m or mm)	σ_1	longitudinal stress, psi (Pa)
x	steam quality, mass fraction steam	σ_2	hoop stress, psi (Pa)
x_{CHF}	steam quality at CHF conditions, mass fraction steam	τ	shear stress, psi (Pa)
x, y, z	dimensions in Cartesian coordinate system, ft or in. (m or mm)	τ	transmissivity, dimensionless
Δx	change in length, ft or in. (m or mm)	ϕ_{LO}^2	two-phase friction multiplier, all fluid as a liquid, dimensionless
X	weight fraction, dimensionless	ϕ	general dependent variable
		Φ	two-phase multiplier for a steam-water separator, dimensionless
Y	compressibility factor, dimensionless		
Y	Schmidt fin geometry factor, dimensionless		
Y_g	concentration in bulk fluid, lb/lb (kg/kg)		
Y_i	concentration at condensate interface, lb/lb (kg/kg)		
Z or z	elevation or length, ft or in. (m or mm)		
Z	atomic number (number of protons in the nucleus)		
Z	Schmidt fin geometry factor, dimensionless		

Greek symbols

α	absorptivity, dimensionless
α	angle, deg (rad)
α	coefficient of thermal expansion, ft/ft (m/m)
α	thermal diffusivity = $k/\rho c_p$, ft ² /s (m ² /s)
α	void fraction, dimensionless
β	deflection or rotation influence coefficients
β	volume coefficient of expansion, 1/R (1/K)
Γ	effective diffusion coefficient
δ	diameter or film thickness, ft or in. (m or mm)
ε	emissivity, dimensionless
ε	roughness, in. (mm)
ε	strain, ft/ft (m/m)
η	efficiency as a fraction or percentage
η	Schmidt fin efficiency, dimensionless
η_{net}	net efficiency, dimensionless
η_{th}	thermal efficiency, dimensionless
θ	angle, deg (rad)
μ	dynamic viscosity, lbm/ft s (kg/m s)
μ	Poisson's ratio, dimensionless
ν	kinetic viscosity, ft ² /s (m ² /s)

Subscripts

1	initial or inlet condition
2	final or outlet condition
a	air
amb	ambient
aux	auxiliary component or system
b	bulk fluid
c	contact or conduction
cg	convection, gas-side
cv	convection
$clean$	unfouled or clean condition
e	node point east
$econ$	economizer
eq or e	equivalent
f	fluid, fin or saturated water
g	gas or saturated steam
i	inside or i th parameter or initial condition
in	entering a system
j	j th parameter
l	liquid
max	maximum
min	minimum
o	outside or final condition
out	leaving a system
p	node point under evaluation
P	products
r	radiation
ref	reference
rg	radiation, gas-side
R	reactants
s	steam
sg	surface-to-gas
SE	stack effect

<i>t</i>	thermal
<i>w</i>	node point west
<i>w</i>	wall
δ	liquid film surface (gas liquid interface)

Acronyms and Abbreviations

AA	atomic absorption
ABMA	American Boiler Manufacturers Association
abs	absolute
ABS	American Bureau of Shipping
A/C	air/cloth
AC	alternating current
ACF	actual cubic feet
ACFM	actual cubic feet per minute
ADS	air density separator
AE	acoustic emissions
AEC	Atomic Energy Commission, U.S.
AECL	Atomic Energy of Canada Limited
AFBC	atmospheric pressure fluidized-bed combustion
AFS	atomic fluorescence spectroscopy
AFW	auxiliary feedwater
AGR	advanced gas-cooled reactor
AH	air heater
AIB	auxiliary input burner
AIG	ammonia injection grid
AISC	American Institute of Steel Construction
ALARA	as low as reasonably achievable
amb	ambient
AMU	atomic mass units
ANSI	American National Standards Institute
API	American Petroleum Institute
approx	approximate
ARIS	Automated Reactor Inspection System
ARTS	Anticipatory Reactor Trip System
ASD	allowable stress design
ASME	American Society of Mechanical Engineers
ASTM	American Society for Testing and Materials
attemp	attenuator
atm	atmosphere
ATOG	abnormal transient operating guidelines
avg	average
AVT	all-volatile treatment
AZS	air zone swirler
B/A	base-to-acid ratio
B&W	The Babcock & Wilcox Company
BAC	boiler as calorimeter
BACT	best available control technology
BAT	best available technology
bbl	barrel
BCC	body-centered cubic
BCCW	boiler chemical cleaning waste
BCM	boiler condenser mode
BCT	body-centered tetragonal
BCTMP	bleached chemical thermomechanical pulp

BFB	bubbling fluidized bed
BFP	boiler feed pump
BFW	boiler feed water
BGC	British Gas Corporation
BH	baghouse
bit or	
bitum	bituminous
BLESS	Boiler Life Evaluation and Simulation System
BLG	black liquor gasification
BLRBAC	Black Liquor Recovery Boiler Advisory Committee
BOF	basic oxygen furnace
BOL	beginning of life
BOOS	burners out of service
BPVC	Boiler and Pressure Vessel Code (ASME)
BRC	below regulatory concern
BSW	bottom sediment and water
Btu	British thermal unit
BWCC	Babcock & Wilcox Construction Co., Inc.
BWR	boiling water reactor
BWST	borated water storage tank
C	Celsius or centigrade degrees
CAA	Clean Air Act, U.S.
CAD	computer-assisted design/drafting
CANDU	Canada Deuterium Uranium
CAP	curved arm primary
CBI	curved backward inclined
CBK	carbon burnout kinetic
cc	cubic centimeter
CC	combined cycle
CCZ	Controlled Combustion Zone
CE	collecting electrode
CEMS	continuous emissions monitoring system
CFB	circulating fluidized bed
CFCC	continuous fiber ceramic composite
CFD	computational fluid dynamics
cfm	cubic feet per minute
CFR	Code of Federal Regulations
CGA	crack growth analysis
CHF	critical heat flux
CHP	combined heat and power
CII	Construction Industry Institute
C.I.S.	Confederation of Independent States
cm	centimeter
CNC	computer numerical control
CNCG	concentrated noncondensable gas
CNSG	consolidated nuclear steam generator
COE	Corps of Engineers, U.S. Army
coef	coefficient
col	column
cond	condenser
COG	coke oven gas
cP	centipoise
CRDM	control rod drive mechanism
CVD	chemical vapor deposition
CWA	Clean Water Act

d	day	FBC	fluidized-bed combustion
DAF	dry ash-free	FBR	fast breeder reactor
dB	decibels	FC	feedwater control subsystem
DC	direct current	FC	fixed carbon
DC	drain cooler	FC/VM	fixed carbon/volatile matter ratio
DCS	distributed control system	FCAW	flux core arc welding
DCS	digital control system	FCC	face-centered cubic
DE	destructive examination	FCC	fluid catalytic cracking
DE	discharge electrode	FD	forced draft
deg	degree	FEA	finite element analysis
DESAH	dual economizer steam air heater	FEGT	furnace exit gas temperature
DGV	sampled dry gas volume	FERC	Federal Energy Regulatory Commission
DHRS	decay heat removal system	FES	finite element system
DNB	departure from nucleate boiling	FGD	flue gas desulfurization
DNBR	DNB ratio	FGR	flue gas recirculation
DNC	distributed numerical control	FHyNES	furnace hydrogen damage nondestructive examination system
DNCG	dilute noncondensable gas	FIV	flow-induced vibration
DOD	Department of Defense, U.S.	FMB	marine package boilers
DOE	Department of Energy, U.S.	FMEC	failure mode evaluation chart
DPFAD	deformation plasticity failure assessment diagram	FOSAR	foreign object search and retrieval
DRB	dual register burner	FPS	Fossil Power Systems
DRE	destruction and removal efficiency	FRP	fiberglass reinforced plastic
DSCF(M)	dry standard cubic feet (per minute)	FS	factor of safety
DSCM	dry standard cubic meter	FSS	flame safety system
EAR	estimated additional resources	FST-GAGE	Fast-Scanning Thickness Gage
EBW	electron beam welding	FSU	former Soviet Union
EC	European Community	ft	foot/feet
ECCS	emergency core cooling system	FT	fluid temperature
ECON	economizer	FURNIS	furnace inspection system
ECP	electrochemical potential	FW	field weld
ECS	environmental control systems	g	gram
ECT	eddy current testing	Ga	gauge
EDC	eddy dissipation concept model	gal	gallon
EDM	eddy dissipation combustion model	GCR	gas-cooled reactor
EDM	electrical discharge machining	gen	generator
EDTA	ethylenediaminetetraacetic acid	GGH	gas-to-gas heaters
eff	efficiency	GJ	giga joule
EI	enhanced ignition (burner)	GMAW	gas metal arc welding
EIA	Energy Information Administration	GPM	gallons per minute
EMAT	electromagnetic acoustic transducer	gr	grains
emf	electromotive force	GR	gas recirculation
EMF	electromagnetic filter	GT	gas turbine
EOR	enhanced oil recovery	GTAW	gas tungsten arc welding
EPA	Environmental Protection Agency, U.S.	GTCC	gas turbine combined cycle
EPFM	elastic-plastic fracture mechanics	h	hour
EPRI	Electric Power Research Institute	HAP	hazardous air pollutant
ERW	electric resistance welded	HAZ	heat-affected zone
ESP	electrostatic precipitator	HCGE	high capacity gas element
ESS	enhanced service structure	HFRW	high frequency resistance welding
ESW	electroslag welding	HFT	hot function testing
EU	European Union	HGI	Hardgrove Grindability Index
evap	evaporation	HHV	higher heating value
F	Fahrenheit degrees	HLW	high level waste
FAC	flow accelerated corrosion	hp	horsepower
FB	firebrick	HP	high pressure (turbine)

HPI	high pressure injection	l	liter
HRSG	heat recovery steam generator	LAER	lowest achievable emission rate
HT	hemispherical temperature	LAF	laboratory ashing furnace
HTM	Heat Transfer Manager	lb	pound
HTW	high temperature Winkler	LBBA	leak before break analysis
HV	high volatile	lbf	pound force
HVOF	high-velocity oxy-fuel	LBLOCA	large break loss of coolant accident
HVT	high velocity thermocouple	lbm	pound mass
HZP	hot zero power	lb-mole	pound-mole
IAPS	International Association for the Properties of Steam	LBW	laser beam welding
IAWPS	International Association of Wood Products Societies	LEA	low excess air
IC	Instrument and Controls	LEFM	linear elastic fracture mechanics
IC	ion chromatography	LEL	lower explosion limit
ICPAES	inductive coupled plasma atomic emission spectrometric (analysis)	LFA	life fraction analysis
ICR	Information Collection Request	LFE	life fraction expended
ICS	integrated control system	L/G	liquid to gas ratio (FGD)
ID	induced draft	LHV	lower heating value
ID	inside diameter	LLW	low level waste
ID	initial deformation (temperature)	LMP	Larson-Miller parameter
IEOTSG	integral economizer once-through steam generator (nuclear)	LMTD	log mean temperature difference
IFGR	induced flue gas recirculation	LNB	low NO _x burner
IGA	intergranular attack	LNCB	low NO _x cell burner
IGCC	integrated gasification combined cycle	LNG	liquefied natural gas
IGSCC	intergranular stress corrosion cracking	LOCA	loss of coolant accident
IMC	integrated master control subsystem	LP	low pressure (turbine)
in.	inch	LPG	liquefied petroleum gas
in. Hg	inches of mercury	LPI	low pressure injection
in. wg	inches water gauge	LPMS	loose parts monitoring system
INPO	Institute of Nuclear Power Operations	LSD	Lagrangian stochastic deterministic (model)
IP	intermediate pressure (turbine)	LVS	limited vertical sweep
IPP	independent power producer	LWR	light water reactor
IR	infrared radiation	m	meter
IR-CFB	internal recirculation circulating fluidized-bed	MA	mill-annealed
ISO	International Standards Organization	MACT	maximum achievable control technology
ISP	intermediate size particles	MAF	moisture and ash free
IT	initial deformation temperature	MARAD	Maritime Administration, U.S.
J	joule	MAWP	maximum allowable working pressure
K	Kelvin degrees	max	maximum
kcal	kilocalories	MCR	maximum continuous rating
kg	kilogram	MD	mass defect
kHz	kilohertz	MDC	multi-cyclone dust collector
kJ	kilojoule	med	medium
km	kilometer	MeV	million electron volts
kmole or kg-mole	kilogram-mole	MFR	mass flow rate
kPa	kilopascal	MFT	master fuel trip
ksi	1000 pounds per square inch	mg	milligram
kV	kilovolt	MHVT	multiple shield high velocity thermocouple
kW	kilowatt	mi	mile
kWh	kilowatt hour	MIC	microbial induced corrosion
		MIG	metal inert gas
		min	minimum or minute
		MIST	multiple loop integral systems test
		MJ	megajoule
		ml	milliliter
		MLR	multi-lead ribbed
		mm	millimeter
		MMP	managed maintenance program

MMT	minimum metal temperature	OD	outside diameter
mol	molecular	ODE	ordinary differential equations
MOV	motor operated valve	OEM	original equipment manufacturer
mPa	millipascal	OFA	overfire air
MPa	megapascal	OMLR	optimized multi-lead ribbed
mph	miles per hour	OPEC	Organization of Petroleum Exporting Countries
MRPC	motorized rotating pancake coil	OSHA	Occupational Safety & Health Administration
MRS	monitored retrievable storage	OT	oxygen treatment
MSDS	material safety data sheets	OTSG	once-through steam generator
MSW	municipal solid waste	oz	ounce
MT	magnetic particle testing		
MTD	mean temperature difference		
mV	millivolt		
MV	medium volatile	Pa	pascal
MW	megawatt, megawatts-electric	PA	primary air
MWd	megawatt-day	PA/PC	primary air and pulverized coal mixture
MW _t	megawatts-thermal	PAC	powdered activated carbon
μS	microSiemens	PAW	plasma arc welding
		PAX	primary air exchange (burner)
N	Newton	PC	pulverized coal
N _{2a}	atmospheric nitrogen	PCB	polychlorinated biphenyl
NAAQS	National Ambient Air Quality Standards	PCDD	polychlorinated dibenzoparadioxin
NAPAP	National Acid Precipitation Assessment Program	PCDF	polychlorinated dibenzofurans
NBIC	National Board Inspection Code	PCFAD	computer-based failure analysis diagram
NC	numerical control	PDE	partial differential equations
NCG	noncondensable gas	PDVSA	Petroleos de Venezuela South America
NDE	nondestructive examination	PFBC	pressurized fluidized-bed combustion
NDTT	nil-ductility transition temperature	PFI	Power for Industry (boiler)
NEI	National Emissions Inventory	PFM	Power for Manufacturing (boiler)
NFPA	National Fire Protection Association	PFT	Power for Turbine (boiler)
NIST	National Institute of Science & Technology	pH	negative log of hydrogen ion concentration
Nm ³	Normal cubic meter	PHWR	pressurized heavy water reactor
NMVOC	nonmethane volatile organic compounds	P&ID	process and instrumentation diagram
NNI	non-nuclear instrumentation	PIP	peak impact pressure
NOTIS	nondestructive oxide thickness inspection system	PM	particulate matter
NPD	nuclear power demonstration	POHC	principal organic hazardous constituent
NPDES	National Pollutant Discharge Elimination System	PORV	power (pilot) operated relief valve
NPHR	net plant heat rate	ppb	parts per billion (mass)
NPSH	net positive suction head	ppm	parts per million (mass)
NRC	Nuclear Regulatory Commission, U.S.	ppmv	parts per million by volume
N.S.	nuclear ship	PPS	polyphenylene sulfide
NSAC	Nuclear Safety Analysis Center	PR	process recovery
NSCW	nuclear service cooling water	PRB	Powder River Basin
NSFO	Navy special fuel oil	press.	pressure
NSPS	New Source Performance Standards	pri	primary
NSR	New Source Review	prox	proximate
NSSS	nuclear steam supply system	PRV	pressure reducing valve
NTU	net transfer unit	PSD	prevention of significant deterioration
NUG	nonutility generator	PSDF	Power Systems Development Facility
NWMS	nuclear waste management system	PSH	primary superheater
NWPA	Nuclear Waste Policy Act	psi	pounds per square inch (absolute or difference)
		psia	pounds per square inch absolute
O/G	oil and gas	psig	pounds per square inch gauge
OBW	oversize bulky waste	P/T	pressure/temperature
		PT	penetrant testing (liquid/dye)
		PTC	Performance Test Code

PUC	Public Utilities Commission	SG	steam generator
pulv	pulverizer	SGTR	steam generator tube rupture
PURPA	Public Utility Regulatory Policies Act	SH	superheater
PVC	polyvinyl chloride	SI	international system of units
PWHT	post weld heat treatment	SIP	state implementation plan
PWR	pressurized water reactor	SLR	single-lead ribbed
PWSCC	primary water stress corrosion cracking	SMAW	shielded metal arc welding
		SMD	Sauter mean diameter
R	Rankine degrees	SNAME	Society of Naval Architects and Marine Engineers
R&D	research and development	SNCR	selective non-catalytic reduction
rad	radian	SNG	synthetic natural gas
RAR	reasonably assured resources	SOG	stripper off gas
RB	Radiant boiler	SPB	Stirling power boiler
RBC	Radiant boiler Carolina-type	sp gr	specific gravity
RBE	Radiant boiler El Paso-type	SR	stoichiometric ratio
RBT	Radiant boiler Tower-type	SS	stainless steel
RBW	Radiant boiler W-type	S.S.	steam ship
RC	reactor coolant	SSH	secondary superheater
RCM	reliability centered maintenance	ST	softening temperature
RCRA	Resource Conservation and Recovery Act	subbitum	subbituminous
RCS	reactor coolant system	SUS	Saybolt Universal Seconds
RDF	refuse-derived fuel	SWUP	spiral wound Universal Pressure (boiler)
recirc	recirculation		
red.	reducing atmosphere	t	ton (English units)
rem	roentgen equivalent man	t _m	metric ton
rev	revolutions	T ₂₅₀	viscosity at 250 centipoise
RH	reheater	TBS	turbine bypass system
RHAS	radiant heat absorbing surface	TC	thermocouple
RHSH	reheat superheater	TD	terminal temperature difference
RH-TRU	remote handled transuranic waste	TDF	tire-derived fuel
RO	reverse osmosis	TDFM	time dependent fracture mechanics
ROTSG	replacement once-through steam generator	TDS	total dissolved solids
rpm	revolutions per minute	TEG	turbine exhaust gas
RPS	reactor protection system	temp	temperature
RRSG	replacement recirculating steam generator	theo	theoretical
RSG	recirculating steam generator	TIG	tungsten inert gas
RT	radiography testing	thk	thick
RVCH	reactor vessel closure head	TLD	thermoluminescent dosimeter
RWP	radiation work permit	TOC	total organic carbon
		TOFD	time of flight defraction
s	second(s)	TR set	transformer rectifier set
SA	secondary air	TRC	total residual chlorine
SAE	Society of Automotive Engineers	TRS	total reduced sulfur
sat.	saturated	TRU	transuranic
SAW	submerged arc welding	TS	tensile strength
SBLOCA	small break loss of coolant accident	TSC	two-stage combustion
SBW	steam by weight	TSP	total suspended particulate
SCC	stress corrosion cracking	TSP	tube support plates
SCC	submerged chain conveyor	TSS	total suspended solids
SCFM	standard cubic feet per minute	TSV	turbine stop valve
SCR	selective catalytic reduction	TTT	time-temperature-transformation
SD	stack draft	TTV	turbine throttle valve
SDA	spray dryer absorber	typ	typical
SE	stack effect		
sec	second(s)	UBC	Uniform Building Code
SFAS	safety features actuation system	UBC	unburned carbon
SFS	Saybolt Furol Seconds	UBCL	unburned carbon loss

UCL	unburned carbon loss	VM	volatile matter
UEL	upper explosion limit	VOC	volatile organic compounds
UGA	undergrate air	vol	volume
UIC	uncompensated ion chamber counter	vs	versus
U.K.	United Kingdom	VSS	vertical steam separator
ULD	unit load demand subsystem		
UP	Universal Pressure (boiler)	W	watt
UPC	Universal Pressure Carolina-type (boiler)	WCT	water collecting tank
UPC	Universal Pressure coal-fired (boiler)	WESP	wet electrostatic precipitator
U.S.	United States	WFGD	wet flue gas desulfurization
USCG	United States Coast Guard	wg	water gauge
USD	United States dollar	WHRB	waste heat recovery boiler
U.S.S.	United States ship	WPS	welding procedure specifications
UT	ultrasonic testing	WRC	Welding Research Council
UTT	ultrasonic thickness testing	wt	weight
UV	ultraviolet	WTE	waste-to-energy boiler
V	volts	YP	yield point
VAC	volts alternating current	yr	year
VIV	variable inlet vanes	YS	yield strength

The Babcock & Wilcox Company Trademarks in Edition: 41

The following is a list of trademarks used in *Steam, Edition: 41* that are owned by The Babcock & Wilcox Company or one of its affiliated companies.

Acoustic Ranger
Auto Spring
B&W
B&W Roll Wheel
B&W-56
B&W-67
